# General report for TC 205 Safety and serviceability in geotechnical design: a reliability-based perspective

Rapport général du TC 205  
Sécurité et maintenance en conception géotechnique : une perspective fiabiliste

Salgado R.

School of Civil Engineering, Purdue University – West Lafayette, United States

**ABSTRACT:** A transition has been underway in geotechnical engineering from design based on analyses that treat problems as if every pertinent variable were deterministic only to recognize at the end that uncertainties exist by using a factor of safety to design based on probability concepts. In probabilistic design, key problem variables are treated, at least implicitly, as random variables, and probabilities of undesired outcomes (defined through the concept of limit states) are kept below certain maximum acceptable values. The ways to perform these analyses are many, depending on choices as to, for example, which variables to treat as random and which method of analysis (e.g., the limit equilibrium method, the finite element method) to use to solve the underlying boundary-value problem. Different approaches have been followed in North American and Europe, the two regions where use of probabilistic, limit states-based design is more common. Many unresolved issues remain. This paper highlights some of these issues in the context of papers submitted on the topic to the 18th ICSMGE.

**RÉSUMÉ:** Une transition s'est déroulée en géotechnique depuis une conception basée sur des analyses qui traitent les problèmes comme si chaque variable pertinente était déterministe vers la prise en compte des incertitudes par l'utilisation de facteurs de sécurité dans le cadre d'une conception basée sur des concepts probabilistes. Dans ce cadre probabiliste, les variables clés du problème sont traitées, au moins implicitement, comme des variables aléatoires et les probabilités des résultats attendus (définis par le concept d'état limite) sont maintenues en-dessous certaines valeurs maximales acceptables. Il y a de nombreux moyens de réaliser ces analyses, selon le choix, par exemple, des variables à traiter comme aléatoires et des méthodes d'analyse utilisée pour régler le problème aux limites considéré (e.g., la méthode des équilibres limites ou les éléments finis). Différentes approches ont été suivies en Amérique du Nord et en Europe, les deux régions où l'utilisation des méthodes probabilistes aux états-limites sont les plus répandues. De nombreuses questions restent posées. Cet article met en évidence ces questions dans le contexte des articles soumis au 18<sup>ème</sup> CIMSG sur ce thème.

**KEYWORDS:** stability, serviceability, geotechnical design, Eurocode 7, load factors, resistance factors, partial factors, characteristic and design values.

## 1 BACKGROUND

Development of the Eurocode started a large-scale effort to address geotechnical engineering problems in a more systematic manner from the point of view of the uncertainties present in these problems. One major theme of this effort has been to allocate uncertainties more precisely, e.g., between loads and resistances or, in the case of the Eurocode, between loads and the quantities that enable calculation of soil resistances. Another important theme has been to transition away from *ad hoc* measures of safety to probabilities of failure, with failure defined rather specifically. This emphasis on probability of failure has started an important debate concerning what probabilities of failure are acceptable given project importance and consequences of failure.

In Europe, the path followed was to account for uncertainties by dividing shear strengths or, more generally, soil properties controlling the specific resistance being calculated by material factors typically greater than one. Actions (defined in the code as loads or applied displacements) would be increased by factors also greater than one. This general approach is usually referred to as a partial factors approach. In North America, a different philosophy developed. In the still-evolving North American practice, an approach called Load and Resistance Factor Design (LRFD) is used. The main difference with respect to European practice is that design is based on the following inequality:

$$(RF)R_n \geq \sum (LF_i)Q_{i,n} \quad (1)$$

where  $R_n$  is the nominal resistance,  $RF$  is the corresponding resistance factor,  $Q_{i,n}$  are nominal loads (with dead load, live load, etc., identified each by a different value of  $i$ ), and  $LF_i$  are the corresponding load factors.

Both the Eurocode and its North American counterparts are based on the concept of Limit-States Design (LSD). Limit states exist on the boundary between acceptable and unacceptable states. They offer a solid conceptual basis for the definition of failure, which then becomes the achievement of an undesirable state as defined by the limit states. The probability of failure then becomes nothing more than the probability of achievement of an undesirable state. Figure 1 shows a hypothetical design problem involving two variables, resistance and load, both of which are random variables. The line in the figure separates acceptable pairings of  $Q$  and  $R$  ( $Q < R$ ) from those that would lead to failure. The line is the locus of limit states, and states above the line are failure states.

The advantage of use of inequality (1) over the European approach is that the resistance factor reflects all of the uncertainties involved in calculating resistance, including uncertainties in both soil property determination and the analysis used to calculate the resistance. This advantage is likely more of a conceptual nature, for it is possible to account for analysis uncertainty also in the European approach, but that must be done through the material factors dividing the strength parameters, which cease to be then pure factors on material properties.

Another important difference between Eurocode-related efforts and development of North American LRFD is in the process. The Eurocode started with an exclusive focus on buildings (Simpson and Driscoll 1998) but then developed into a code with broad application in geotechnical design. In North America, particularly in the United States, the effort targeted transportation infrastructure, leaving state DOTs and individual researchers with the task of developing load and resistance factors that made sense and could be used in a practical manner. This has in a way been an incentive for performing research in the subject.

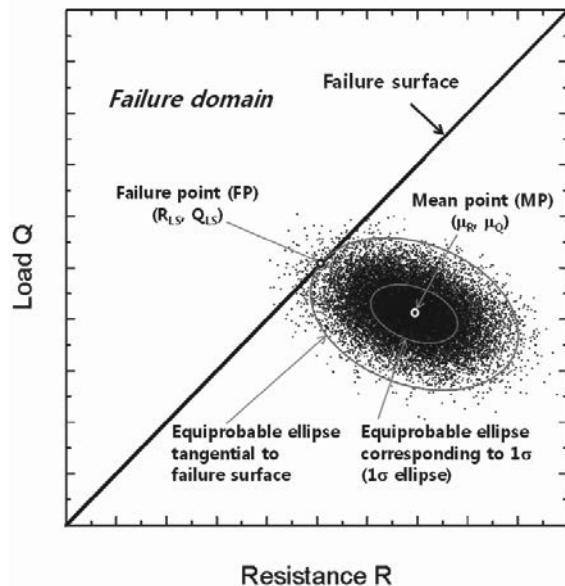

Figure 1– Design problem with load and resistance being random variables (after Salgado and Kim 2013).

The topic of safety and serviceability in geotechnical engineering, which involves design methods and approaches for a variety of geotechnical problems based on analyses that account for probabilities and variability in pertinent variables, is complex and should evolve over the years with the development of better methods of analyses and a greater understanding of variability in geotechnical problems. The following sections summarize current knowledge and challenges, together with the contributions of papers submitted to the XVIII ICSMGE.

## 2 RELIABILITY ANALYSIS

Research on limit-states design (LSD) in its various forms has ranged from simple calibrations of material factors (in the Eurocode framework) or resistance factors (in the LRFD framework) so that results would match those obtained using traditional methods with accepted values of factors of safety to reliability analysis performed with various levels of sophistication. The tools to perform sophisticated reliability analysis have evolved considerable in the last 20 years, and most advances that will be useful to code designers in the future are likely to result from this type of analysis.

Figure 1 shows a cloud of points representing pairings of load  $Q$  and resistance  $R$  around the mean point  $(\mu_R, \mu_Q)$  of these two variables. Each of these points is a simultaneous realization of random variables  $R$  and  $Q$ . Since  $Q$  and  $R$  are more likely to be close to their respective mean, there is a heavier concentration of points near  $(\mu_R, \mu_Q)$ ; however, if the load and resistance in a hypothetical problem deviate from their means by sufficiently large amounts,  $Q$  may end up exceeding  $R$ , which would, by definition, constitute failure. This cloud of points may be obtained using Monte Carlo simulations if the

probability distributions of  $Q$  and  $R$  are known. The probability of failure can be estimated from the ratio of the number  $n$  of points above the limit state line shown in the figure to the total number  $N$  of points. Mathematically:

$$p_f = \lim_{N \rightarrow \infty} \frac{n}{N} \quad (2)$$

where  $N$  must be large enough for  $p_f$  to converge.

Also shown in Figure 1 are dispersion ellipses. A dispersion ellipse represents the locus of the resistance-load pairings with the same level of deviation from the mean. Note that there is one dispersion ellipse that is tangential to the failure line at a point known as the most likely "failure point" FP, also known as the "design point". From the point of view of development of material factors or resistance factors, if the probability of failure calculated for the simulations of Figure 1 is the value that should be targeted in design, the relationship between the design point FP and the mean point MP yields directly the factors that would be used in design. This is easiest to show for LRFD, in which case the factors RF and LF shown in inequality (1) would follow from:

$$RF = \frac{R_{LS}}{\mu_R} \quad \text{and} \quad LF = \frac{Q_{LS}}{\mu_Q} \quad (3)$$

where  $R_{LS}$  and  $Q_{LS}$  are the resistance and load at the design point FP; and  $\mu_R$  and  $\mu_Q$  are the means of resistance and load.

For different reasons, code designers may set load factors  $LF_i^*$  that must apply to a range of design settings. If a resistance factor is developed using reliability analysis (calculated from an equation like (3)), this resistance factor is consistent with the load factor calculated using the same equation. If it is to be used with a different load factor specified in a code, it must be adjusted. If we refer to the adjusted resistance factor as  $RF^*$ , it may be computed by requiring that inequality (1) apply equally whether  $RF^*$  and  $LF_i^*$  or  $RF$  and  $LF_i$  are used:

$$RF^* = RF \frac{\sum (LF_i^*) Q_{i,n}}{\sum (LF_i) Q_{i,n}} \quad (4)$$

## 3 CODE DESIGN

The main goal of modern LSD-based codes is to prevent the occurrence of limit states or, more precisely, to guide or prescribe designs so as to keep the probability of such occurrence acceptably small. The concepts presented in Figure 1 apply equally to ultimate (ULS) and serviceability (SLS) limit states.

One of the key points in connection with LRFD and with partial factor design if model (analysis) uncertainty is included in the factors is that factors are specific to a given analysis. It is not possible to use resistance factors in an *ad hoc* manner or the purpose of LRFD or partial factor design is lost. This is a significant culture change for geotechnical engineers, for factors of safety have traditionally been used with considerable flexibility. This significant difference between practice as it is evolving at present and the practice of years back has important implications. It becomes difficult, for example, to use a method of analysis or design for which factors have not been developed. There are also ethical and professional conduct implications, as touched upon by Redaelli (2013), who points out that ethics should constrain engineers from selecting factors of safety based on financial motivations. In geotechnical engineering, Redaelli (2013) argues, the high level of uncertainty invites a reliance on judgment, which in turn enables geotechnical engineers willing to deliberately distort design outcomes for their own interests or for the interest of their direct employer to easily do so. Redaelli (2013) believes that honest and scrupulous engineers in a consulting company may meet with

resistance from clients and colleagues when attempting to incorporate into their design uncertainty that others may wish to ignore. It can be argued that codes containing partial factors or load and resistance factors determined carefully and scientifically would be of assistance in minimizing this problem.

Limit states design codes have not been and could not be based primarily on reliability analysis and research, largely because the research was not available. Many challenges remain, chiefly among them a proper assessment of soil variability both for code design and for specific projects. Although it is a stated goal of modern limit states codes to use acceptable probability of failure as a design reference and a basis to develop values of materials or resistance factors, the present reality is that codes have been largely developed based on calibrations, as noted by Länsivaara and Poutanen (2013), and code development committee deliberations. As results of better, more specific research become available, code designers may be able to take advantage of these results to modify values and recommendations in future editions of design codes.

Although this paper focuses on safety and serviceability as addressed by codes and design calculations, not every risk can be quantified; some are best avoided. For example, blunders can be avoided by having layers of checks on procedures and calculations put in place. Other risks may be avoided by taking a broad view of the project, looking for things that can go wrong and adapting designs and construction procedures based on this assessment. Robert (2013) discusses this type of project-management approach to risk management.

The next sections examine specific aspects of the design of slopes, foundations and retaining structures using modern limit states codes.

## 4 STABILITY OF SLOPES

### 4.1 General Remarks

Stability limit states, also known as ultimate limit states, are associated with dangerous outcomes. In mechanics terms, they would often be associated with collapse. A loss of slope stability would be associated with large slope movements after driving actions overcame available resistance. This is the primary design check for slopes, although more contained slope movement that would not be analyzed in the same manner are also sometimes critical.

Loads are, for the most widely used slope stability analysis methods, expressed through driving moments. The driving moment due to dead loads (self-weight of a potential sliding mass or permanent external loads acting on the boundary of the sliding mass) may be denoted by  $M_{d,DL}$ . The driving moment due to live loads (nonpermanent loads on the crest of the slope, such as vehicular loads) may be denoted by  $M_{d,LL}$ . Resistances are expressed through a resisting moment  $M_r$ . In terms of driving and resisting moments, inequality (1) becomes:

$$(RF)M_{rn} \geq (LF_{DL})M_{d,DL}|_n + (LF_{LL})M_{d,LL}|_n \quad (5)$$

Studies on probabilistic stability analysis of slopes and embankments started in the early 1970s and have continued (e.g., Cornell 1971, Tang et al. 1976, Christian et al. 1992). In early slope reliability analysis studies, the first-order second-moment method was popular for the assessment of probability of slope failure. More recent studies have made use of the first-order reliability method (FORM) and Monte Carlo simulations (MCSs) to assess the probability of slope failure (Christian et al. 1994, Tobutt 1982).

In probabilistic slope stability analysis, it is essential to consider the spatial variability of the soil in the slope. This is the most significant shortcoming of original studies on this topic. If a soil slope is assumed to remain homogenous when soil properties are varied (say, using Monte Carlo simulations)

in an analytical study, the reality that these properties in fact vary with some degree of independence across the slope is completely ignored, and probabilities of failure calculated in this manner will not be accurate. Salgado and Kim (2013) have used an advanced FORM method, coupled with random field modeling of the slope, to develop resistance factors for use in slope stability as a function of soil spatial variability. Although the results have been consolidated in terms of resistance factors, it would be possible to develop partial material factors from their reliability analyses. The fact that model uncertainty in slope stability analysis is small to negligible (Kim et al. 1999, Kim et al. 1992, Yu et al. 1998) makes it relatively easy to obtain Eurocode-like material factors from reliability analyses such as those performed by Salgado and Kim (2013).

As pointed out by Länsivaara and Poutanen (2013), use of (5) or another inequality like it requires the slope stability software to provide the values of moments from permanent, temporary and other loads separately. Although not yet common, this will not be an impediment for long (STABL WV, for example, is a slope stability software that already provides this level of information detail).

A key decision in performing reliability-based design or developing resistance or material factors is what the acceptable probability of failure  $p_f$  is. Christian (2004) characterized risk as a function of number of fatalities, referring to various efforts by regulators and others. Most slopes would be well designed with  $p_f = 10^{-3}$ , but lower values of  $p_f$  might be needed for structures whose failure would lead to large economic or human loss.

### 4.2 Papers

Länsivaara and Poutanen (2013) review the prescriptions of the Eurocode (EN-1997) regarding slope stability. The Eurocode prescribes three different ways of checking stability: design approaches DA1, DA2 or DA3.

According to these authors, DA1 with combination 2 and DA3 are most commonly used for slope stability analysis. There are also three different reliability classes (RC1, RC2 and RC3), which allow the accounting for consequences of attainment of a limit state, into which a slope would be fit before analyses are done. Another way allowed by the code to account for consequences of attainment of a limit state is to increase material factors for cases with more consequential failures.

As seen earlier, material strength is divided by a material factor, and this is supposed to account for uncertainties in shear strength and any analysis uncertainty. The material factor for effective stress analyses for soils modeled as Mohr-Coulomb materials is 1.25; for a total stress analysis of a slope with soil modeled as a Tresca material, it is 1.4. Self-weight is left unfactored but live (temporary) loads (actions) on the slope are factored by 1.3. Länsivaara and Potanen (2013) suggest that there is an "overestimation of safety" implied in typical factors of safety used in total stress analysis of the stability of clay slopes. Salgado and Kim (2013) also observed this possibility in the results of reliability analysis of slopes modeled using random fields.

Lechwicz and Wrzeński (2013) report on field-scale staged construction of an embankment on top of an organic soil deposit, the last stage built up until failure occurred. The shear strength of the soil profile on which the embankment was built was characterized using results of the vane shear test corrected according to the Swedish Geotechnical Institute method (Larsson et al. 1984) with correction factors determined based on triaxial compression (TC), triaxial extension (TE) and direct simple shear (DSS) testing of the materials in the laboratory. The shear strength data determined in this manner allowed estimation of the probability distributions of the undrained shear strength. Their analysis of the results of these field experiments focused on testing the Eurocode 7 DA1, DA2 and DA3 design approaches.

The embankment was constructed in three stages on organic subsoil from 1983 to 1987. The structure was then brought to failure by increasing the height of the fill (Wolski et al. 1988, 1989). The organic soil at the site, present as two separate layers (a 3.1-m-thick amorphous peat layer and a 4.7-m-thick calcareous-organic soil layer) is underlain by a sand layer. The water table is located near the ground surface, but the sand layer was subjected to artesian conditions, with the piezometric level as much as 1.5 meters above the ground surface. Effective stresses *in situ* were in the single digits (in units of kPa). The OCR of the organic soils was estimated to decrease from 5 near the surface to 2 at depth. The undrained shear strength was determined both before and after construction of the embankment. After consolidation, the strength was observed to increase below the embankment, with larger increases near the center. Interestingly, there seems to have been a slight reduction, on average, of the coefficients of variation of the shear strength from the values before embankment construction (all except one greater than 0.11 and as high as 0.19) after the embankment was constructed and consolidation completed; originally, these values were as low as 0.03, with several observations below 0.1. Consolidation may have evened out some spatial variability initially present.

The stability analysis performed for the third stage and the failure test assumed the organic subsoil to be divided into three different shear zones: A – below the embankment crest, B – below the embankment slope and C – to the side of the embankment. In these analyses, which relied on the Bishop Simplified Method, various approaches to account for uncertainty in shear strength were considered: direct use of mean values, use of characteristic values determined as the mean less 0.5 or one times the standard deviation, and application or not of a partial factor  $\gamma_m = 1.25$  to the mean and characteristic values of shear strength. This value is not the 1.4 prescribed by the Eurocode for Tresca materials, but the authors did not elaborate.

Based on comparisons between these different analyses and the results of the test embankment, the authors recommended use of design approach DA1 with combination 1 and use of characteristic values of undrained shear strength defined as a conservative mean (mean less a fraction of the standard deviation) for slope stability analysis under similar conditions. Design Approaches DA1 with combination 2 and DA3 were deemed excessively conservative.

One of the most challenging aspects of probabilistic stability analyses of slopes is that the spatial nature of the variability of slopes must be taken into account in order to produce reasonable results, as noted earlier. Lechwicz and Wrzesiński (2013) attempt to assess, using judgment, the degree of conservativeness of different approaches to determination of characteristic strengths and partial factors to use in design, but that appears to be a difficult task to complete until more rigorous analyses that fully consider spatial variability of the slope are properly done and scrutinized. The test to failure of the embankment slope that they describe is precisely the type of field result needed to combine with the rigorous reliability analyses done today to validate theoretical work. More information on spatial variability, which is difficult to assess, particularly in the horizontal direction, is certainly needed in field tests of this type.

## 5 FOUNDATIONS

### 5.1 General Remarks

Foundation engineering problems are interaction problems: a foundation element (e.g., a footing or a pile) or a collection of foundation elements interact with the soil around them through the interface between the elements and the soil. The presence of this interface can be exploited in probabilistic analyses of foundation limit states: the variability, spatial in nature, of soil

properties result in contact stresses at this interface that are a function of the response of the entire soil mass. It is customary to observe (directly measure or deduce from instrumentation using load cells and strain gauges) the values of these boundary loads on foundation elements, and the variability of these stresses can be used, combined with specific methods of analysis, to perform reliability analyses. This approach, as already discussed, is not viable for slope stability analysis.

Basu and Salgado (2012), for example, performed such an analysis for drilled shafts in sand. They placed the analyses of Loukidis and Salgado (2008) and Lee and Salgado (1999) on a probabilistic basis and used Monte Carlo simulations to determine the resistance factors corresponding to probability of failure equal to  $10^{-3}$  and  $10^{-4}$ . Rigorous reliability analysis combined with realistic and appropriate soil models, with a rigorous method of analysis of a particular boundary-value problem, and with careful accounting of variability of every random variable entering the calculation produces excellent and transparent results. The body of work of this type is still limited, but it is likely to produce results that will be useful to code designers.

Differently from slopes, which are most often checked for stability, deflection-based limit states, whether potentially leading to ultimate or serviceability limit states, are more frequent for foundations than a classical foundation plunge limit state. In more complex structures, such as piled rafts, analyses are more involved, often requiring numerical solutions, which makes a reliability analysis more challenging and makes it more difficult to consider spatial variability indirectly.

One of the hardest decisions for engineers to make in the context of reliability-based design is on the acceptable probability of failure. In every geotechnical design problem, the answer can be different. For example, in connection with pile foundations used in traditional solutions (not in a piled raft), a possible way to think of probability of failure  $p_f$  would be to pose a question such as "how often would an engineer be willing to deal with cracking of the superstructure (an indicator of a possible ULS) to keep initial foundations cost low?" A possible answer would be that no more often than would be the case if one pile in ten thousand settled too much, which could then lead to an acceptable probability of failure of  $10^{-4}$ .

### 5.2 Papers

Loehr et al (2013) discussed work that they have done for the Missouri Department of Transportation attempting to develop state-specific resistance factors for Missouri. The guidance offered by AASHTO on which resistance factors to use is very general, prompting this type of effort by individual states in the United States.

The work of Loehr et al (2013) aimed to develop prescriptions for drilled shaft design that would not be overly constraining. The authors worked with epistemic probabilities, which they however do not provide details on. One of the main advantages of LRFD, in these authors' view, is that LRFD enables placing a value on the marginal boring, CPT log or laboratory test, which in turn allows advocacy for a more complete site characterization. The authors illustrate this point with an example of drilled shaft design with site characterization done with different levels of detail. This potential use of LRFD, of facilitating the economic evaluation of site characterization and other decisions affecting design, has also been remarked on by other authors (e.g., Foye and Salgado 2005, Foye et al. 2011a and b).

Katzenbach et al. (2013) review a relatively new soil improvement method that resembles a piled raft. In this method, (usually unreinforced) concrete columns are installed beneath a raft (mat). The mat and columns do not actually touch, being separated by a layer of stone or gravel (Figure 2). The concrete columns, in effect piles, have diameter ranging from 0.25 to 0.80m.

A fundamental difference between design of this foundation solution and that of a piled mat is the presence of negative skin friction, as the layer of gravel pushes down on the soil, which compresses over time between the piles. The authors review French and German prescriptions for design of this type of foundation solution.

Figure 2 Comparison of common foundations solutions with pile-supported blanket solution (after Katzenback et al. 2013).

### 5.3 Discussion

Figure 3 Occurrence of negative skin friction along unreinforced concrete piles caused by load applied by the layer of gravel on top of the column on the soil between the columns (after Katzenback et al. 2013).

## 6 EARTH RETENTION

### 6.1 General Remarks

Fundamental work on the probabilistic analysis of retaining walls has tended to focus on mechanically stabilized earth (MSE) walls. This work has resulted in part from the interest sparked by the AASHTO LRFD mandate in North America and the fact that MSE walls are widely used in transportation infrastructure.

While retaining wall limit states in general should be treated similarly to the slope stability limit state (because the pressure on the walls results from shear surfaces that develop in the backfill and that depend very much on spatial variability of shear strength in the backfill), the presence of an interface (the back of the wall) again allows the effects of the spatial variability of soil variables in the backfill to show as variability in contact pressure on the wall. Likewise, reinforcing elements in MSE walls will develop pullout resistance and exert stabilizing action on the backfill through the shear stresses (unit resistances) between them and the soil; variability of these unit resistances are then used in reliability analyses. In the case of MSE walls, instrumentation of reinforcements, including near the wall facing, provide data that can be used for estimation of both earth pressures and unit interface resistance of reinforcing elements (see, for example, Kim and Salgado 2012a,b).

An interesting issue in connection with retaining walls is the choice of limit states that must be checked in design. The traditional, idealized retaining wall limit states are sliding, overturning, bearing capacity failure and general instability. In MSE walls, the additional limit states of pullout and reinforcing element rupture must also be checked. However, as pointed out by Loukidis and Salgado (2012), realistic limit states tend to be a composition of these idealized limit states. Equally interesting, there is a relationship between mobilization of shear strength (and consequently pressures on the wall) and wall movement, and this relationship has implications for the setting up of

design situations. Merrifield et al. (2013) discuss aspects of this issue as well, as did Loukidis and Salgado (2012) and Simpson and Driscoll (1998).

### 6.2 Papers

Ho et al. (2013) used the design approach proposed in CIRIA Report C580 in the design of a permanent cantilevered, large-diameter, bored-pile wall (Figure 4) for the support of sloping ground bordering a new road, which now exists in front of the wall. This is the first known Hong Kong project in which a permanent retaining structure was designed using the C580 design approach. The wall, which is approximately 110m long, is made of 33 bored piles with diameter equal to 3.0m. Figure 5 shows a cross section of the wall as well as the original and post-construction ground profile.

Figure 4 Bored-pile wall in Hong Kong (after Ho et al. 2013).

Figure 5 Cross section of bored pile wall in Hong Kong (after Ho et al. 2013).

The ground profile at the site consists essentially of fill and weathered granite. In the original ground profile, the fill had a maximum thickness of 8m and contained loose to medium dense, gravely silty sand or sandy clayey silt, with some rock and concrete fragments as well as domestic waste. Completely decomposed granite (CDG) and highly decomposed granite (HDG) are present below the fill. The granites in the area are commonly fine- to medium-grained and greyish pink to pinkish grey in their fresh state. The thickness of the CDG ranges from 5 m to 10 m with SPT blow counts ranging from 15 to 100. The HDG occurs with SPT blow counts greater than 100. The maximum depth to moderately to slightly decomposed granites (M/SDG) ranges from 15m to 40m below original ground level. The water level was assumed at the excavation level on the excavation side of the wall and within the the CDG layer on the

retained side. In the site characterization stage, a total of 105 consolidated undrained (CU) triaxial tests, with pore water pressure measurement, were carried out. Soil design parameters for the fill, CDG and HDG were determined based on this testing program.

Ho et al. (2013) used two methods to design the wall. One method is the traditional method used in Hong Kong. The other is the CIRIA C580 method. Use of the C580 design approach netted 10 % overall cost savings over what the wall would have cost if designed using the traditional method. This represented an amount of HK\$ 9.6 million saving on this project. This case history illustrates that geotechnical engineering still relies on design methods that may be too conservative, and that savings can be significant when more recent knowledge is put into use.

Merrifield et al. (2013) review the history of and difference in current practice of design and testing of ground anchors in Europe. Ground anchors were first used in rock applications, but found their way into soil retention systems in the 1950s. Ground anchors are routinely used in connection with embedded (cantilevered) walls and may be viewed as enablers of this type of retaining wall, which would otherwise be prohibitively expensive.

Merrifield et al. (2013) discuss the differences between the treatment of anchors in European national codes and provisional (draft) prescriptions in Eurocode (EN-1997:2004). Prescriptions must address the two primary limit states: an ultimate limit state that will prevent pullout of an anchor under the maximum expected load it will be subjected to during its service life and a serviceability limit state related to deflections, which may be stated in terms of loss of load or creep (in fact, an anchor is likely to both move or deform and see a degradation in the load it carries over its service life).

The authors call attention to an important, if not universally recognized, detail concerning definition of limit states for walls: serviceability limit states develop with retaining wall movement that is typically not sufficient to develop active or passive pressures historically assumed to act behind or in front of the wall. As a consequence, serviceability limit states must be defined separately from ultimate limit states. From the point of view of anchor design, anchor resistance must be sufficient to carry loads transferred to it by either serviceability or ultimate limit states, and the draft provisions do account for that as well.

In part because of the empirical basis for anchor design, proof loading has always been part of ground anchor design and installation practice. Again, each country handles testing and proof loads differently, a point that Merrifield et al. (2013) discuss in detail.

## 7 SUMMARY AND CONCLUSIONS

Safety and serviceability are the requirements that any geotechnical design must meet. These requirements are met through risk management, specific design checks and proper construction. The design checks are calculations that show that no limit state is achieved or exceeded. One of the main tasks of the geotechnical designer is to properly identify applicable limit states and then produce a design that keeps the probabilities of their occurrence below threshold levels. Guidance on identification of limit states and specific checks to be done in connection with these limit states are often prescribed by codes. Recent codes, such as the Eurocode and LRFD codes attempt to anchor the design process the notion of an acceptable probability of failure, which depends on the problem and consequences of achievement of a specific limit state. In the absence of specific guidance, definition of what these limiting probability values are sometimes must also be defined by the designer.

The papers submitted to the XVIII ICSMGE illustrate the complexity of probabilistic limit-states based design and encapsulation of it in design codes. Much work still remains for

researchers and code development agencies to produce codes and methods of analysis that will enable engineers to produce designs that achieve safety and serviceability in an optimal and economical manner.

# L'expérience française insolite d'un encadrement juridique : une certaine maîtrise du risque du sol

Unusual French experience of a legal frame: a certain mastery of ground risk management

Carrière M.-L.  
Avocat au Barreau de Paris

**RÉSUMÉ :** Au début des années 1990 la géotechnique est considérée aux yeux des juges comme une science quasi-occulte, affaire de spécialistes. En vertu d'une jurisprudence constante, les tribunaux et cours condamnent systématiquement le bureau d'étude spécialisé, au motif qu'il est le seul à connaître les règles de l'art géotechnique et doit le maîtriser. Pourtant, dans une science incertaine par nature, un risque du sol résiduel est inéluctable et d'autant plus, dans un contexte de recherche d'économie et de limitation des missions d'ingénierie. L'article montre comment le cadre juridique a pu évoluer par une formation réciproque des juges et des ingénieurs. Une formation géotechnique basique de l'avocat permet une vulgarisation de l'art géotechnique à l'attention du juge pour apprécier les limites de cette science naturelle. Une formation des ingénieurs sur les risques encourus et un accompagnement de la profession pour l'élaboration d'une norme délimitant les missions aident à encadrer juridiquement l'activité géotechnique. A l'aube du troisième millénaire la responsabilité du géotechnicien n'est plus une fatalité. Le juge est devenu familier de cette science et maîtrise désormais les contours des missions, pour imputer le risque du sol à qui de droit !

**ABSTRACT:** On the early 90's, the geotechnical matter is considered as occult from the jury's point of view: it's a business for specialist people. Under a law, tribunals and courts routinely condemn consulting firm specializing on the grounds that it is the only one to know the rules of the geotechnical art and should control it. However, in an uncertain science by nature, a residual risk due to soil is inevitable, even more in the context of limited budgets and missions. The article shows how the legal framework can evolve by a mutual training of the judge and the engineer. The judges must be taught on the particularity of this natural science to enable them to appreciate the limitations faced by these soil engineers, but also create a legal framework around geotechnical activity. A basic geotechnical training for the lawyer is necessary with a possible extension to geotechnical art to the attention of the judge. The training course for engineers on the risks and the accompaniment of the profession enable to develop a standard for a legal framework defining missions. At the dawn of the third millennium the responsibility of geotechnical is no longer inevitable. The judge became familiar with the science and now controls the contours of missions, to allocate the risk of soil to the one who is responsible.

**MOTS-CLÉS:** sol, risque du sol , vice du sol, norme géotechnique, responsabilité.

**KEYWORDS:** soil, soil risk ,standard geotechnical , responsibility

## 1 UN CONSTAT : UNE JUSTICE INJUSTE

Début des années 1990, en France, un constat : La géotechnique est une science quasi occulte aux yeux des juges ; elle est affaire de spécialistes.

Et avec un esprit quelque peu provocateur, il n'est pas interdit de penser que cette science demeure souvent mystérieuse pour l'homme de l'art lui-même.

En vertu d'une jurisprudence constante, les tribunaux et cours condamnent systématiquement le bureau d'étude spécialisé, au motif qu'il est le seul à connaître les règles de l'art géotechnique et doit le maîtriser.

Mission impossible.

### 1.1 *Un certain droit, « spécificité française »*

La société occidentale a vu naître le principe de précaution, consacré en droit communautaire. Ce concept flou vient satisfaire la société du risque : Le caractère plausible du risque dans l'incertitude scientifique, la proportionnalité entre l'objectif poursuivi et les mesures prises, mais des méthodes

finaleme nt définies pour évaluer les risques qui engendrent une mise en œuvre délicate et source d'interprétation.

Au-delà de ce droit, finalement européen, qui ne saurait susciter une quelconque envie de nos voisins puisqu'ils en bénéficient, où est la « spécificité française » ?

Dans un Etat qui se revendique « de droit », l'exigence du risque 0, pourtant inaccessible, se dessine. « Au commencement, la terre était déserte et vide... » La société exige désormais la sécurité ; la perception des risques évolue. Parallèlement, les risques en font de même : Une urbanisation massive, la perte de mémoire collective, le progrès comme facteur de risques, les risques naturels et technologiques...

On note également une extension de la notion de préjudice, des risques considérés classiques dans des temps anciens, étant plus difficilement acceptés.

Ainsi, la mutualisation se fait socialisation du risque pour répondre à un grand principe sans cesse réaffirmé en droit français : la réparation intégrale du préjudice.

Mais la socialisation du risque n'exclut pas la responsabilité, elle répond à un besoin d'indemnisation. La médiatisation ayant un effet important sur la perception du risque, la responsabilité sans faute est souvent la règle pour parvenir à une réparation aisée du préjudice et la « punition » pénale, recherchée en tant que sanction.

En droit de la construction, la justice est rendue dans un cadre législatif rigoureux pour les intervenants à l'acte de construire. Après réception de l'ouvrage et durant dix ans, le maître de l'ouvrage bénéficie d'une présomption de responsabilité de plein droit des constructeurs, pour les dommages graves, « même résultant du vice du sol », selon la terminologie de l'article 1792 du Code civil, en vertu d'une loi Spinetta édictée en 1978 difficile à exporter...

En matière de sol et fondations, les dommages sont toujours graves en ce qu'ils compromettent la solidité de l'ouvrage ou le rendent impropre à sa destination. Ces dommages engendrent d'ailleurs les sinistres les plus coûteux.

Mais le sol est-il réellement vicié ?

### 1.2 Une science incertaine par nature

Le sol, fondement de la construction, constitue un élément difficile à appréhender, tant eu égard aux limites scientifiques pour le prévenir, qu'au coût de cette prévention.

Les difficultés pour limiter l'incertitude liée à la nature du sol et déterminer par avance le comportement des ouvrages devraient inciter le maître d'œuvre, « chef orchestre » de l'opération, à prévoir l'intervention d'un spécialiste aux différentes phases de construction, et non uniquement en amont, souvent avant démolition. Le géotechnicien, intervenu au stade de la faisabilité du projet, pourrait ainsi contrôler son adéquation à la nature des terrains rencontrés après excavation et le cas échéant, modifier son étude préalable.

Souvent mal reconnu, ou d'une telle hétérogénéité difficilement appréhendable, le sol demeure un milieu empreint d'incertitudes. Sa connaissance, par sa reconnaissance, dépend en outre de l'investissement du maître de l'ouvrage, bénéficiaire de l'opération de construction, le plus souvent propriétaire du terrain.

A ce titre, selon une jurisprudence [Cass. 3<sup>e</sup> civ. 19 juin 2003] désormais bien établie, le propriétaire du terrain en est le gardien au sens de l'article 1384 al. 1<sup>er</sup> du Code civil.

Il est ainsi responsable du risque du sol, puisque contraint d'indemniser les dommages engendrés au fonds voisin par un glissement de terrain. Est-ce toujours aussi simple ?

Un cas d'école géotechnique sans force majeure pour le juge: selon Philippe Guillermain, éminent expert judiciaire, spécialiste en géotechnique, « ce constructeur n'avait aucune raison, ni obligation technique, d'aller rechercher la présence d'hypothétiques marnières inconnues sur ce site à l'époque, à une profondeur de 12 m » et « la maison s'est normalement comportée de 1990 à décembre 1999, délai d'épreuve technique probant, confirmant le bien fondé du choix initial de fondation. » Puis, l'expert précise : « L'effondrement s'est produit brutalement à la faveur de fortes précipitations de fin décembre 1999. On connaît par expérience l'effet néfaste de l'eau dans un tel contexte. Un arrêté de catastrophe naturelle a d'ailleurs été pris pour cette Commune. Il correspond très exactement à la nature du désordre "mouvement de terrain" et à la période d'apparition "du 25 au 29.12.1999" »

Comment le juge, en première instance, puis en appel, a-t-il pu condamner dans un tel contexte ? En l'occurrence, en l'absence d'étude de sol ! Mais cela n'est tout de même pas justifié, à défaut de lien de causalité, élément substantiel pour retenir la responsabilité.

## 2 UN PARADOXE : UN GÉOTECHNICIEN RESPONSABLE MAIS NON COUPABLE

Un paradoxe : Un bureau d'étude géotechnique spécialisé, donc très exposé en termes de responsabilité et pourtant intervenant le plus souvent en amont de l'opération, sans aucunement participer à la conception, ni à la réalisation de l'ouvrage et sans pouvoir influencer sur la nature et l'ampleur des études au cours de l'élaboration du projet.

### 2.1 Un certain art de construire...

Ces hommes d'un art si particulier savent que la géotechnique comporte des risques importants eu égard aux incertitudes naturelles et qu'une pratique trop audacieuse emporte inéluctablement la sanction du juge. Mais rien ne justifie qu'ils supportent abusivement les conséquences de choix techniques ou économiques qu'ils n'ont pas maîtrisés au seul prétexte qu'ils sont les spécialistes du sol et en sont garants à ce titre.

Or, le géotechnicien est souvent perçu à tort comme le maître d'œuvre des infrastructures même s'il s'est vu confier la réalisation de quelques sondages et a donné des principes généraux de fondation en fonction des caractéristiques des terrains, avant élaboration du projet. Il fut un temps, pas si ancien, où le contrat d'un tel bureau d'étude spécialisé se résumait à une liste « ésotérique » d'appellations savantes (pressiomètres, pénétromètres, carottages...), auxquelles le juge répondait par une simplification extrême de sa pensée : un sinistre de sol est imputable au spécialiste du sol.

Pourtant, à un stade très préalable, sans définition du projet et communication des descentes de charges, parfois dans un site partiellement inaccessible avant démolition, avec des moyens financiers restreints limitant les investigations, le géotechnicien ne peut sérier le risque du sol pour le rendre résiduel.

Si l'objet de la géotechnique est d'étudier le sous-sol, elle ne saurait pallier le « vice du sol », au sens de l'article 1792 du Code civil, expression considérée impropre par Jacques Catz [Les constructeurs et le risque du sol], *Editions du Moniteur*, 1985], car le sol n'est jamais vicié, il est seulement mal reconnu.

En effet, deux évidences s'imposent :

- Il est impossible de reconnaître l'intégralité du sous-sol et l'étude sera nécessairement fondée sur un nombre limité de sondages.

- Le risque 0 n'existe pas ; un aléa géologique ou une simple hétérogénéité entre deux sondages peut être décelé ultérieurement.

L'hétérogénéité est propre au sous-sol puisqu'il est constitué de sols et de roches de nature et de consistance très variées façonnés par le temps, le climat, les événements tectoniques à l'échelle géologique, mais aussi par l'action de l'homme qui en a tiré profit (exploitations de carrières et de mines).

La connaissance partielle du sous-sol acquise par l'étude à un instant donné peut également être remise en cause par une évolution dans le temps (variation du niveau des nappes – gonflement et retrait des argiles – dissolution de gypse et création de cavités...).

De surcroît, l'ouvrage lui-même peut avoir une incidence sur le comportement du sol (ex : paroi moulée qui crée un barrage à l'écoulement naturel des nappes).

Tous ces facteurs excluent une analyse trop simpliste en termes de responsabilité ; le juge doit apprendre à s'adapter à la complexité de la matière. Sinon, c'est le terrain juridique qui s'en trouvera vicié.

## 2.2 *Avec un risque délibérément accepté*

L'étude géotechnique, masquée dans le sous-sol, ne procure rien de concret au maître de l'ouvrage et il fut un temps – et parfois on s'y croirait encore de nos jours –, où elle n'était qu'un « ersatz » d'étude géotechnique.

En toute conscience, il s'agissait de passer le cap de la réception pour bénéficier d'une assurance tous risques durant la vie décennale de l'ouvrage. Quelquefois, même relativement souvent en la matière, la nature ne le permettait pas. Le sinistre résultant d'une inadaptation de l'ouvrage au sol survient en toute logique en cours de chantier sans même attendre la superstructure.

Alors le juge a pris conscience. Dans le cadre d'un régime juridique immuable, « exceptionnellement », de la garantie décennale, il a compris qu'il lui appartenait en quelque sorte de « moraliser » le secteur de la construction, en appréciant la prise de risques, en particulier celui relatif au sol, et de la sanctionner.

Ainsi est née la notion jurisprudentielle d'acceptation délibérée d'un risque par le maître de l'ouvrage. En l'espèce, il avait été informé du risque d'effondrement de la falaise par un précédent entrepreneur qui avait refusé le chantier [Cass. 3<sup>e</sup> civ. 19 janvier 1994].

Il est édifiant de constater que les arrêts de la Cour dite « suprême » consacrant cette notion sont très souvent relatifs au risque du sol. Cela ne peut surprendre que les juristes, car les ingénieurs sont nécessairement convaincus du caractère aléatoire de la géotechnique.

Toutefois, la reconnaissance d'une acceptation délibérée des risques par le maître de l'ouvrage reste réservée à un nombre infime de cas. En effet, le juge a quelques exigences à l'égard de l'homme de l'art : le maître de l'ouvrage doit avoir été parfaitement informé d'un tel risque [Cass. 3<sup>e</sup> civ. 11 déc. 2007]. Et la perfection n'est pas de ce monde...

Le devoir de conseil est apprécié de manière extensive et en devient « irrésistible » : Dans le cas d'un glissement de terrain, alors que le maître de l'ouvrage était passé outre les conseils des constructeurs pour une solution de confortement de talus, il a été jugé « ... qu'il n'était pas démontré que cette société employait du personnel ayant une expérience et des connaissances spécifiques lui permettant d'appréhender dans le détail l'ensemble des questions techniques... » [Cass. 3<sup>e</sup> civ. 14 mars 2007] Comment le juge peut-il imposer une telle condition alors qu'un maître de l'ouvrage, le plus souvent profane, doit s'en remettre à la compétence de ses constructeurs et suivre leurs conseils ?

## 3 UNE CONVICTION : "LA GÉOTECHNIQUE POUR LES NULS"

Une conviction : Il faut enseigner aux juges la particularité de cette science naturelle pour leur permettre d'apprécier les limites auxquelles se heurtent ces mécaniciens du sol, mais également encadrer juridiquement l'activité géotechnique.

Deux moyens : une formation géotechnique « basique » de l'avocat pouvant offrir ainsi une vulgarisation de l'art géotechnique à l'attention du juge ; un accompagnement de la profession pour l'élaboration d'une norme juridique délimitant les missions et une formation des ingénieurs sur les risques encourus.

### 3.1 *La formation réciproque*

Faire entrer la science dans les prétoires pour mettre fin à ce dialogue de sourds, apparut comme une évidence. Il fallut déjà acquérir quelques notions de ce langage scientifique auprès d'un consultant en géotechnique, Francis Blondeau, acceptant de délaissé quelque peu le prestige de l'Ecole Nationale des Ponts et Chaussées, pour une mission plus terre-à-terre, celle de servir la cause d'un avocat en quête de vérité. Ce fut le temps des

pâtés de sable et de l'apprentissage des formations géologiques, sans réelle cohésion...

Globalement, on aura compris l'incidence de l'eau dans le sol sans jamais maîtriser les calculs de perméabilité et encore moins, cette ignorance hydrogéologique revendiquée de manière péremptoire par des géotechniciens. A l'échelle des temps géologiques, la géotechnique est récente en tant que science rationnelle, même si la technique empirique doit être aussi vieille que l'humanité. Dès lors, il est raisonnable de penser que son exercice devrait encore évoluer.

L'expérience des sinistres aidant, les fondations posées, le langage acquis, il n'était pas encore temps de prétendre donner la leçon au juge, et encore moins à l'adversaire, tous deux empreints de certitudes acquises au fil de décennies passées dans le flou artistique de cette science quasi-occulte.

La communication entre deux mondes est d'autant plus aisée par le balbutiement réciproque : les géotechniciens devaient apprendre des bribes du langage juridique pour mieux appréhender leurs risques en termes de responsabilité, avec les aléas judiciaires, aussi inéluctables que les incertitudes terrestres de leur science.

Ce fut le temps de la formation juridique axée sur les risques à partir de la relecture de sinistres. Et là, l'avocat a perdu tout sentiment de fierté face à ses châteaux de sable, devant la maîtrise par les ingénieurs de l'emploi des adverbes, de la conjugaison au conditionnel et autres artifices cherchant à les prémunir contre toute certitude. Une belle leçon d'humilité par le géotechnicien, « maître » en modestie, car la nature le commande.

Enfin, la liste de sondages faisant office de devis a pris la forme plus adéquate d'un contrat en bonne et due forme, avec des conditions générales d'intervention annexées permettant de mettre en exergue les incertitudes inhérentes à la science géotechnique. Mais surtout, l'intervention du bureau d'étude est désormais encadrée par la normalisation des missions géotechniques, principal acquis du siècle dernier en la matière.

### 3.2 *L'élaboration d'une norme*

An 2000... A l'issue de plusieurs années d'application d'un projet de normalisation, le nouveau millénaire a vu la naissance de la norme géotechnique NF P 94-500, fruit du travail de recherche de l'homme de l'art pour préserver ses droits face à une justice plus rigoureuse à l'égard du spécialiste de sol, dans les limites d'une science incertaine par nature qui dépend de l'investissement du maître de l'ouvrage.

Par un avant-propos très explicite, la norme expose la problématique des risques liés aux aléas géologiques pour sensibiliser le maître de l'ouvrage, mais également tous les intervenants à l'acte de construire. Par analogie aux missions de maîtrise d'œuvre, l'objectif est de les convaincre de la nécessité d'un enchaînement des missions géotechniques G1, G2, G3 et G4, le cas échéant G5, à tous les stades d'élaboration et de réalisation du projet pour identifier les risques et prendre les dispositions qui s'imposent.

La norme ne donne aucune illusion : il demeure toujours des risques de sol résiduels. Mais elle permet d'en prendre conscience et de les limiter. Nul n'est censé l'ignorer. Lorsqu'un prétendu expert judiciaire feint de l'ignorer, la sagesse du juge rétablit la vérité.

Un autre cas d'école sur un terrain glissant : Chargé d'une mission de diagnostic G5 en cours de chantier, dans un laps de temps très bref de quatre jours, un géotechnicien a donné des principes généraux à partir d'hypothèses en émettant des réserves sur un problème d'emprise qui ne pouvait être respectée et sur la nécessité d'une adaptation du projet.

Un glissement de terrain étant survenu, le réquisitoire de l'expert fut dirigé exclusivement contre cet intervenant spécialiste du sol aux motifs : de ne pas avoir consulté la carte géologique et effectué de recherche bibliographique de PPR, de ne pas avoir exécuté de sondages carottés et d'essais de

laboratoire, de ne pas avoir respecté l'emprise initiale du projet, de ne pas avoir proposé d'ouvrages de collecte des eaux, de ne pas avoir suivi le chantier et enfin, de ne pas avoir exigé une mission complète, étant de ce fait un piètre commercial !

Bénéficiant d'une « vulgarisation » géotechnique acquise par l'expérience, le juge - pourtant souvent enclin à suivre l'expert judiciaire, d'ailleurs nommé à cet effet -, a analysé tous les reproches dans leurs « aspects scientifiques, d'abord : essais de laboratoire (carottages, triaxiaux), principes d'analyse d'un glissement de terrain (cisaillement et étude de la résistance des sols, courbes de glissement, coefficient de sécurité)... ». Par une logique rigoureuse, le juge a mis en exergue le défaut de lien causal entre les insuffisances relevées par l'expert, notamment au titre de l'étude des couches profondes, et, le sinistre, avec un cercle de glissement à 4 m de profondeur. De surcroît, le juge a également apprécié les limites du diagnostic géotechnique G5 au sens de la norme NF P 94-500 et écarté le reproche afférent à l'absence de qualité commerciale du géotechnicien qui n'avait pas su vendre une mission complète : « *Ce reproche, outre qu'il révèle un acharnement certain à vouloir trouver en dépit des faits un chef d'incrimination, méconnaît le rôle du maître d'œuvre... et voudrait en outre voir le spécialiste des sols se transformer en commis voyageur préoccupé de placer un produit ou un service...* »

#### 4 CONCLUSION

Troisième millénaire : La responsabilité du géotechnicien n'est plus une fatalité. Le juge est devenu familier de cette science et maîtrise désormais les contours des missions, pour imputer le risque du sol à qui de droit !

Et contrairement à la garantie décennale, la norme... nos voisins nous l'envient : « *la mission confiée se situe au stade de l'avant-projet (G1) et non au stade du projet définitif lequel tombe dans la mission G2* » [Tribunal civil de Luxembourg 2 juin 2010]. Une nouvelle étape : l'exportation de la norme...

# Ideas for improved geotechnical structures for natural disaster mitigation

## Idées pour l'amélioration des ouvrages géotechniques pour l'atténuation des catastrophes naturelles

Heerten G.

*Naue GmbH & Co. KG, Germany*

Vollmert L.

*BBG Bauberatung Geokunststoffe GmbH & Co. KG, Germany*

**ABSTRACT:** Floods, earthquakes, tsunamis, landslides or avalanches / rock fall are current threats to human beings around the world. Geotechnical structures can be improved or developed with the use of geosynthetics to mitigate the impact of these kinds of natural disasters and to minimize damage and casualties. With erosion-resistant dykes the impact of flooding can be significantly reduced when the overtopping of a dyke cannot lead to a dyke failure with a big gap in the dyke with concentrated discharge. Embankment dams reinforced with geosynthetics are much more resistant to earthquake loading than conventional concrete structures. Artificial tsunami shelters as artificial hills are currently discussed to establish safe places near the coast. Finally new model studies are showing that the behaviour of embankments against dynamic rock fall impact can be significantly improved by reinforcing the structure with geogrids

**RÉSUMÉ :** Les inondations, tremblements de terre, tsunamis, glissements de terrain ou avalanches / chutes de pierres, sont des menaces courantes pour les êtres humains partout dans le Monde. Les ouvrages géotechniques peuvent être améliorés ou développés par l'utilisation de géosynthétiques pour atténuer l'impact de ces catastrophes naturelles et minimiser les dommages et causalités. L'impact des inondations peut être considérablement réduit avec des digues résistantes à l'érosion, car en cas de débordement, un déversement concentré n'entraînerait pas de rupture dans la digue. Les digues en remblai renforcé par géosynthétiques sont beaucoup plus résistantes aux contraintes sismiques que les ouvrages conventionnels en béton. Les abris artificiels contre les tsunamis, tels que des collines artificielles, sont actuellement considérés pour établir des lieux sûrs à proximité des côtes. Enfin, les études menées sur de nouveaux modèles montrent que le comportement des remblais de protection contre les chutes de blocs à impact dynamique peuvent être considérablement améliorés par le renforcement de la structure avec des géogrilles.

**KEYWORDS:** geosynthetics /geogrids, natural disasters mitigation, dykes/levees, embankments, tsunami shelter, rock fall protection.

### 1 INTRODUCTION

World's population is growing further. Increasing numbers of people are living in mega cities close to flood plains of rivers and oceans endangered by floods or tsunamis, but also in areas endangered by earthquakes or landslides. Natural disasters have created and will create huge material damage and a high number of casualties. But already after a short time the experience is forgotten and the intention to spend money for improving the safety fades away. But it is the responsibility of governments and authorities to ensure that appropriate strategies and measures for risk mitigation are in place and applied. And it is our obligation as geotechnical engineers to communicate improved design and construction methods for geotechnical structures for natural disaster mitigation. Ideas for safer dykes of higher erosion resistance, for embankments with improved resistance to earthquake loading and/or higher protection against impacts from rockfall, avalanches or landslides and tsunami shelters are presented.

### 2 EROSION-RESISTANT DYKES / LEVEES

In the aftermath of past disastrous flood events in Germany and other European countries it became evident that levees are part of the society's infrastructure and need careful control and maintenance. Immediately after major flood events the willingness to improve flood protection structures is great and (tax) money is available. These programs to improve the flood protection should consider the present technical improvements e.g. for the construction of levees. The improvement of levee cross-sections by using different geosynthetics has developed to

be state-of-the-art (Heerten 2010). The use of nonwoven filter materials to form a filter-stable, erosion-resistant transition between levee core and the air-side drain and ballast body or the arrangement of geosynthetic clay liners (bentonite mats) as a water-side surface seal have already been included as established alternatives in current regulations and guidelines. Beyond the three-zone levee the effects of geosynthetics integrated into levees as safety measures have been investigated and documented to have a high resistance capability during overflow load conditions. Erosion processes on the inner embankment and the risks of unexpected levee breaches can be minimized with geosynthetic construction techniques; geosynthetics can also be employed as support facilities for emergency reinforcing measures. Internal erosion in the embankments and sudden breaches to the surface of dykes can be prevented with knowledge and implementation of geosynthetics. Thus, these technologies provide not just structural defences but more time for evaluating risk and providing emergency response to populated areas that are threatened by rising water levels.

Geosynthetic clay liners (GCL) as needle-punched bentonite mats have gained widespread acceptance for levee improvement projects in a lot of countries because these products create a simple, effective, economical seal for a levee that simultaneously provides erosion protection for the levee body (Heerten and Horlacher 2002). Following the Elbe River floods that took place in Germany between 2002 and the end of 2005, about 150 levee reconstruction projects are known, being carried out in this period, in which about 2.2 million m<sup>2</sup> of needle-punched nonwovens, about 300 000 m<sup>2</sup> of geogrids and about 700 000 m<sup>2</sup> of needle-punched geosynthetic clay liners

(bentonite mats) have been employed (Heerten and Werth 2006). One example is shown in Figure 1. In the meantime, needle-punched geosynthetic clay liners are considered as state-of-the-art construction materials in levee/dyke construction (DWA 2005) in Germany and show increasing acceptance and use also in other countries.

The installation of a GCL can be carried out in a simple manner with a minimum use of technical equipment. After construction of the profiled bedding the GCLs are unrolled and overlapped. Afterwards the GCL is covered with soil. According to DWA (2005), a cover layer thickness of 80 cm is recommended for both types of mineral sealing (GCL and compacted clay liner (CCL)) in order to withstand climatic influences like wet-dry or freeze-thaw cycles considering German climate conditions. Bentonite mats offer the advantages of low sensitivity to settling without degradation to seal characteristics (deformation up to 25 % for needle-punched GCLs), consistent quality even after installation as well as good friction behaviour for steeper embankment slopes. However, the potential effects of root penetration and/or rodent infestation must be given attention just the same as with classic compacted clay liner made of cohesive soil. These effects can be counteracted by the design of the levee's project-oriented cross-section geometry, the use of non-cohesive cover layers which are unattractive to burrowing animals (Figure 2) or by additional engineering measures. Further information about planning and building with geosynthetic clay liners can be found in Heerten and Werth (2010).

Figure 1. Cross-section of a levee after rehabilitation at Oder River, Poland (Heerten 1999).

### 3 IMPROVING SEISMIC STABILITY OF STRUCTURES

#### 3.1 Geosynthetic reinforced soil structures (GRS structures)

In different regions of the world with potential high risks of earthquakes the advantages of geogrid reinforced embankments with reference to higher resistance to earthquake loading are well known and experienced. Based on the authors knowledge most know-how and experience with geogrid/geosynthetic

reinforced soil structures (GRS structures) under earthquake loading have been generated in Japan, where even fast train tracks are constructed on embankments by using GRS structures.

This development is based on the very positive experience with geosynthetic reinforced soil structures under seismic loading in Japan e.g. during the Kobe earthquake. Figure 3 is showing a GRS structure before and after the Kobe earthquake (Tatsuoka 2008).

Figure 3. Geosynthetic reinforced soil structure (GRS structure) as railway embankment after completion 1992 and after the Kobe earthquake 1995 (Tatsuoka 2008).

The synthetic polymeric materials used for soil reinforcement applications (mainly geogrids) are thermoplastic materials with visco-elastic material properties. The partial safety factor for creep (A1) is often the most important reduction factor to calculate the (long-term) design strength (F<sub>Bi,d</sub>) of a geosynthetic reinforcing element based on the characteristic (short-term) tensile strength (F<sub>Bi,K0</sub>) estimated for a given reinforcing product by lab testing.

It has to be pointed out again and again that creep of a synthetic reinforcing product is a product-specific visco-elastic material response and not a deterioration or damage to the product like e.g. corrosion for metal products. Therefore the special product characteristics of polymeric geogrids for soil reinforcement show that after a period of sustained loading in a soil structure an additional spontaneous dynamic load can be met by the original short-term tensile strength of the product. In a new seismic design code for Japanese railway structures this background is considered for the first time in geotechnical engineering. NO creep reduction factor is considered to obtain the design tensile strength of geosynthetic reinforcement under additional seismic loading.

The NO-creep-reduction-approach for seismic loading of geosynthetic reinforced structures (GRS) is part of the new concepts and procedures for the recent developed design code for Japanese railway structures reported by Tatsuoka (2009) with the following key elements:

- a) very high design seismic loads (i.e. , level 2), as those experienced during the 1995 Kobe earthquake;
- b) design against level 2 based on residual displacement;
- c) the use of both peak and residual shear strengths with well-compacted backfill;
- d) design based on the limit equilibrium stability analysis;
- e) control to high backfill compaction and good drainage;
- f) strong recommendation of GRS structures as highly earthquake-resistant soil structures;
- and
- g) no creep reduction to obtain the design tensile strength of geosynthetic reinforcement.

When following this design code, engineers naturally chose GRS structures.

### 3.2 Geogrid reinforcement for masonry walls in houses

It is also known that a lot of casualties during earthquakes are caused by falling bricks, when masonry walls in the houses e.g. between steel frames are collapsing. An important improvement of stability under seismic loading can be achieved by geogrid reinforcement of masonry walls (Figure 4) as investigated and developed in Germany at Bauhaus-University Weimar (Burkhardt et al 2005).

Figure 4. Strength test of geogrid reinforced masonry wall (Burkhardt et al 2005).

## 4 TSUNAMI SHELTER

When a tsunami warning is given people have to leave low coastal areas as quick as possible. After the devastating tsunami of 2004 in the Indian ocean in the meantime a “Tsunami Early Warning System” is in operation. But a big challenge still is the organization of an effective evacuation of the people living in the endangered big cities at the coast in the available very short time of about 30 minutes between “Tsunami Warning” and the arrival of the tsunami wave. In Indonesia for instance “raised earth parks” as cost effective tsunami shelter are discussed to establish safe places right at the coast. These artificial hills have to be high enough, stable against earthquake loading and erosion-resistant to the wash of the tsunami wave. It should also be easy for all people to get up to the safe top of the hill. Structures of geosynthetic-reinforced soil (GRS structures) can fulfil these requirements. Figure 5 is showing the idea of “TEREP – Tsunami Evacuation Raised Earth Park” as proposed for the city of Padang, Indonesia. For Padang five evacuation parks are discussed, each park as refuge for 15.000 people out of a 1.5 km radius. As of the author’s actual knowledge the construction of TEREP is still delayed. Let’s hope that fading away of the remembering of the last tsunami disaster is not the reason – the next tsunami will come!

Figure 5. Idea of “Tsunami Evacuation Raised Earth Park” for the City of Padang, Indonesia (Tucker, 2010).

Tsunami defense systems can be separated into different “defense lines” as shown in Figure 6 (Recio, J. and Oumeraci, H. 2007). The artificial hills or “raised earth parks” are subject of the 4<sup>th</sup> defense line.

Figure 6. Different four defense lines for tsunami protection structures at endangered coast lines (Recio and Oumeraci 2007).

In the first off-shore defense line geosynthetic sand container which can be filled and placed with up to approx. 500 tons of sand have to be considered as cost efficient and environmental friendly solutions. The very positive results from e.g. the design and construction of the Narrowneck-Reef at the Goldcoast of Queensland, Australia with mega-sandcontainer made of needle-punched nonwoven staple-fibre geotextiles can be considered (Heerten 2010). At Narrowneck Reef the mega-sandcontainers have been hydraulically filled and installed with a special split-bottom hopper dredger (Figure 7).

In Japan geosynthetic reinforced structures for tsunami protection seawalls (defense line 2, Figure 6) are considered to improve the protection of nuclear power plants after the Fukushima disaster.

## 5 ROCKFALL-PROTECTION EMBANKMENTS

Much infrastructure buildings and densely populated areas with increasing population are located in rock fall areas. As rock fall protection by net-fences is restricted by the energy adsorption capacity (approx. 8000 kJ), embankments are built for higher design energies. New model studies to improve the prediction of dynamic rock fall impact on embankments have shown that the behaviour of embankments can be improved by reinforcing the structure with geosynthetics (geogrids). The lessons learned from the tests with geosynthetics are (Hofmann, R., Vollmert, L. and MÖlk, M. 2013):

- The model tests with the geosynthetics all showed a significantly larger lateral distribution (influence width) of the displacements. An influence width of at least 8 - 9 times the diameter of the sphere (the impact) can be estimated from the measurements and the pictures taken with the high-speed camera.

- Very slim constructions with uphill and downhill slope angles of 70° and 60° were also investigated. These exhibited a noticeably more elastic behaviour than pure soil embankments (Figure 8)
- However, they require a markedly greater freeboard than embankments with stacked-rock facing. For geogrid-reinforced structures, a freeboard of 1.5 times the sphere diameter can be considered as being on the safe side.

Figure 7. Hydraulic filling and placing of mega-sandcontainers with a split-bottom hopper dredger at Narrowneck Reef, Queensland, Australia (Heerten, 2010).

Figure 8. Possible slim and cost effective construction of rockfall embankments reinforced with geosynthetics. (Hofmann, R., Vollmert, L. and Molk, M. 2013).

Corresponding structures can also be used for torrent-control and avalanche-protection structures.

## 6 CONCLUSIONS

Considering geosynthetics for design and construction of dykes/levees, embankments in earthquake endangered areas, tsunamia protection structures and rockfall protection embankments can considerably improve the function of the structures. An important improvement of stability under seismic loading can also be achieved by geogrid reinforcement of masonry walls.

It is the task of the (geo)engineering community to inform the public about these improvements and the possible higher

level of safety for material goods and people in case of natural disasters. Let's hope that the last natural disaster experiences of earthquakes, tsunamis, floods and landslides and the need and intention to spend money for improving our safety does not fade away.

# Deep Excavation in Hong Kong – Cantilever Bored Pile Wall Design Using CIRIA Report No. C580

Excavation profonde à Hong Kong - Conception de mur cantilever à pieux forés suivant le rapport CIRIA n° C580

Ho A., Wright M., Ng S.

Ove Arup & Partners Hong Kong Ltd, Hong Kong Special Administrative Region, China

**ABSTRACT:** The design of cantilever retaining walls in Hong Kong is mainly carried out in accordance with Geoguide 1 (Second Edition) where a simplified model is adopted for the determination of the embedment depth of the pile. Following publication of CIRIA Report No. C580 (Embedded Retaining Walls – Guidance for Economic Design) several Hong Kong projects have adopted the design approach for temporary deep excavation works. This paper describes the first local application to a permanent cantilever wall approved by the Government of the Hong Kong Special Administrative Region, Geotechnical Engineering Office.

This paper compares the design approach of a large diameter bored pile cantilever wall for a large site formation development in Hong Kong using the traditional simplified model approach and the rational, safe and economic approach described in CIRIA C580. Detailed monitoring of the wall performance during construction is also described as a review of the C580 approach.

**RÉSUMÉ:** La conception des murs de soutènement cantilever à Hong Kong est principalement réalisée en conformité avec GeoGuide 1 (deuxième édition), où un modèle simplifié est adopté pour la détermination de la profondeur d'ancrage de la pile. Après la publication du rapport CIRIA C580 No. (incorporés Murs de soutènement - Lignes directrices pour la conception économique) plusieurs Hong Kong projets ont adopté l'approche de conception pour des travaux d'excavation temporaires profondes. Cet article décrit la première application locale d'un mur en porte à faux permanent approuvé par le Gouvernement de la RAS de Hong Kong, Bureau administratif du génie géotechnique.

Cet article compare la démarche de conception d'un diamètre foré grand mur en porte à faux poils pour un développement formation grand site de Hong Kong utilisant la méthode simplifiée modèle traditionnel et le rationnel, sûre et économique décrit dans CIRIA C580. Un suivi détaillé de la performance du mur en cours de construction est aussi décrit comme un examen de l'approche C580.

**KEYWORDS:** C580, Geoguide 1, cantilever retaining wall, case study, and cost saving.

## 1 INTRODUCTION

In Hong Kong, the CIRIA Report C580 – Embedded Retaining Walls – Guidelines for Economic Design (Gaba et al. 2003) has been critically reviewed by the Hong Kong industry and academic research community since its publication in 2003 and has been widely used in the design of temporary works for excavations and lateral support (ELS), (Sze et al 2005).

The authors have adopted the design approach of CIRIA Report C580 for the design of a permanent cantilever large diameter bored pile wall for the support of sloping ground and retaining around 20 m level difference for the construction of a new road in front of the wall. This is the first recorded Hong Kong project adopting the C580 design approach for a permanent application.

Analyses using the two design methods, Geoguide 1 (Second Edition) and CIRIA Report No. C580, for cantilever bored pile wall are discussed in this paper and the performance of the permanent cantilever wall during excavation is also presented.

## 2 SITE DESCRIPTION AND GROUND CONDITIONS

### 2.1 The Site

The Site is located at the north-eastern part of Kwun Tong, Kowloon, Hong Kong, see Figure 1. This Project comprises site formation works for a Public Housing development forming about 20 hectares of useable land on a sloping site. For the formation of the development platforms, retaining walls and slopes are required to create level platforms with significant level difference between platforms. Reinforced earth walls, reinforced concrete retaining walls as well as cut and fill slopes are proposed for retaining the level difference.

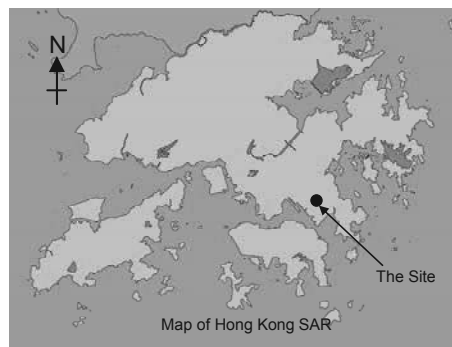

Figure 1. Site Location

The proposed works include construction of a new road as one of the principal vehicle accesses to the proposed development. The level difference between the proposed new road and an existing road and service reservoir varies from about 10m to 20m while the available horizontal clearance is approximately only 11m and 5m respectively. Different schemes were explored in the design stage including reinforced earth wall, reinforced concrete wall and steep cut slope with soil nails. These were found not feasible due to the extremely onerous space constraint. Therefore, a 3.0m diameter bored pile wall was eventually adopted. The proposed bored pile wall is approximately 110m long with 33 nos. of bored piles. The plan view of the proposed cantilever bored pile wall is illustrated in Figure 2 and the typical geological section is shown in Figure 3.

Figure 2. Layout of the bored pile wall with adjacent constraints

Figure 3. Geological section

### 2.2 Geological Conditions

The soil stratigraphy of the site comprises Fill and weathered granite. The fill was generally present within the Site with maximum thickness of fill up to 8m below existing ground level. The fill comprises loose to medium dense, gravely silty sand or sandy clayey silt, with some rock and concrete fragments and occasional domestic waste. The SPT 'N' values ranged from 5 to 15 indicating a loose state. Completely to highly decomposed granite is present beneath the superficial deposits. The granites are commonly fine to medium grained greyish pink to pinkish grey in colour in fresh state and the granite is weathered to varying depths. The thickness of completely decomposed granite (CDG) weathering Grade V ranges from 5 m to 10 m with SPT-N values from 15 to 100. Highly decomposed granites (HDG) of weathering Grade IV occurs with SPT 'N' value larger than 100. The maximum depth to moderately to slightly decomposed granites (M/SDG) encountered ranges from 15m to 40m below existing ground level. The uniaxial compressive strength of the M/SDG ranging from 40 to 135mPa. A geological section along the proposed cantilever bored pile wall is presented in Figure 4.

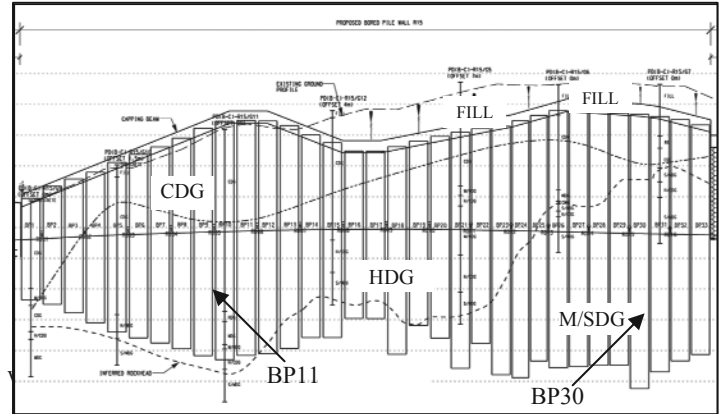

Figure 4. Geological long section

### 2.3 Geotechnical Design Parameters

The engineering properties of soils and rocks have been assessed using the field and laboratory test data. A total of 105 nos. consolidated undraining judgment with reference to the 'best fit', 'lower bound' and average values. The adopted design parameters are listed in Table 1.

Table 1. Summary of adopted soil parameters

Soil Stratum	Density ( $kN/m^3$ )	Cohesion, $c'$ (kPa)	Fictional Angle, (degree)	E value (MPa)
FILL	19	0	35	10
CDG	19	7	38	20
HDG	19	7	38	40

### 2.4 Groundwater levels

Piezometers and standpipes have been installed over the Site to provide groundwater information during construction. Generally, groundwater levels tend to be at or near the rockhead level and typically rise by up to about 3m after rainfall. The groundwater level is assumed to be +166 mPD on the retained side and at the excavation level (approximately +159 mPD) at the excavated side.

## 3 DESIGN OF CANTILEVER BORED PILE WALL

### 3.1 Design considerations

The results of analyses using the two design methods, Geoguide 1 (Second Edition) using a simplified model and CIRIA Report No. C580, for cantilever bored pile wall are presented. These calculations assume that the entire embedded portion of the cantilever bored pile wall is in soil. The effect of the capping beam is ignored in the analysis and the long term creep effect is to be controlled by the post construction of a 500mm thick skin wall.

### 3.2 Traditional Approach (Geoguide 1)

The traditional approach of the design of a cantilever bored pile wall was carried out in accordance with the recommendation given in Section 11.2.3 and Figure 50(c) of Geoguide 1 (Second Edition) where a simplified model was adopted for the determination of the embedment depth of the pile, (Pang et al 2005).

### 3.3 C580 Approach

In the CIRIA C580 design approach, the embedment depth is determined by achieving equilibrium in a soil-structure interaction analysis using a pseudo-finite element program FREW (Oasys 2007).

In the C580 design, partial factors as suggested in “Notes on Design of excavation and Lateral Support works Using the Limited State Partial Factor Method” (BD 2005) were adopted instead to reflect the application of limit state design.

The cantilever bored pile wall is subjected to the unbalanced loading of sloping ground and hydrostatic pressure. In both calculations, the pile heads deflections are controlled to be within 1% of the excavation depth.

### 4 DESIGN COMPARISON

Two sections are reviewed in this paper: BP11, which is the closest pile to the existing service reservoir, with retained height of 18.0 m and BP30, with retained height (deepest excavation) of 19.4 m.

The results of the deflection and internal structural force for both of the sections are presented in Figures 5 and 6 respectively.

Figure 5. Calculated deflection, bending moment and shear force along cantilever bored pile wall (BP11)

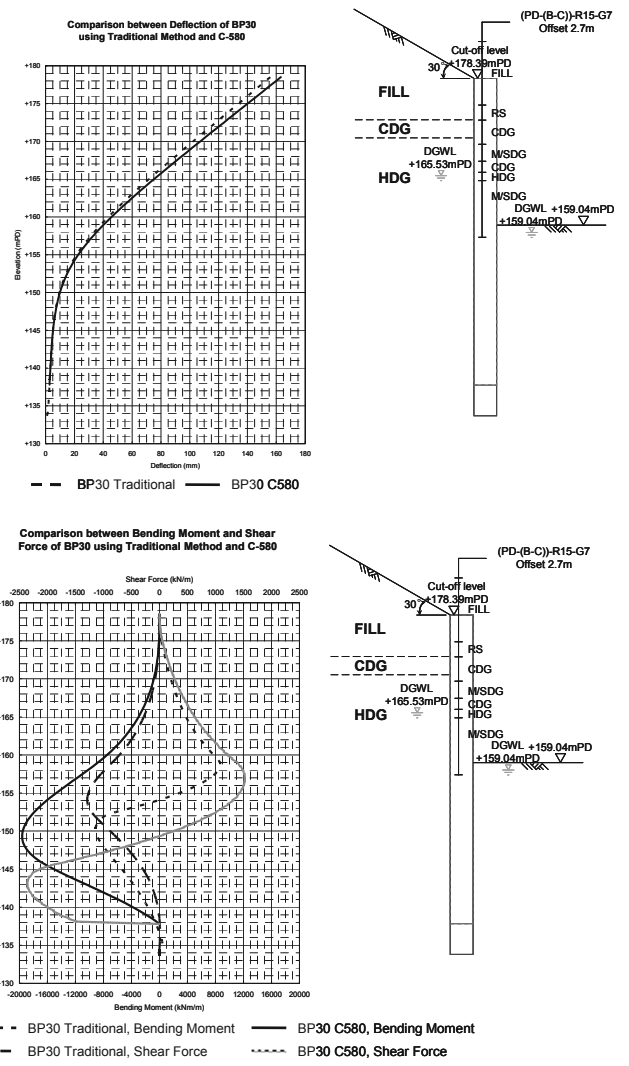

Figure 6. Calculated deflection, bending moment and shear force along cantilever bored pile wall (BP30)

The wall deflection, bending moment, and shear force of the two methods calculated using FREW at the final stage of the excavation were compared and summarized in Tables 2 and 3.

Table 2. Comparison of forces in wall and deflection (BP11\*)

	Embedment (m)	Bending Moment (kN-m/m)	Shear Force (kN/m)	Deflection (mm)
Traditional Approach (Geoguide 1)	23.21	8,267	1,041	146.7
C580	20.20	15,710	2,108	146.7
% Change	- 13%	+ 90%	+ 102%	No Change

\* BP11 is the closest pile to the existing service reservoir with retaining height of 18.0m

Table 3. Comparison of forces in wall and deflection (BP30#)

	<i>Embedment (m)</i>	<i>Bending Moment (kN-m/m)</i>	<i>Shear Force (kN/m)</i>	<i>Deflection (mm)</i>
Traditional Approach (Geoguide 1)	25.26	10,320	1,269	184.8
C580	21.24	19,610	2,403	193.9
% Change	- 16%	+ 90%	+ 89%	+ 5%

# BP30 is a pile with the highest retaining height of 19.4m

Based on the table above, there is an average decrease of 3m embedment by using C580 approach which is about 14% reduction to the original proposed embedment. However, the advantage of the reduction of embedment by using C580 results in a substantial increase in structural forces. Thus, it would require an increase of structural capacity by increasing the steel ratio in these cases.

## 5 COST SAVING

Although, the bending moment and shear force of the cantilever bored pile wall increased 90% in average as shown in Tables 2 and 3 above, the increase of the steel reinforcement percentage is only from 1.32% to 1.78% mainly due to the use of 3 m diameter bored pile with high bending capacity. The cost comparison using the two approaches is presented in Table 4.

Table 4. Summary of cost difference

	<i>Average pile length (m)</i>	<i>Steel percentage (%)</i>	<i>Total cost per pile (million HK\$)</i>
Traditional Approach (Geoguide 1)	43.0	1.32	3.03
C580	39.5	1.78	2.74
% Change	- 3.5	+ 0.46	- 0.29 (Saving of 10%)

The increase of the construction cost of the bored piles is not directly proportional to the increase of pile depth. Normally, it is an exponential increase with depth. Thus, the reduction of a pile embedment results in a saving in the overall construction cost. From the table above, there is about 10 % of overall cost saving on the cantilever bored pile retaining wall system when using C580 approach. This represents an amount of HK\$ 9.6 million saving on this project.

Besides the cost saving, there is also a non-quantified saving by using C580 approach such as the reduction of construction risk for deeper pile, (Sze et al 2005).

## 6 PERFORMANCE AND MONITORING

A 2.0 m deep capping beam was installed onto the pile heads before excavation and deformation markers were provided for the measurement of the wall top movement by land surveying methods. The excavation commenced in December 2011 and was completed by stages in June 2012, The condition of the cantilever wall during the excavation stage in January 2012 is shown in Figure 7.

Figure 7: Excavation of the cantilever bored pile wall (January 2012)

The monitoring results of the wall top movement by land survey is compared with the design predictions are shown in the Table below. It is concluded that the use of C580 is a safe approach for the design of a permanent cantilever bored pile wall.

Table 5. Comparison of predicted and actual wall deflection

	<i>Traditional Approach (Predicted)</i>	<i>C580 (Predicted)</i>	<i>Actual lateral movement</i>
BP11	146.7 mm	146.7 mm	21 mm
BP30	184.9 mm	193.9 mm	20 mm

The actual movement from monitoring results maybe less than predicted due to:

1. the beneficial effect from the capping beam is not accounted for in the design
2. the slopping ground on the retaining side was significantly reduced in height due to the formation of a temporary piling platform and hence loading was reduced
3. local variations in the bedrock weathering profile was not accounted for in the design

A comprehensive and continuous monitoring of the wall movement was conducted throughout the construction period comprising the followings will be discussed in future:

1. Piezometers provided behind the wall to monitor the groundwater conditions.
2. Inclinometers and B-OTDR (Brillouin Optical Time Domain Reflectometer) optical fibres were installed into ducts reserved in the piles to monitor the behaviour of the cantilever bored pile wall.

## 7 CONCLUSIONS

The use of C580 design approach together with partial factors as suggested in "Notes on Design of Excavation and Lateral Support Works Using the Limit State Partial Factor Method" (BD 2005) is a safe and economic design for a cantilever bored pile wall. In general, there is a cost saving by using C580 design in comparison with the traditional design approach as described in Geoguide 1 (Second Edition)

However, the pile deflection profile and the long term effect (i.e creep effect) of a cantilever bored pile wall system using C580 design approach should be further reviewed.

## 8 ACKNOWLEDGEMENTS

Authors would like to thank Dr. P.L.R. Pang of Geotechnical Engineering Office, HKSAR for the review and guidance of the first C580 permanent cantilever wall design report.

# Comparison of the safety concepts for soil reinforcement methods using concrete columns

## Comparaison des concepts de sécurité pour les méthodes de renforcement de sol avec colonnes en béton

Katzenbach R., Bohn C.

Technical University Darmstadt, Institute and laboratory for geotechnics

Wehr J.

Keller Holding GmbH

**ABSTRACT:** The rigid inclusion concept is a soil reinforcement method using concrete columns with a small diameter compared to usual piles. The load bearing behaviour of such systems is presented in comparison to pile foundations and to combined pile-raft foundations. The safety concept developed in the French recommendations ASIRI for rigid inclusions is divided in two domains depending on the use of the columns, either to enhance the bearing capacity (analogy to piles) or only to reduce the settlements. The safety factors considered for the bearing capacity are compared with those in pile standards (Eurocode 7) and with those in different recommendations for similar reinforcement systems. The particular sensitivity of columns with small diameter is highlighted.

**RÉSUMÉ :** Les inclusions rigides sont une méthode de renforcement de sol avec colonnes en béton de diamètre faible par rapport aux pieux usuels. La répartition des charges au sein d'un tel système est présentée en comparaison avec les pieux et les fondations mixtes. Le concept de sécurité développé dans les recommandations ASIRI pour les inclusions rigides se divise en deux domaines d'utilisation, soit comme augmentation de la portance (analogie avec les pieux), soit uniquement comme réduction des tassements. Les facteurs de sécurité considérés pour la portance sont présentés en comparaison avec les normes de pieux (Eurocode 7) et avec différentes recommandations pour des systèmes similaires. On insiste sur la sensibilité particulière des colonnes de faible diamètre.

**KEYWORDS:** rigid inclusion, soil reinforcement, safety concept, Eurocode 7, column diameter, sensitivity

## 1 INTRODUCTION

One of the existing soil reinforcement methods with concrete columns is the so-called „rigid inclusions“ method, which has experienced a fast development in the last years, in particular in France (Briançon et al. 2004). This technique consists of a soil improvement method using in general non-reinforced concrete columns with a column diameter of 25 cm up to 80 cm with a soil displacement method. The rigid inclusions are in general separated from the structure by a granular load transfer layer (Figure 1).

Figure 1. Rigid inclusions system in comparison with usual foundation systems

To some extent, these columns can be compared to usual piles. But in the case of rigid inclusions, the bearing capacity of the soil itself is taken into account in the design, like for combined pile-raft foundations (CPRF), which leads to considerable savings of concrete in the columns and of steel reinforcement in the foundation slab.

The technique with rigid inclusions is employed as well under shallow or raft foundations (e.g. industry halls, water tanks) as under embankments (e.g. high speed railway lines).

The French recommendations of the national research project ASIRI („Améliorations de Sols par Inclusions RIGides“), which have been published in 2012, provide a harmonization for the (in particular numerical) calculations (Jenck et al. 2004), for the safety requirements and for the execution of rigid inclusions. The initial point of the safety

theory is the European standardization, that is the French applications of the Eurocode 7 for the geotechnical safety checks, in general based on the pressuremeter design theory in France (Frank 2009), and the Eurocode 2 for concrete. Two different application cases are distinguished in ASIRI: the rigid inclusions can be either used to guarantee the stability of the structure or only as settlement reducers. These different application cases either in analogy to foundations systems or to soil reinforcement methods are reflected in the recommended safety concept in ASIRI.

## 2 LOAD BEARING AND DEFORMATION BEHAVIOUR OF RIGID INCLUSIONS

Rigid inclusions can both be embedded in a bearing layer or – in the general case – designed as floating elements in a compressible soil. The applied load from the structure on the system is distributed between the soil and the column heads. A so-called efficiency of the system can be defined from this load distribution as the ratio of the total load in the column head to the total vertical load. This definition corresponds to the pile-raft-coefficient for CPRF (Hanisch et al. 2002). The load distribution depends on different factors, in particular the rigidity of the foundation and of the soil, the thickness of the load transfer layer, the spacing between the columns and the rigidity of the columns (Okyay 2010).

The interactions between soil and columns in the case of a vertical load are presented in Figure 2. A negative skin friction affects the upper part of the columns due to the separation between slab and columns and because of the compressibility of the soil to be improved. This leads to a reduction of the load in the soil over the depth and to an increase of the force in the columns until the depth where the differential settlement between soil and column is equal to zero. Below this neutral plane, the force in the column is transferred to the soil through

positive skin friction and tip resistance, like for usual deep foundations.

Figure 2. Load bearing and deformation behaviour of rigid inclusions

Horizontal loads can be supported by such systems as well, for example in the case of horizontally loaded isolated footings or when reinforced columns are used as nails against slope failure.

The usual applications of rigid inclusions are the following:

- Under large embankments or raft foundations to reduce settlements
  - At the border of embankments (slope) and potentially of raft foundations against slope failure, or to reduce settlements
  - Under isolated footings against failure of bearing capacity or sliding, or to reduce the settlements

### 3 SAFETY CHECKS IN THE FRENCH RECOMMENDATIONS ASIRI

First of all, the load distribution in the system without inclusions has to be determined, using the usual calculation methods for foundations or slopes. If the safety according to the French standards against failure of bearing capacity, sliding or slope failure in the ultimate limit state (ULS) is not guaranteed without columns, the subsequent safety checks correspond to the so-called „domain 1“ (Figure 3). Otherwise the columns can be used only to reduce the deformations („domain 2“). The required calculation of the load distribution with columns has to be carried out using comprehensive numerical models or using one of the recommended simplified models in ASIRI.

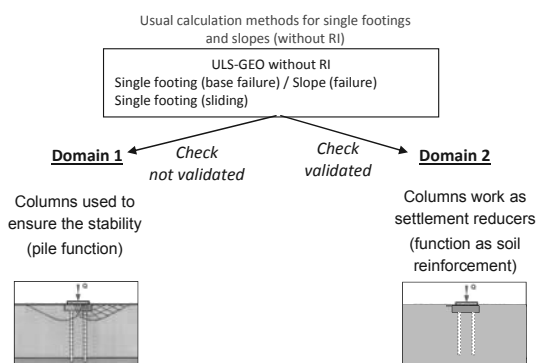

Figure 3. Classification in domain 1 and 2 in ASIRI

In the domain 1, the safety checks are carried out in analogy with the French Eurocode 7 application standards for deep foundations in addition to the standards for isolated footings and slope stability. The favourable action of the columns is taken into account by reducing the foundation load on the soil. Then, the checks of bearing capacity for the foundation or the slope are carried out normally with this reduced load. Besides, the bearing capacity of the columns has to be checked as well against ultimate limit states (ULS) against serviceability limit states (SLS) under the neutral plane (Figure 2), just like for piles after the French standard for deep foundations. The structural capacity of the columns, which are in general not reinforced,

has to be verified by means of a limitation of the compression and shear stresses in the column section in the ULS and SLS. The compatibility of the calculated vertical and horizontal deformations has to be checked in SLS.

In the domain 2, the columns are considered as pure settlement reducers. Therefore, no check of the bearing capacity is required in this domain, like in the design philosophy of the CPRF-guideline (Hanisch et al. 2002) or in the case of the so-called “creep piles”. Only SLS-checks have to be carried out here.

In both cases, compatibility verifications have to be done after the checks, in particular to verify the compatibility of the stresses in the load transfer layer.

### 4 COMPARISON WITH STANDARDS AND RECOMMENDATIONS

In this section, the recommended safety checks in ASIRI for the domains 1 and 2 are compared with the French and German piling standards and with recommendations for similar piles or columns systems, i.e. the German CPRF-Guideline (Hanisch et al. 2002) and the German guideline for stabilizing columns "Merkblatt für die Herstellung, Bemessung und Qualitätssicherung von Stabilisierungssäulen zur Untergrundverbesserung" (CSV-Merkblatt, DGGT 2002). Only the persistent load situation (BS-P in Germany) is considered here. The partial safety factors for the actions in this load case are the same in all regulations, that is 1,35 (respectively 1,5) for the permanent (respectively variable) loads in the case of foundations, and 1,0 (respectively 1,3) for the slope stability.

#### 4.1 External bearing capacity (GEO)

In ASIRI, only the domain 1, where the columns are necessary for the stability, is concerned by the safety checks in the ULS (Table 1). The verifications correspond to those of the French application standard of Eurocode 7 for compression piles (with a diameter of usually 1 m up to 3 m), in general with the use of empirical resistance values from pressuremeter tests (Table 2). The favourable effect of the columns in the checks of the footing or the slope is taken into account by reducing the total load by the force taken in the columns. After ASIRI, no pile loading test has to be done in the design phase for the determination of the bearing capacity. However, loading tests have to be carried out in the execution phase according to ASIRI to verify the previously determined bearing capacity.

In the CPRF-guideline (Hanisch et al. 2002), no distinction is made between a use as “settlement reducer” or as “resistance increaser”. The maximum characteristic resistance is defined here from the load-settlement curve of the global system, and divided by a safety factor to obtain the design value (Table 3). The bearing capacity of the piles themselves has not to be verified, since the whole system made of the slab, the piles and the soil has already to be stable. In the CSV-guideline on the contrary the bearing capacity of the single columns always has to be checked, with the additional assumption that the total applied load from the structure is taken by the columns (here diameter 12 cm up to 20 cm), which is on the safe side.

Table 1. Partial safety factors – ASIRI ULS-GEO

ULS-GEO (BS-P)	ASIRI (France)							
	Domain 1				Domain 2			
	Isolated footing		Slope	RI	Isolated footing		Slope	RI
Failure	Sliding	Failure			Sliding			
Partial safety factor for resistance	$\gamma_{R,v} \times \gamma_{R,d}$ = 1,4 x 1,2 = 1,68	$\gamma_{R,h} \times \gamma_{R,d}$ = 1,1 x 1,0 = 1,1	$\{\gamma_{\varphi} = \gamma_c\} \times \gamma_{R,d}$ = 1,25 x (1,1 bis 1,2) = 1,38 bis 1,5	$\{\gamma_b = \gamma_s\} \times \gamma_{R,d1} \times \gamma_{R,d2}$ = 1,1 x 1,15 x 1,1 = 1,39	/	/	/	/
Remark	load reduction due to RI (Slope only drained here model factor for reinforced soils depending on the sensitivity towards deformations)			like piles under the neutral plane empirical values (pressuremeter method)	no stability check	no stability check	no stability check	no stability check

Table 2. Partial safety factors – Eurocode ULS-GEO

ULS-GEO (BS-P)	Eurocode 7 Germany				Eurocode 7 France			
	Isolated footing		Slope	Piles	Isolated footing		Slope	Piles
	Failure	Sliding			Base failure	Sliding		
Partial safety factor for resistance	$\gamma_{R,v}$ = 1,4	$\gamma_{R,h}$ = 1,1	$\gamma_{\varphi} = \gamma_c$ = 1,25	$\gamma_b = \gamma_s$ = 1,4	$\gamma_{R,v} \times \gamma_{R,d}$ = 1,4 x 1,2 = 1,68	$\gamma_{R,h} \times \gamma_{R,d}$ = 1,1 x 1,0 = 1,1	$\gamma_{\varphi} = \gamma_c$ = 1,25	$\{\gamma_b = \gamma_s\} \times \gamma_{R,d1} \times \gamma_{R,d2}$ = 1,1 x 1,15 x 1,1 = 1,39

Table 3. Partial safety factors – Recommendations ULS-GEO

ULS-GEO (BS-P)	CPRF-Guideline (Germany)			CSV-Guideline (Germany)			
	Combined pile-raft foundation		Slope	Isolated footing		Slope	Columns
	Failure	Sliding		Failure	Sliding		
Partial safety factor for resistance	$\gamma_{R,v}$ = 1,4	$\gamma_{R,h}$ = 1,1	/	/	$\gamma_{\varphi} \times \lambda_{pv}$ = 1,25 x 1,15 = 1,43	$\gamma_{sp}$ = 1,25 bis 1,4	
Remark	as global system		/	not taken into account	only drained here $\lambda_{pv}$ against chain reaction of columns	Assumption: total load in the columns; depending on number of load tests (in execution phase)	

According to the French application standards of Eurocode 7, safety checks for the resistance have to be carried out in the SLS as well. This has been adopted in ASIRI for the domain 1. Therefore a so-called "pile creep load" has been defined in the French standards as 70% (for displacement piles) of the total resistance as a reference in the SLS. The safety against failure of bearing capacity of single footings also is increased in comparison with the ULS. In the domain 2, only the compatibility of the displacements has to be investigated. In the German application standards of the Eurocode 7, only the limits of deformation have to be controlled in the SLS.

#### 4.2 Internal structural capacity (STR)

The safety factors for the maximum compression in the section of the rigid inclusions in the ULS and SLS are similar to those for piles in Eurocode 7 (with reference to Eurocode 2 for the concrete). The safety factor for the resistance in ASIRI is up to approximately 2 to 11 depending on the limit state, the execution type, the slenderness of the column and the quality controls. In order to avoid very small column diameters, the mean compression stress in the section is in all cases limited to 7 MPa in the ULS (domain 1). Adapted values have to be considered for domain 2 (SLS).

Although the rigid inclusions are not used as tension piles, tension stresses can develop in the section resulting from bending moments. In the domain 1, the columns have to be

reinforced in the same way as piles according to Eurocode 2 as soon as tension stresses appear in the section. On the other hand, in the domain 2 tensile stresses up to the characteristic value of the tensile strength of the concrete are allowed. If this value is exceeded, the columns have to be reinforced as well.

The internal resistance can be particularly endangered in the case of unreinforced columns with very small diameter (Wehr & Sondermann 2011). For this reason, no shear stresses are allowed in ASIRI for unreinforced columns with a diameter smaller than 30 cm (cp. 40 cm for conventional piles). Buckling effects have to be analysed also for these small diameters and for very soft soils (pressuremeter modulus EM smaller than 3 MPa). The minimum allowed diameter in ASIRI for unreinforced columns is 25 cm.

In the CPRF-guideline (Hanisch et al. 2002) the internal resistance has to be checked in the same way as for conventional pile foundations.

According to the CSV-guideline (DGGT 2002), a safety factor of 2 has to be considered for the mean compression, in comparison with 2 up to 6 for the maximum compression stress in the ULS and 7 MPa for the mean compression stress in ASIRI. According to this guideline, the buckling has to be checked only in soft layers with an undrained cohesion smaller than 10 kPa. This is not in accordance with the present state of the art for slender piles: buckling effects can already appear for

soils with greater undrained cohesion (Vogt et al. 2005 and Eurocode 7 - DIN 1054 - 2010).

#### 4.3 Sensitivity of columns with small diameter

Two different design philosophies exist concerning the check of the bearing capacity of the column in the case of column diameters greater than 25 cm. The philosophy can be either without safety check (ASIRI in the domain 2 or CPRF-guideline, where the system is checked as a global system including slab, piles and soil), or with safety check in accordance with the piling standards (ASIRI in the domain 1). For smaller column diameters with a load transfer layer there is no recommendation for the use as pure settlement reducers, use which namely is only applicable for systems with a sufficient ductility and possibilities of load redistribution (flexible connection between piles and slab or relatively large column diameter).

Special attention must be paid to the particular sensitivity concerning the internal resistance of columns beneath the load transfer platform under horizontal loadings. Horizontal loads from the structure lead to shear, bending moments and thus possibly tension in the column section. Though the concrete design is regulated uniformly and with an adequate safety factor for all diameters, the particular importance of the interactions between the structure and the system made of soil and columns is not completely described in the current state of the art, in particular for very slender elements and under special temporary loading cases.

On the safe side, it can be assumed that the total horizontal load is taken by the columns, but this may lead to an uneconomical design. Furthermore, any execution imperfections in the position of the columns (eccentricity), in the column diameter or in their inclination can have a considerable influence in the case of small column diameters and induce undesigned shear stresses, even in compliance with the given tolerances. Attention must be paid to the execution stages too, where the top of the columns can be particularly endangered due to heavy vehicle traffic.

## 5 CONCLUSIONS

The soil reinforcement method with rigid inclusions is a soil stabilization system with columns which are separated from the structure by a load transfer layer, and which work either by analogy with a pile foundation or with a conventional soil reinforcement technique. The distinction between two application domains 1 and 2, either for an increase of the bearing capacity (1) or for a settlement reduction (2) reflects this difference. In the domain 1, the safety checks are similar to those for conventional pile foundations. In the domain 2, only SLS checks have to be carried out, including a control of the internal resistance of the columns.

The use of such column systems in the domain 2 corresponds to the design philosophy of the CPRF-guideline (Hanisch et al. 2002), in which no verification of the bearing capacity of single piles has to be done, and where only the stability of the global system and of course the structural capacity have to be checked.

In the CSV-guideline (DGGT 2002), a higher safety level than in ASIRI and in the CPRF-guideline is considered for the external resistance for the relevant small diameters. Indeed, the bearing capacity of single columns must always be carried out with the assumption of the total load in the columns, and the approach as settlement reducer without safety check for the single columns is not permitted for those diameters.

The internal resistance of columns with small diameters can be particularly threatened because of the significant influence of potential imperfections in the execution in this case. In the current state of the art of the soil-columns-structure interactions, an increased safety level should be taken into account for columns with small diameters under horizontal loads.

## 6 ACKNOWLEDGEMENTS

Special thanks go to Professor Roger Frank of Ecole des Ponts ParisTech (Navier-Cermes), Bruno Simon from the French company Terrasol and scientific director of ASIRI and Serge Lambert from the French company Keller Fondations Spéciales for the scientific and practical explanations of the recommendations ASIRI.

# Slope stability with partial safety factor method

## Stabilité des pentes à l'aide de la méthode de sécurité partielle

Lämsivaara T., Poutanen T.

*Tampere University of Technology, Tampere, Finland*

**ABSTRACT:** In most European countries Eurocode 7 (EN 1997) has been taken into use in geotechnical design. Although there are several design approaches in EN 1997, slope stability is commonly addressed by applying partial safety factors to material properties and variable loads. The outcome of such procedure has been evaluated with emphasis on uncertainty and consequences of failure. An attempt to improve the EN-1997 partial safety method by the introduction of consequence classes into stability analysis is then presented. Therein the partial safety factors for soil strength will be connected into consequence classes, i.e. the consequences of possible failure. Eurocode 1990 defines the minimum reliability index values for different Reliability Classes, which are then associated with the consequences classes. The result by the alternative method is then compared with results from the original approach.

**RÉSUMÉ :** Dans la plupart des pays européens, l' Eurocode 7 (EN 1997) a été mis en service dans la conception géotechnique. Bien qu'il existe plusieurs approches de conception de la norme EN 1997, la stabilité des pentes est généralement abordée en appliquant des facteurs de sécurité partiels pour les propriétés des matériaux et des charges variables. Le résultat d'une telle procédure a été évaluée en mettant l'accent sur l'incertitude et les conséquences de l'échec. Une tentative pour améliorer la méthode de sécurité EN-1997 partielle par l'introduction de classes de conséquence dans l'analyse de la stabilité est ensuite présentée. D'après celle-ci, les facteurs partiels de sécurité pour la résistance du sol seront connectés en classes de conséquence, c'est à dire les conséquences d'un échec possible. L' Eurocode 1990 définit les valeurs minimales indices de fiabilité pour les différentes classes de fiabilité, qui sont ensuite associées à des classes de conséquences. Le résultat par la méthode alternative est finalement comparé avec les résultats de l'approche originale.

**KEYWORDS:** slope stability, partial safety method, reliability, consequence class

## 1 INTRODUCTION

In most European countries, Eurocodes have been taken into use as the main design standard. Eurocodes are based on the principles of limit states design in conjunction with the partial factor of safety method. EN 1990 describes the principles and requirements for safety, serviceability and durability of structures for all materials, whilst EN 1997 sets the rules for geotechnical design. For ultimate limit states design, Eurocode requires the verification of various ultimate limit states by applying partial safety factors to actions or the effect of actions, material properties or resistances. For geotechnical design, it has so far been impossible to find a single way of combining factors between actions, ground properties and resistances, and thus three different design approaches (DA) are permitted in EN1997. However, for slope stability there seems to be a rather large consensus on how safety should be applied. Most countries have chosen either design approach 1 (DA1) or 3 (DA3) for slope stability. DA1 consists of two combinations of sets of partial factors, of which combination 2 is the one relevant for slope stability and analogous to DA3. As there is such a large agreement on applying safety for slope stability it could be considered that this part of the geotechnical design is well formulated in the Eurocodes. The intention of this article is to critically review the applied partial factor of safety method for the slope stability with respect to reliability and consequences of failure.

## 2 SHORT OVERVIEW ON THE EUROCODES

### 2.1 *Safety in Eurocodes*

According to EN-1990 the partial safety factors should account for the possible unfavourable deviation of the property from its characteristic value and the uncertainties in the model used in calculations. The consequences of the ultimate limit states are further considered based on three consequences classes. Therein the consequence of failure is accounted by multiplying the factors for actions by a separate factor depending on the consequence. In principle the partial factors of safety can be determined in two ways. One is the conventional method where the factors are calibrated to past experience. The other is to use probabilistic methods and calibrate the factors against a target reliability index value.

For the most common design situations, corresponding to the reliability class RC2, the recommended reliability index  $\beta$  for a 50 years reference period is 3.8. This corresponds to nominal probability for ultimate limit states of approximately 1/15 000. Whilst some of the partial factors for actions have been determined based on probabilistic methods, it is the understanding of the authors that material and resistance factors for geotechnical design has mainly been determined based on calibration to old codes.

### 2.2 *Slope stability in EN-1997 according to DA1 and DA3*

As previously discussed, most European countries have chosen either DA1 combination 2 or DA3 to be used in slope stability.

In practice this means, that safety is placed on material properties (strength) and on actions. The recommended values for partial factors on soils strength are  $\gamma_{\phi} = \gamma_c = 1.25$  for effective stress analysis and  $\gamma_{cu} = 1.4$  for total stress analysis. The largest action on slope stability comes often from the soil weight itself. It is often considered difficult to factor soil weight properly and thus permanent loads are, also in the Eurocodes, left unfactored. Actions from variable loads like e.g. traffic load are on the other hand factored. Accordingly, the recommended values for permanent actions in EN-1997 is  $\gamma_G = 1.0$  and for variable actions  $\gamma_Q = 1.3$ .

According to the principles of EN1997 the overall stability is checked by requiring that the design value of the effects of actions  $E_d$  driving instability is less than the design value of the resistances  $R_d$ , i.e.  $E_d \leq R_d$ . However, the common methods for slope stability don't usually provide these values, but rather their ratio as an overall factor of safety. Thus an over-design factor ODF is introduced (Frank et al.), and the requirement for overall stability for DA 1 combination 2 and DA 3 is written as the factor of safety calculated using design values equal to  $ODF \geq 1$ .

In short the recommended values mean that if only effective stress parameters are used for all soil layers, and there is no variable load, the total factor of the safety requirement is  $F = \gamma_{\phi} = \gamma_c = 1.25$ . Similarly, if only undrained shear strength is used and there is no variable load, the total factor of safety requirement is  $F = \gamma_{cu} = 1.4$ .

Traditionally, slope stability analysis is most commonly done applying the total safety factor approach. There is a lot of experienced based data on total safety factors and many engineers feel that it is easy to relate to a single safety factor. As discussed by Leroueil et al. (1990) based on the observations by Bourges et al (1969) a reduction of the total safety factor below a certain limit, increases the settlements due to increasing horizontal movements in the soil. The use of such empirical knowledge supports the continuous use of a total safety approach for slope stability.

The application of partial factors of safety in the Eurocodes is indirectly implying that safety is placed where uncertainty is found accounting also for the consequences of failure. It is the intention to evaluate how true this implication is in relation to slope stability and to consider what could be done to improve it.

### 3 RELIABILITY BASED PARTIAL SAFETY FACTORS

#### 3.1 Introduction

In the following material partial safety factors are calculated based on reliability theory. Firstly the theoretical bases and the assumptions made in the calculations will be presented. Thereafter the calculations will be done corresponding to the present system in the Eurocodes placing safety on both the variable action and on material properties. An alternative calculation will then be presented where both the uncertainty related to loads and material properties will be placed on the material partial safety factor. In both the influence of a general uncertainty will also be studied.

In the alternative approach, the influence of the consequence classes into stability analysis will also be considered. As for now, the reliability differentiation in Eurocodes is done by applying a multiplication factor  $K_{FI}$  to unfavourable loads. The recommended values for the factor are 0.9, 1.0 and 1.1 corresponding to Reliability classes RC1, RC2 and RC3. For slope stability problems the effect of external actions on the stability varies from zero to rather substantial. It seems thus rather random to apply safety related to reliability and consequence of failure on such basis. On the other hand it is also uncertain should the factor be applied only to variable loads or also for permanent loads. In the latter case the problem on how to treat ground weight arises again. However, in EN 1990 it is also stated that, quote "Reliability differentiation may also

be applied through the partial factors on resistance  $\gamma_M$ .". The material partial factors for the alternative approach will thus be calculated for different target reliability index values corresponding to the different reliability classes.

#### 3.2 Theoretical bases

Firstly, the design point, the target reliability, the uncertainty, load distributions and the basic parameters must be set. The design point is set at unity and the target reliability feasible in the reliability calculation is chosen according to EN 1990. The permanent load distribution is assumed to be normal, the coefficient of variation equal to 0.1, the cumulative distribution is  $FG(x, \mu_G, \sigma_G)$  and the density distribution is  $fG(x, \mu_G, \sigma_G)$ . For variable load a normal distribution is also used, although Gumbel distribution might also be considered. The distributions are  $FQN(x, \mu_{QN}, \sigma_{QN})$ ,  $fQN(x, \mu_{QN}, \sigma_{QN})$ , 0.98 fractile is set at the design point according to one-year load. The coefficient of variation used for the variable load is 0.4 as in EN 1990.

The material property distribution is assumed lognormal, the cumulative distribution is  $FM(x, \mu_M, \sigma_M)$  and the density distribution is  $fM(x, \mu_M, \sigma_M)$ , the characteristic value is a 5 % fractile value which is set at the design point.

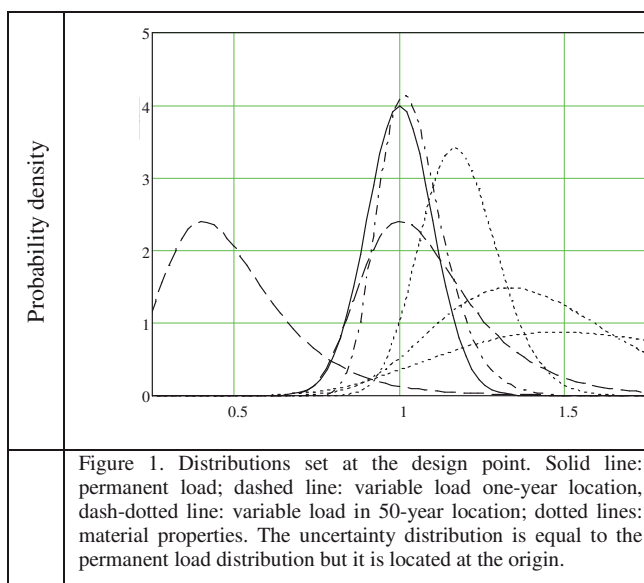

When the cumulative distribution of the load is  $FL(x, \mu_L, \sigma_L)$ , density distribution of the material property  $fM(x, \mu_M, \sigma_M)$ , the load safety factor is  $\gamma_L$  and the material safety factor  $\gamma_M$ , the formula for the failure probability  $P_f$  calculation is

$$1 - \int_0^{\infty} FL(x, \mu_L, \sigma_L) \cdot fM(x, \mu_M \cdot \gamma_L, \gamma_M \cdot \sigma_M \cdot \gamma_L, \gamma_M) dx = P_f \quad (1)$$

When two loads  $F_1(x, \mu_1, \sigma_1)$ ,  $f_1(x, \mu_1, \sigma_1)$  and  $F_2(x, \mu_2, \sigma_2)$ ,  $f_2(x, \mu_2, \sigma_2)$  with items  $x_{1,i}$  and  $x_{2,i}$  in fractile  $i$  are combined dependently in proportion  $\alpha$  and  $1-\alpha$ ,  $\alpha$  is the proportion of the load 1 in the total load, to obtain item  $x_{1,2,i}$  of the combination load in fractile  $i$ , is calculated by adding up the partial items:

$$\mu_{1,2,i} = \mu_{1,i} \cdot \alpha + \mu_{2,i} \cdot (1 - \alpha) \quad (2)$$

The graphs of the used distributions are presented in Figure 1.

#### 3.3 Calculated material factors for DA3

Herein the calculations are done to resemble the present partial safety factor approach DA3 in the Eurocodes. The loads are combined dependently and the partial safety factors for the

loads are  $\gamma_G = 1$  and  $\gamma_Q = 1.3$ . The load distribution for both permanent and variable loads is assumed to be normal. The variable load distribution is set at 50-year loads and the target reliability corresponds to RC2 of the Eurocodes, i.e.  $\beta_{50} = 3.8$ .

The calculations are done for material variation of  $V_M = 0.1$ ,  $V_M = 0.2$  and  $V_M = 0.3$ . In addition a general uncertainty following a normal distribution and 0.1 deviation is added into a parallel calculation. The results of the calculations are shown in Figure 2 as the function of the load ratio (the proportion of the variable load in the total load, %).

Figure 2. Material factors of the Eurocodes corresponding to  $\gamma_G = 1$ ,  $\gamma_Q = 1.3$  and  $\beta_{50} = 3.8$  as function of load ratio. The lowest, black lines denote to  $V_M = 0.1$ ; red lines, middle to  $V_M = 0.2$  and blue lines, highest to  $V_M = 0.3$ . The dotted lines correspond to values without uncertainty,  $V_U = 0$  and the solid lines with uncertainty,  $V_U = 0.1$ .

The results presented in Figure 1 are of course dependent on the assumptions made. It is though notable, that the material factors are not constant while they depend on the load ratio. For an independent load combination the material factors would also be highly non-linear. The application of a constant material factor as in EN 1997-1 does not thus result in a constant reliability index. Considering effective stress analysis, the variation of the parameter is according to data gathered by Abramson et al. (2002) in the range of 2-21%. On average one could use the value of 10 % corresponding to the black line in Figure 2. The recommended partial safety factor for friction in EN 1997-1 is 1.25, which corresponds to a load ratio of 60% in Figure 2. Stability problems are often less load driven while in some cases the external load has no significant effect on safety. For such cases DA3 would according to Figure 2 clearly overestimate the safety.

#### 3.4 Calculated material factors for alternative approach

Next an alternative approach will be presented where all uncertainty is placed on the material partial safety factor, i.e.  $\gamma_G = \gamma_Q = 1.0$ . In addition the material factors are calculated for three different reliability index values, corresponding to the three reliability classes in the Eurocodes. The target  $\beta$  values are  $\beta_{50} = 4.3$  (RC3),  $\beta_{50} = 3.8$  (RC2) and  $\beta_{50} = 3.2$  (RC1).

Figure 3. Material factors corresponding to  $\gamma_G = \gamma_Q = 1.0$  and a)  $\beta_{50} = 4.3$  (RC3), b)  $\beta_{50} = 3.8$  (RC2) and c)  $\beta_{50} = 3.2$  (RC1) as function of load ratio. The lowest, black lines denote to  $V_M = 0.1$ ; red lines, middle to  $V_M = 0.2$  and blue lines, highest to  $V_M = 0.3$ . The dotted lines correspond to values without uncertainty,  $V_U = 0$  and the solid lines with uncertainty,  $V_U = 0.1$ .

As can be seen, the material safety factors are the same as in Figure 2 for equal reliability index when the load proportion is zero. When Figure 2 and Figure 3 b) are compared we find out that an equal design outcome is obtained when the safety is set both in the action and in the resistance or in the resistance only (e.g. load proportion 60 %,  $V_M = 0.1$ , Figure 2:  $\gamma_M = 1.53$ , i.e.  $(0.4+0.6 \cdot 1.3) \cdot 1.53 = 1.81$  which is equal to the value of Figure 3 b).

#### 4 EXAMPLE OF APPLICATION

In the following the Eurocode EN 1997 will be applied in an example and compared to the alternative method presented in the previous section. The intention is to outline some issues the authors consider as problematic in a simplistic way. The example is thus very simplified and does not as such represent a true case study.

Let us consider the situation given in Figure 4. The soil conditions are the following. A 1m thick embankment is laid upon a dry crust layer. The unit weight of the embankment material is  $\gamma = 20\text{kN/m}^3$  and the characteristic friction angle is  $\phi = 38^\circ$ . The dry crust layer is 1m thick and has a unit weight of  $\gamma = 17\text{kN/m}^3$  and the characteristic undrained shear strength is 30kPa. Under the dry crust there is a layer of soft clay with a unit weight of  $\gamma = 16\text{kN/m}^3$  and a characteristic undrained shear strength of 10kPa at top of layer increasing with 1.4kPa/m depthwise. A 5m wide load of 40kPa is placed two meters from the crest of the embankment. The problem in question is much load driven. The total safety factor without any load is around 4 while the 40kPa load decreases it to 1.46 for a circular failure surface analysed by the Bishop method.

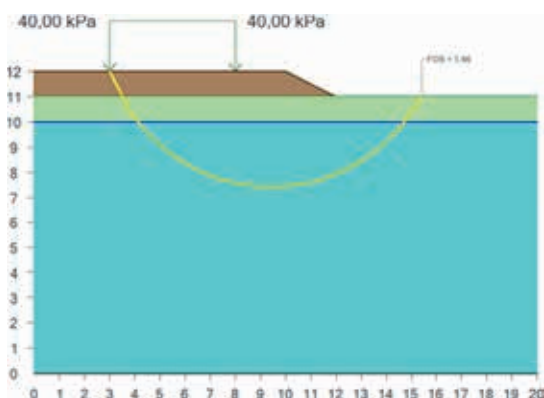

Figure 4. Geometry of the problem and calculated total factor of safety.

According to the recommended values to EN 1997 the partial safety coefficient for effective stress strength parameters is  $\gamma_{\phi} = \gamma_c = 1.25$  and for total stress analysis  $\gamma_{cu} = 1.4$ . Applying these yields for design values a friction angle of  $\phi = 32^\circ$  and undrained strength values of 21.4kPa for the dry crust and 7.1kPa + 1kPa/m for the soft clay. If the load comes from a permanent load, the recommended partial factor is 1.0 while it is 1.3 for variable loads. So in case of variable loads the design value entering the calculation is 52kPa.

In case of a permanent load the resulting over dimensioning factor is ODF = 1.04 indicating that the situation is safe. For the variable load case the ODF reduces to ODF = 0.88. To have enough safety, the characteristic initial value of undrained shear strength of the clay should increase by some 30 % to 13kPa. This corresponds to a total safety factor of 1.69 for the situation. Is it then reasonable to require a higher safety for the variable load case? A general argument in favour of this is that there might be more uncertainty for the variable load than for the permanent one. This is however not necessarily true. A typical high variable load representative to embankment stability would be train load from a heavy freight train. However, railway tracks are classified and there is an upper load allowed for a certain track part. So the characteristic load is rather a maximum load. In such cases the partial factor for action should rather be calculated using a log-normal distribution than a normal distribution. Also, there will always be uncertainty also in the permanent load which is disregarded in EN 1997-1. It is perhaps also more important to consider the consequences of failure. A permanent load might come from a residential building. The consequence of failure might thus be very severe with lots of casualties. On the other hand if the variable load is due to a

freight train carrying e.g. iron ore the consequences of failure in an uninhabited area are perhaps not that severe – at least the risk for loss of lives is minor. However, if a train with toxic material goes through an inhabitant area the consequences of failure are of course harsh.

The alternative approach presented in 3.4 allows for such considerations. It is emphasized that the results presented are aimed to give an example how safety could be applied. The assumed distributions, variations and target reliabilities needs of course careful consideration. However, if one assumes a variability of 0.1 for friction and 0.2 for the undrained shear strength one finds, that the recommended partial safety factors  $\gamma_{\phi} = \gamma_c = 1.25$  and  $\gamma_{cu} = 1.4$  in EN 1997-1 corresponds to the calculated one at approximately a load ratio of 80% assuming no additional uncertainty. While this is a very high load ratio its use is justified by the sake of comparison and the fact that the case is highly load driven. For the alternative approach corresponding safety factors for same  $\beta$  would be  $\gamma_{\phi} = \gamma_c = 1.52$  and  $\gamma_{cu} = 1.73$ . Applying this as a load factor on unity yields an ODF = 0.84. Now to have enough safety the undrained shear strength of the clay would need to increase to 13.3 kPa. This corresponds to on total safety factor of 1.71 i.e. close to the partial safety factor used for the undrained shear strength. Similarly the total safety requirement for a high consequence class (RC3) would be close to 2.0 and for a minor consequence class (RC1) approximately 1.5.

#### 5 CONCLUSIONS

The partial safety factor approach in EN 1997-1 adopted in most European countries for slope stability is reviewed. The author's conclusions are that risk and consequence of failure are not necessarily properly accounted for. For situation with no variable loads the safety level applied in EN 1997-1 does not correspond to the implied reliability index, but is below that. Also the consequence of failure is not properly addressed, as the load factor in EN 1990 have a negligible affect to safety for some slope stability problems. An alternative approach is presented, where all uncertainty is placed on the material partial safety factor and the consequence of failure is accounted by calculating the material safety factors separately for different consequence classes with different target reliability index values.

# Assessment of embankment stability on organic soils using Eurocode 7

## Évaluation de la stabilité des remblais sur sols organiques en utilisant l'Eurocode 7

Lechowicz Z., Wrzesiński G.

Department of Geotechnical Engineering, Warsaw University of Life Sciences - SGGW, Poland

**ABSTRACT:** A problem of the stability assessment of stage-constructed embankment on soft organic subsoil is discussed. Calculations were performed for the first and the third stage of embankment construction at the Antoniny site and for the failure test. The analysis contains measured and corrected shear strength values of organic soils obtained in the virgin and consolidated organic subsoil by staged construction. The statistical analysis of the field vane test results was performed to obtain mean values, standard deviations and probability distribution. Derived, characteristic and design values of undrained shear strength of organic soils were determined. The stability analysis according to design approaches of Eurocode 7 was carried out using mean values of undrained shear strength of organic soils. Additionally, the stability analysis was carried out using undrained shear strength reduced by 0.5 and 1.0 standard deviation. Based on probabilistic stability analyses the safety factor and the reliability index  $\beta$  were calculated.

**RÉSUMÉ:** Le problème présenté est celui de l'évaluation de la stabilité d'un remblai expérimental construit par étapes sur un sous-sol organique. Les calculs ont été effectués pour la première et la troisième étape de la construction du remblai sur le site d'Antoniny et pour l'essai de rupture. L'analyse contient les valeurs mesurées et corrigées des valeurs de résistance au cisaillement des sols organiques obtenus dans le sous-sol vierge et consolidé par les étapes de construction. L'analyse statistique des résultats d'essais sur le terrain a été réalisée pour obtenir des valeurs moyennes, l'écart-type et la loi statistique de distribution. Les valeurs, caractéristiques de la résistance au cisaillement non drainé des sols organiques ont été déterminées pour la conception. L'analyse de stabilité selon les approches de l'Eurocode 7 a été réalisée à l'aide des valeurs moyennes de la résistance au cisaillement des sols organiques. L'analyse de stabilité a été réalisée également en utilisant la résistance au cisaillement réduite de 0.5 et 1.0 écart-type. Les acteurs de sécurité et de fiabilité de l'indice  $\beta$  ont été calculés sur la base de l'analyse probabilistique de la stabilité.

**KEYWORDS:** organic soils, undrained shear strength, embankment stability, Eurocode 7, characteristic and design values.

### 1 INTRODUCTION

Geotechnical problems associated with embankments located on organic soils are more difficult than on soft mineral soils mainly due to their higher compressibility and very low virgin shear strength (Hartlen and Wolski 1996). The variability in the value of soil properties is a major contributor to the uncertainty in the stability of an embankment located on soft and highly compressible subsoil. This means that even construction of an embankment of only several meters height may lead to failure. As a result, the methods of design and construction that are normally used in other soft soils, may not be adequate in organic soils.

However, in many countries there are large areas with organic soils where different kinds of embankments have to be constructed. In such cases, the prediction of soil behaviour and the selection of a proper design method become an important as well as a difficult engineering task. In practice, embankment construction by stages utilizing the change in shear strength due to consolidation process is often selected solution. For such a stage constructed embankment, time and money can be saved if the embankment stability is accurately predicted.

Stability analysis according to Eurocode 7 can be performed using following Design Approaches: DA1 (Combination 1), DA1 (Combination 2), DA2 or DA3. Many countries as well as Poland accepted in 2010 Design Approach DA3 for design of slopes. In particular Design Approaches are applied different partial factors to characteristic values of parameters (Frank et al. 2004, Bagdahl 2005, Frank 2007, Bond and Harris 2008, Van Seters and Janses 2011, Orr 2012).

To assess the variability in the value of soil properties the statistical analysis should be performed. Statistical analysis allows to obtain mean values, standard deviations and

probability distribution. Thus, characteristic values of geotechnical parameters used in calculations can be obtained.

The characteristic value  $X_k$  used in geotechnical calculations corresponding to a 95% confidence level that the actual mean value,  $X_m$  is greater than this value, is given by Schneider (1999):

$$X_k = X_m(1 - k_n V) \quad (1)$$

where:

$k_n$  - the factor, depending on the type of statistical distribution and the number of test results,

$V$  - variation coefficient.

Schneider (1999), on the basis of calculations, has shown that a good approximation to  $X_k$  is obtained when  $k_n = 0.5$ ; i.e. if the characteristic value is chosen as one half a standard deviation below the mean value, as in the following equation:

$$X_k = X_m - 0.5SD \quad (2)$$

In this paper a problem of the assessment of embankment stability on soft organic subsoil is discussed based on the Antoniny test site. This is an adequate example to perform stability

analysis and research of organic subsoil under stage constructed embankment because each case of embankment construction, from loading of virgin subsoil to failure test can be considered.

### 2 DESCRIPTION OF THE ANTONINY SITE

The Antoniny test site is located in north-western Poland in the Noteć river valley. In 1980s the Department of Geotechnical Engineering of Warsaw University of Life Sciences in cooperation with the Swedish Geotechnical Institute performed extensive field and laboratory investigations.

At this test site the embankment was constructed in three stages on organic subsoil from 1983 to 1987. The structure was then brought to failure by increasing the height of the fill (Wolski et al. 1988, 1989). The schedule of construction is presented in Figure 1.

Figure 1. Construction schedule of embankment at the Antony site (Wolski et al. 1988).

At the Antony site the virgin subsoil consists of an amorphous peat layer and a calcareous-organic soil layer called “gyttja” underlain by a sand layer. The organic subsoil, 7.8 m thick, consists of 3.1 m peat and a 4.7 m gyttja. The results of the index properties of organic soils are summarized in Table 1 and Table 2. Based on the index properties the peat layer was divided into two layers: the first one being fibrous peat from the ground surface to depth 1.0 m and the second one amorphous peat below 1.0 m to depth 3.1 m. The gyttja layer was divided into three layers, the first one being calcareous-organic gyttja extending from 3.1 m to 4.5 m and the second and third layer calcareous gyttja from 4.5 m to 6.8 m and below 6.8 m, respectively. The ground surface is covered with grass vegetation. In the first layer of peat is an abundance of cracks and root channels.

Table 1. Index properties of peat at the Antony site (Wolski et al. 1988, 1989).

Properties	Peat	
	Fibrous	Amorphous
Water content $w_n$ [%]	420-450	310-340
Unit density $\rho$ [ $t/m^3$ ]	1.05-1.1	1.05-1.1
Specific density $\rho_s$ [ $t/m^3$ ]	1.4	1.45
Liquid limit $w_L$ [%]	-	305-310
Organic content [%]	8-85	65-75
CaCO <sub>3</sub> content [%]	5-10	10-15

Table 2. Index properties of gyttja at the Antony site (Wolski et al. 1988, 1989).

Properties	Gyttja		
	Calcareous-organic	Calcareous	Calcareous
Water content $w_n$ [%]	130-140	105-110	110-115
Unit density $\rho$ [ $t/m^3$ ]	1.25-1.30	1.35-1.40	1.40-1.45
Specific density $\rho_s$ [ $t/m^3$ ]	2.2	2.3	2.4
Liquid limit $w_L$ [%]	100-110	80-90	90-100
Organic content [%]	15-20	8-10	5-7
CaCO <sub>3</sub> content [%]	65-75	80-85	85-90

In the virgin subsoil the static ground water level was present in peat layer at the depth of 0.2 m below the ground surface. In the underlying sand at the 7.8 m depth the water pressure is artesian and has been measured to correspond to a water head of 1.0 to 1.5 meters above the ground surface. The high ground water level, combined with the artesian pore water pressure and with relatively low bulk densities of organic soils

resulted in the effective vertical stresses in organic soils being only a few kPa and almost constant in depth.

The preconsolidation pressure obtained from oedometer tests is higher than the initial values of effective vertical stresses, which shows that organic soils are overconsolidated with an overconsolidation ratio, OCR, decreasing from 5 to 2 with depth. However, in first stage the effective stress was only smaller than the initial preconsolidation pressure. During staged construction the effective vertical stress exceed the initial preconsolidation pressure several times.

### 3 UNDRAINED SHEAR STRENGTH

#### 3.1 Undrained shear strength from field vane tests

The field vane test is relatively simple and quick in situ method of shear strength measurement of organic soils. In order to evaluate undrained shear strength ( $\tau_{fu}$ ) from vane shear tests, the measured values of shear strength ( $\tau_{fv}$ ) have to be corrected using correction factor ( $\mu$ ).

In this paper the correction factors evaluated according to Swedish Geotechnical Institute method (Larsson et al. 1984) and average correction factors which was determined based on laboratory tests: triaxial compression (TC), triaxial extension (TE) and direct simple shear (DSS) (Lechowicz 1992). Values of correction factors are shown in Table 3.

Table 3. Correction factors for field vane tests obtained at the Antony site:  $\mu(w_L)$  – correction factor recommended by SGI,  $\mu(\text{lab})$  – correction factor based on laboratory tests.

Type of soil	$\mu(w_L)$	$\mu(\text{lab})$
Peat (0-3.1 m)	0.50	0.51
Gyttja 1 (3.1-4.5 m)	0.70	0.56
Gyttja 2 and 3 (4.5-7.8 m)	0.80	0.61

Mean values of corrected shear strength were calculated based on early corrected values of measured shear strength. Measured, corrected and mean values of undrained shear strength in the virgin organic subsoil before loading are shown in Figure 2.

Figure 2. Profile of undrained shear strength based on field vane tests at the Antony site: 1 - results of field vane tests, 2 - values corrected according to SGI, 3 - mean values, 4 - mean values  $\pm$  standard deviation; TC - triaxial compression test, TE - triaxial extension test, DSS - direct simple shear test, LAB - mean value from laboratory tests.

Mean values of corrected shear strength ( $\tau_{fu}$ ) in the virgin organic subsoil before loading and in the consolidated organic subsoil before failure test are presented in Tables 4 and 5.

Table 4. Mean values, standard deviations and variation coefficients of undrained shear strength before loading at the Antony site (Lechowicz 1992, Batory 2004).

Layer	Undrained shear strength $\tau_{su}$ [kPa]	Standard deviation SD [kPa]	Variation coefficient V
peat 1	12.8	2.40	0.19
peat 2	6.4	0.71	0.11
gyttja 1	7.7	1.12	0.15
gyttja 2	7.0	0.49	0.07
gyttja 3	7.5	0.92	0.12

Table 5. Mean values, standard deviations and variation coefficients of undrained shear strength before the failure test at the Antony site. A - under embankment crest, B - under embankment slope, C - outside of embankment (Lechowicz 1992, Batory 2004).

Zone	Layer	Undrained shear strength $\tau_{su}$ [kPa]	Standard deviation SD [kPa]	Variation coefficient V
A	peat 1	28.0	2.40	0.09
	peat 2	24.5	0.71	0.03
	gyttja 1	20.2	1.56	0.08
	gyttja 2	18.7	1.38	0.07
	gyttja 3	22.3	2.62	0.12
B	peat 1	18.0	1.40	0.08
	peat 2	15.7	1.11	0.07
	gyttja 1	13.2	2.12	0.16
C	gyttja 2	12.6	1.84	0.15
	gyttja 3	13.4	1.29	0.10
	peat 1	12.5	2.40	0.19
	peat 2	7.7	0.73	0.09
	gyttja 1	10.3	1.53	0.15
	gyttja 2	9.9	1.23	0.12
	gyttja 3	10.2	0.91	0.09

Undrained shear strength values obtained by the field vane tests show a considerable increase in undrained shear strength due to the loading and subsequent consolidation. The highest strength increase was measured under the centre of the embankment and the increase was most evident in the peat layer. A smaller increase in undrained shear strength was obtained under the slope of embankment, while the measured shear strength values under the toes of slopes and outside the embankment remained practically unchanged.

### 3.2 Statistical analysis of the field vane test results

The statistical analysis of the field vane test results was performed to obtain mean values, standard deviations and probability distribution. For statistical analysis of shear strength normal distribution was used. Additionally, for comparison also other type of statistical distribution were tested (Lechowicz et al. 2004).

The statistical analysis was carried out using program Statgraphics Plus 4.1 (Batory 2004). In this program goodness-of-fit test is performing by the Kolmogorov-Smirnov test for a 95% confidence level.

The mean values, standard deviations and variation coefficients of corrected shear strength for each geotechnical layer are shown in Tables 4 and 5.

## 4 STABILITY ANALYSIS

### 4.1 Selection of shear zones and design parameters

In stability analysis performed for the first stage the same parameters for whole geotechnical layers were used. For the third stage and the failure test the organic subsoil was divided into three different shear zones: A - under embankment crest, B - under embankment slope, C - outside of embankment.

Division of organic subsoil into shear zones is presented in Figures 3 and 4.

Figure 3. Division of organic subsoil into shear zones for the third stage at the Antony site.

Figure 4. Division of organic subsoil into shear zones for the failure test at the Antony site.

In the stability analysis mean values of undrained shear strength were used. The characteristic values of undrained shear strength determined as mean values reduced by half and one standard deviation were also used. In stability analysis design values of undrained shear strength were received by using partial factors ( $\gamma_M$ ) to mean and characteristic values.

In Design Approach DA1(C1) partial factor recommended by Eurocode 7 is equal to 1.0 so values of design parameters used in calculations are the same as characteristic ones. In DA1(C2) and DA3 recommended partial factor ( $\gamma_M$ ) on undrained shear strength is equal to 1.25, so design parameters used in stability analysis are reduced by that factor.

### 4.2 Calculation results

The stability analysis was carried out for the first and the third stage as well as for the failure test of the embankment at the Antony site. The safety factor was calculated using the GeoSlope program with the use of Bishop's simplified method. The calculations were performed according to Eurocode 7 using Design Approaches: DA1(C1), DA1(C2), DA3 and also using probabilistic method. The stability analysis was carried out for subsoil divided into geotechnical layers and zones presented in Figures 3 and 4. Results of stability analysis performed according to Eurocode 7 of embankment at the Antony site are shown in Table 6.

Calculations performed for the first stage of embankment at the Antony site prove that the embankment was stable. Both for calculations carried out according to Eurocode 7 and using probabilistic method the safety factor was much higher than required. For DA1(C1) safety factor was equal to 1.82 assuming mean values while for DA1(C1) and DA3 was equal to 1.46. For comparison, safety factor using probabilistic method and normal distribution was equal to 1.52 assuming mean values of undrained shear strength. In this case reliability index  $\beta = 4.7$ . Using characteristic values of undrained shear strength evaluated based on Schneider's recommendation the safety factor for DA1(C1) was equal to 1.71, and for DA1(C2) as well as DA3 was equal to 1.39. For characteristic values reduced by one SD the safety factor was equal to 1.60 for DA1(C1) and 1.28 for DA1(C2) as well as DA3. Obtained values are less than permissible for this class of construction.

Table 6. Results of stability analysis performed according to Eurocode 7 at the Antony site.

Stage	Mean and characteristic values of undrained shear strength	Safety factor F	
		DA1(C1)	DA1(C2), DA3
1	$\bar{\tau}_{fu}$	1.82	1.46
	$\tau_{fu} - 0.5SD$	1.71	1.39
	$\tau_{fu} - SD$	1.60	1.28
3	$\bar{\tau}_{fu}$	1.41	1.12
	$\tau_{fu} - 0.5SD$	1.33	1.07
	$\tau_{fu} - SD$	1.26	1.01
Failure test	$\bar{\tau}_{fu}$	0.75	0.60
	$\tau_{fu} - 0.5SD$	0.71	0.57
	$\tau_{fu} - SD$	0.67	0.54

Calculation results show that after construction the first stage of embankment with a height of 1.2 m exists a large reserve of safety. In connection with it, for the embankment with a height of 1.7 m additional calculations were carried out using mean values of undrained shear strength. Then, safety factor was equal to 1.16 while  $\beta = 3.4$ . Using logistic type of distribution which better characterized distribution of shear strength the safety factor was close to one and  $\beta = 2.2$ . Performed calculations shows that the first stage of embankment could be constructed higher.

The stability analysis after consolidation of the third stage of embankment performed according to Eurocode 7 (Table 6) and probabilistic method assuming mean values of undrained shear strength shows that construction was stable. The safety factor using probabilistic method was equal to 1.48 and  $\beta = 8.9$ . Taking into consideration partial factors for undrained shear strength (DA1(C2) and DA3) the safety factor was insufficient.

During failure test the thickness of the fill was increased from 3.9 m to a final 7.95. The safety factor determined according to Eurocode 7 was less than permissible (Table 6) both using mean values of undrained shear strength and designed ones. Also calculations using probabilistic method prove that the construction was unstable.

It is important to pointed out the fill constructed in the failure test had approximately the shape of a truncated pyramid. The simplified Bishop's method modified to three-dimensional analysis to estimate the safety factor for the test fill during the failure test was used. Half of the sliding body of the fill was divided into cylindrical part with semi-ellipsoidal end. The three-dimensional calculations of stability for the final stage in the failure test indicate that the factor of safety was close to 1. The two-dimensional calculations carried out for the cross-section of the cylindrical part yielded a safety factor of about 0.75.

Performed stability analysis shows, that in case of Design Approach DA1(C1) the embankment stability in organic soils during construction can be assessed using the characteristic values of undrained shear strength determined according to Schneider's recommendation based on mean values and standard deviation of undrained shear strength derived from field vane tests.

Experience shows that in case of Design Approaches DA1(C2) and DA3 the assessment of embankment on organic soils based on the design values of undrained shear strength evaluated using partial factor  $\gamma_M = 1.25$ , characteristic values of  $\tau_{fu}$  from Schneider's recommendation, mean values of  $\tau_{fu}$  determined from undrained shear strength derived after correction of measured values of  $\tau_{fv}$  introduce too much safety for embankment during construction. The calculation results show that after third stage the safety factor form DA1(C2) and DA3 approaches is closed to one while in real case the embankment height was increased almost double, from 3.9 to 7.95 m in failure test.

## 5 CONCLUSIONS

The example of the determination of derived, mean, characteristic and design values of undrained shear strength of organic soils obtained from field vane tests for stage-constructed embankment at the Antony site was presented.

Performed stability analysis shows, that Design Approach DA1(C1) for stability assessment of embankment on organic soils during construction using the characteristic values of undrained shear strength evaluated based on Schneider's proposal from mean values and standard deviation of undrained shear strength derived from field vane test is recommended.

Experience indicates that Design Approaches DA1(C2) and DA3 introduce too much safety for the embankment on organic soils during construction. In this case the mean values of undrained shear strength evaluated based on corrected values from field vane tests, as characteristic values are recommended.

# Implementation of LRFD Methods to Quantify Value of Site Characterization Activities

Mise en œuvre des méthodes de conception LRFD pour quantifier la valeur des activités de caractérisation du site

**ABSTRACT:** A comprehensive research program was recently completed to develop "state specific" LRFD guidelines for the Missouri Department of Transportation in the United States of America (USA). The new guidelines implement improvements to current AASHTO LRFD specifications that provide minimum national standards for design of transportation projects in the USA. The most notable of these improvements are specification of resistance factors that are dependent upon the variability of input parameters. One product of these improvements is to produce designs that more closely achieve target levels of reliability. Perhaps more importantly, the guidelines provide designers with explicit means to quantify the potential value of site characterization activities during the design phase. The latter outcome allows designers to make more rational decisions regarding the type and scope of site characterization activities and provides quantitative support for such decisions so that designers can more effectively convey the value of site characterization to others.

**RÉSUMÉ :** Un vaste programme de recherche a été récemment mené pour adapter des directives LRFD spécifiques au Département des Transports du Missouri (USA). Les nouvelles recommandations apportent des améliorations aux normes actuelles nationales AASHTO LRFD qui fournissent des normes minimales pour la conception de projets de transport aux Etats-Unis. La plus notable de ces améliorations est la spécification de facteurs de résistance qui dépendent de la variabilité des paramètres d'entrée. Un résultat de ces améliorations est de produire des modèles qui permettent d'atteindre un plus grand niveau de fiabilité. Peut-être plus important encore, les directives fournissent aux concepteurs de moyens explicites pour quantifier le niveau de qualité des reconnaissances géotechniques permettant de caractériser un site. Le dernier résultat permet aux concepteurs de prendre des décisions plus rationnelles concernant le type et l'étendue des reconnaissances du site et leur offre un outil quantitatif pour évaluer et transmettre plus efficacement à d'autres la valeur de la qualité des investigations.

**KEYWORDS:** load and resistance factor design, geotechnical site characterization, variability, uncertainty.

## 1 INTRODUCTION

Current practice for geotechnical design of transportation infrastructure in the U.S. utilizes load and resistance factor design (LRFD) techniques. In these methods, load factors and resistance factors are respectively applied to different load effects and resistance components to produce designs intended to achieve some established target probability of failure. A national code developed by the American Association of State Highway and Transportation Officials (AASHTO) serves as a baseline for such design, but individual state transportation agencies are allowed to develop their own "state specific" LRFD methods to reflect differences in design practices.

This paper describes characteristics of one such state-specific code developed by the authors for the Missouri Department of Transportation (MoDOT). Unique features implemented in the new MoDOT design guidelines include:

- Resistance factors are explicitly selected based on variability and uncertainty in input parameters, and
- A practical technique to quantify uncertainty in design parameters from lab and field measurements is provided.

Practice using the new MoDOT design guidelines is compared to traditional design practice and current AASHTO practice. Methods used for calibration of resistance factors are then

described followed by description of the procedure recommended for quantifying variability and uncertainty from laboratory or field measurements. Finally, an example is provided to illustrate how the methods can be used to quantify the value of potential site characterization activities.

## 2 SOURCES OF VARIABILITY AND UNCERTAINTY

Variability and uncertainty arise from a multitude of sources in geotechnical design. However, these sources can be generalized into three broad categories:

- Variability and uncertainty in design input parameters,
- Variability and uncertainty in design methods, and
- Variability and uncertainty attributed to construction.

These sources are at times inter-related, especially for empirically based design methods. Nevertheless, it is useful to consider them as being separate because of the degree of influence that designers have over the different sources.

Designers generally have the greatest, and most direct, influence over variability and uncertainty in design parameters, principally through affecting the scope of site characterization activities. Designers can also affect variability and uncertainty in design methods by selecting from among several alternative

methods, but this influence often has a lesser effect on resulting designs. Designers can also influence variability and uncertainty in construction, by developing “constructable” designs, as well as by requiring and/or engaging in effective QC/QA. However, the influence is again generally smaller than what can be achieved through effective site characterization.

### 3 COMPARISON OF TRADITIONAL & LRFD PRACTICE

While traditional “allowable stress design” (ASD) and LRFD practices seek to account for variability and uncertainty introduced by all three sources, they do so differently. Differences among traditional geotechnical practice, current AASHTO specifications, and the new MoDOT guidelines arise primarily from differences in how these sources are addressed.

#### 3.1 Traditional ASD Practice

Traditional practice for geotechnical site characterization, in terms of the specific types of measurements made and the quantity of such measurements, is largely dictated by the judgment of the designer. In establishing the scope of site characterization activities, designers generally consider (often local) standards of practice for structures of similar complexity and importance as well as general characteristics about the site. The actual site characterization activities undertaken are also subject to the designer’s ability to “sell” the importance of the activities to those that are paying for the characterization. This task is often challenging because it can be difficult to quantify the potential value of site characterization activities in ways that are meaningful to those outside the profession.

Importantly, traditional geotechnical practice also provides some flexibility in selection of appropriate values for the factor of safety to be used in design. In selecting a specific value for a specific project, designers generally consider the importance and complexity of the structure, the complexity of the site, and the appropriateness of site characterization that has been performed. Thus, there is an implicit link between the quality and rigor of the site characterization and the safety margins that are employed in design. This link is clearly subjective, which introduces the potential for inconsistent application and inconsistent reliabilities for resulting designs. The subjectivity may also expose designers to substantial risk, since it can be difficult to justify specific design postures when performance does not meet expectations (e.g. if a problem occurs, one can often easily argue that site characterization was insufficient or that sufficient margins of safety were not used).

#### 3.2 AASHTO LRFD Practice

Design according to the AASHTO LRFD specifications largely follows traditional practice, but with two important distinctions. First, the AASHTO LRFD code explicitly establishes minimum standards for the quantity and type of site characterization that must be performed in order for the standards to be used. These minimum requirements enhance the designer’s ability to “sell” site characterization and provide some minimum level of confidence in the design parameters. However, the requirements also pose challenges for some regions of practice where traditional site characterization practices do not work well. Secondly, the AASHTO code stipulates fixed values for the margin of safety, via resistance factors. Table 1 shows a listing of resistance factors for side resistance of drilled shafts from the AASHTO LRFD specification (AASHTO, 2010). These “method specific” resistance factors are “lumped” factors in that they account for all three sources of variability and uncertainty collectively.

Fixing the magnitude of resistance factors results in more consistent designs and likely produces the intended effect of achieving more consistent reliability compared to ASD practice.

However, fixing the magnitude of resistance factors also eliminates the flexibility provided in ASD to select appropriate safety margins and limits the capability to improve design efficiency through improved site characterization. Conducting more tests, or higher quality tests, to improve confidence in design parameters does not allow one to use more advantageous resistance factors. Improving the scope or quality of site characterization may have a second order effect of changing predictions of nominal capacity, but it does not allow designers to exploit the improved confidence in design parameters.

Table 1. Resistance factors from AASHTO LRFD Specifications for side resistance of drilled shafts (AASHTO, 2010).

Soil/Rock Type	Design Method	Resistance Factor, $\phi$
Clay	O’Neill & Reese (1999)	0.45
Sand	O’Neill & Reese (1999)	0.55
IGM	O’Neill & Reese (1999)	0.60
Rock	Horvath and Kenney (1979)	0.55
	O’Neill & Reese (1999)	0.55
	Carter & Kulhawy (1988)	0.50

The AASHTO code may reduce the risk to geotechnical designers in the sense that they may have stronger defense against litigation as long as the minimum requirements are satisfied. However, the code also requires designers to employ judgment to expand the site characterization where conditions warrant so the practical truth for this is at least debatable.

#### 3.3 MoDOT LRFD Practice

The MoDOT design guidelines seek to address limitations in traditional ASD and AASHTO LRFD practices by linking the resistance factors used with the quality of site characterization performed, and simultaneously improving consistency by restricting this link so that the target reliability is more consistently achieved. The “link” in this case is formed by implementing resistance factors that depend on the variability and uncertainty in design input parameters, which in turn depends on the quality of the site characterization conducted. In implementing this link, the guidelines also provide designers with practical means to estimate the potential value of site investigation activities on a project specific basis so that more effective site characterization decisions can be made.

## 4 GUIDING PRINCIPLES

The principal objective for development of the MoDOT design guidelines was to provide procedures that would save agency funds by more precisely and consistently achieving target probabilities of failure in design (i.e. applying appropriate conservatism for the variability and uncertainty present for each specific project). The primary means for improving the precision of the procedures is by considering the variability and uncertainty in design input parameters separately from the variability and uncertainty in design and construction methods.

The predominant cost savings are expected to be savings in construction costs rather than savings in site characterization costs. However, it was recognized that conducting advanced or extensive site characterization to reduce variability and uncertainty in design parameters is not always justified and will not always produce net cost savings. The overall intent was therefore to provide the agency with practical procedures to identify conditions where more extensive investigations are likely to produce cost savings, considering the costs for site investigation, costs for construction, as well as potential future costs for maintenance and repair.

Conscious effort was also made to avoid overly prescriptive provisions. Rather, the intent was to provide methods that inform the judgment of the designer about the value of

alternative site characterization activities. In this way, the opportunity to apply sound judgment remains, but it can be made more knowledgeable and consistently.

In the context of the guidelines, the probabilities of failure considered were epistemic, or “degree of belief” probabilities, which reflect level of knowledge, rather than aleatory probabilities that are related to actual performance. Thus, the probabilities of failure considered are related to the level of knowledge and confidence in the design input parameters and design methods rather than an actual statement about performance rates, although the two are clearly related.

## 5 CALIBRATION OF RESISTANCE FACTORS

Calibration of resistance factors to separate consideration of variability and uncertainty in design and construction methods from variability and uncertainty in design parameters requires only minor changes to common procedures. The most significant change is to use a performance function,  $g$ , of the form:

$$g = R(x) \cdot M(\bar{x}) - LL - DL \geq 0 \quad (1)$$

where  $R(x)$  is a deterministic design relation for geotechnical resistance,  $x$  represents the probabilistic design input parameter(s),  $\bar{x}$  is the mean value of the design input parameter(s),  $LL$  is the probabilistic live load effect,  $DL$  is the probabilistic dead load effect, and  $M(\bar{x})$  is a probabilistic “model uncertainty” parameter used to represent the bias, variability and uncertainty attributed to design and construction.  $M(\bar{x})$  reflects the conditional variability of the design method established from load tests, from numerical analyses, or based on judgment, while  $x$  reflects the variability and uncertainty in the design input parameter(s). For design methods without substantial bias,  $M(\bar{x})$  is taken to have a mean value of 1.0 and a distribution that reflects the variability of the design method.

Given the performance function for a specific design method, calibrations are then performed for a range of assumed coefficients of variation ( $COV$ ) for the design input parameter(s). Figures 1 and 2 show results of calibrations conducted for two illustrative design methods: design for tip resistance of drilled shafts in clay and design for side resistance of drilled shafts in rock, respectively. In each figure, curves are shown for four categories of structures. Each of these curves represents resistance factors to achieve a target probability of failure established by agency policy. The curves reflect the magnitude of resistance factor needed to achieve the target probability of failure based on the variability and uncertainty present in relevant input parameters, as represented by the  $COV$ .

Simple observation of the curves shown in Figs. 1 and 2 provides valuable qualitative information regarding the importance of site characterization for the respective design methods. Comparison of resistance factors for  $COV = 0$  (corresponding to perfect information about the input parameters) reveals that the variability and uncertainty attributed to the method for side resistance in rock (Fig. 2) is substantially greater than that for tip resistance in clay (Fig. 1). Furthermore, the steepness of the curves in Fig. 1 indicate that the resistance factor needed to achieve a given target probability of failure is highly sensitive to the variability and uncertainty of the undrained shear strength, thus indicating that the quantity and quality of site characterization will have a substantial impact on the resulting design. Conversely, the curves shown in Fig. 2 are much flatter, indicating that reduction of the  $COV$  for uniaxial compressive strength via expanded testing will have a lesser effect on the resulting design. These simple qualitative comparisons can also be quantified if specific values of  $COV$  for the design input parameters are estimated as will be illustrated through a subsequent example.

Figure 1. Resistance factors for tip resistance in clay.

Figure 2. Resistance factors for side resistance in rock.

## 6 ESTIMATION OF PARAMETER UNCERTAINTY

Use of resistance factors established as described in the previous section is straightforward once  $COV$ -values for the input parameters are known. The primary complication introduced compared to current AASHTO specifications is that the MoDOT guidelines require estimation of parameter  $COV$ s. Fortunately,  $COV$  values can be established using practical means that introduce little complexity to the design process.

The general approach to establishing  $COV$  values closely follows conventional procedures for interpretation of design parameters. The process is based on establishing a “design profile” that reflects conditions present at a particular site. These design profiles establish a “model” describing how the magnitude of a design parameter varies with depth or elevation, as well as the variability and uncertainty of the model.

For the MoDOT guidelines, design profiles are assumed to be composed of a number of individual strata. The design parameter within an individual stratum is assumed to have values that are either constant, or linearly varying with depth or elevation as illustrated in Figure 3. As a practical matter, any design profile can be reasonably represented as some combination of strata that have either a constant or linearly varying property within each stratum. Regardless of whether the parameter value is assumed to be constant or linearly varying, the variability or uncertainty in the parameter within a single stratum is assumed to be constant, and represented by a constant value of the coefficient of variation ( $COV$ ).

Once individual strata are established, design values for parameters in a stratum judged to have constant values are taken to be the arithmetic mean of the available measurements:

$$y = \bar{y} = \frac{\sum_{i=1}^n \hat{y}_i}{n} \quad (2)$$

where  $y$  is the design, or “model” value of the parameter,  $\bar{y}$  is the mean value of the parameter measurements,  $\hat{y}_i$  is a measured value of the parameter, and  $n$  is the number of

measurements. The coefficient of variation of the mean value for the design parameter in a stratum with constant properties is established from available measurements as:

$$COV_y = \frac{\zeta \sigma_y}{y} = \frac{\zeta \sigma_y}{y} \quad (3)$$

where  $COV_y$  is the coefficient of variation of  $y$ ,  $\sigma_y$  is the standard deviation of  $y$ ,  $\zeta$  is an empirical modifier to account for the fact that  $COV_y$  may be underestimated for small numbers of tests, and  $\sigma_y$  is the standard deviation of the measurements.

Slightly different equations are used for strata where design parameters are deemed to vary linearly with depth (MoDOT, 2010). Fig. 3 illustrates results of such calculations.

Figure 3. Example “site model” developed for design of drilled shafts.

### 7 EXAMPLE APPLICATION

To illustrate how the methods described can be used to quantify the potential value of site characterization activities, a conceptual design of drilled shafts for a highway bridge was conducted using measured values of uniaxial compressive strength for a shale site. Two designs were completed: the first using a small randomly selected subset of the available test measurements (Fig. 4) to reflect design based on a limited site investigation and testing program; the second was completed using a larger subset of the available measurements (Fig. 5) to reflect design based on a more typical site investigation for a bridge design. As shown in the figures, the more extensive investigation produces a slightly greater mean value for the uniaxial compressive strength in Maquoketa Formation C, but reduces the  $COV$  of the mean value by a factor of two. This, in turn, allows greater resistance factors to be used for design. Considering the same 13 MN axial load for both designs, the design completed based on the limited site investigation (Fig. 4) leads to use of 7.5 m long, 1200 mm diameter drilled shafts while the design completed based on the more typical site investigation (Fig. 5) leads to use of 5 m long, 1200 mm diameter drilled shafts. The estimated cost differences between these two designs is approximately \$5,000 per shaft. Thus, the value of the additional testing is approximately \$5,000 per shaft.

In practice, such direct comparisons are not possible *a priori*. However, designers can estimate how increasing the number of measurements will affect the  $COV$  of design parameters to develop estimates of potential costs savings as in the example. The estimated cost savings can, in turn, inform judgement regarding the scope of testing that may optimize final designs. If costs for additional characterization are not commensurate with estimated cost savings, then the additional characterization should not be undertaken as it is unlikely to “pay off”. While such estimation is unfamiliar, it is likely that one’s judgment regarding expected reductions in the  $COV$  with additional testing will improve with experience so that practices regarding effective scoping of site investigations will improve over time.

Figure 4. Uniaxial compressive strength measurements from site characterization with limited scope.

Figure 5. Uniaxial compressive strength measurements from more extensive site characterization.

### 8 CONCLUSION

Variability and uncertainty attributed to design parameters and due to design and construction methods can be practically separated within an LRFD framework by using resistance factors established as a function of the  $COV$  of the design parameter(s). Use of such resistance factors can improve the efficiency of geotechnical designs by more precisely and consistently achieving target probabilities of failure. This implementation also provides means to practically quantify the potential value of additional site characterization during design, which can improve design decisions and help convince owners/clients of the value of additional characterization.

**ABSTRACT:** EN 1997-1:2004 (Eurocode7, Part 1 - EC7) is the European Standard for Geotechnical Design. Ground anchors are addressed in Section 8 of this standard, EN 1537:1999 (execution)(under revision) and it is planned that testing will be covered by prEN ISO 22477-5. EC7 Section 8 has been little used and is now under revision. Discussions between European experts on ground anchors have highlighted the diversity of current design practices used in different countries. This paper explores this diversity and highlights the variations in the approaches to the design and testing of ground anchors, dealing exclusively with grouted ground anchors which are able to be tensioned. The existing practices of Denmark, France, Germany, Ireland and the UK are considered in relation to the EC7 requirements for verification of ultimate and serviceability limit states. It is shown how the draft now proposed of EC7 for the design and testing of anchors accommodates the approaches currently used in European countries within a single framework.

**RESUME :** L'EN 1997-1:2004 (Eurocode 7, Par 1 - EC7) est la norme pour la conception des ouvrages géotechniques. Les tirants d'ancrage sont traités dans le chapitre 8 de cette norme, dans la norme d'exécution EN 1537 :1999 en révision et dans le projet de norme d'essais pr EN ISO 22477-5 en cours de rédaction. Le chapitre 8 de l'EC7 bien qu'encore peu utilisé, est en cours de révision. Les discussions entre les experts européens sur les tirants d'ancrage ont mis en lumière la diversité des pratiques couramment appliquées dans les différents pays. Cet article présente cette diversité et montre les différences d'approche tant au niveau de la conception que des essais, en particulier avec les tirants d'ancrage scellés au terrain qui peuvent être mis en tension. Les pratiques existantes au Danemark, en France, en Allemagne, en Irlande et au Royaume-Uni sont présentées selon les exigences de l'EC7 dans le cadre d'une vérification aux états limites ultimes et de service. L'article montre comment le projet proposé pour l'EC7 concernant la conception et les essais des tirants d'ancrage prend mieux en compte et de façon simple approches actuellement utilisées dans les pays européens.

**KEYWORDS:** Anchors, Eurocode, Standards, Design

### 1 INTRODUCTION AND HISTORICAL CONTEXT

Ground anchor design as it is today has been derived from many years of field tests, performance monitoring and field scale research, resulting in an empirical approach of anchor performance linked to soil parameters. Early use of anchors included the application of rock bolts for roof stability in Poland in 1918 and later in Czechoslovakia in 1926 to support an inclined shaft. The mining industry led the field in anchoring ground at this stage. Anchors were first introduced into civil engineering in 1934 by the French engineer André Coyne who devised strand anchors in sandstone to allow the raising of the Cheurfas dam in Algeria. The first use of anchors in soil was by Karl Bauer GmbH in Munich in 1958 to tie back retaining walls. The site agent, noting the difficulty in withdrawing steel drill casing developed a system which included 20m bars with 3m bond lengths installed with working loads of 25 tonnes. Development of anchor design accelerated between 1966 and 1969 with the use of anchors in stiff clays, marl, fine to medium sand and chalk (Littlejohn, 1970).

The developing design process was based on observations from field anchor tests taken to failure and long term behaviour of prestressed anchors. Empirical design rules with realistic factors of safety were being produced relating ultimate pull-out resistance to soil properties and anchor dimensions. The relationship between soil parameters and anchor performance was the basis of extensive research between 1970 and 1980, when many of the empirical relationships were developed upon which calculation of anchor/soil bond resistance, creep and multiple interface resistance are based (Littlejohn, 2012).

The methods of designing the anchor to contribute to the overall structural stability of, say, an anchored retaining structure were based on limit equilibrium stability analyses applying linear, active and passive pressure distributions. Where the design required the minimisation of wall displacement, the same approach was adopted using different pressure distributions. With the relatively recent availability of accessible FE approaches these conditions, taking into account the effect of anchor prestress, are examined routinely today.

With the expansion of anchor use throughout Europe, individual countries developed design guides and codes of practice (BS8081, DIN 4125, SIA V 191, TA95 for example) to promote safe design. Inevitably there were variations of design practice between these standards reflecting regional practices. In 1975, the Commission of the European Community initiated an action programme to develop a set of harmonised rules for the structural design of construction works based on Article 95 of the Treaty. This was transferred to CEN in 1989 guaranteeing them the status of European standards. EC7 (EN 1997-1:2004) was subsequently published and is intended to be used as a general basis for the geotechnical aspects of the design of buildings and civil engineering works. The design of anchors is accommodated in Section 8, for which a new draft has recently been prepared, which is referenced as EN 1997-1:2004/prA1, to be published. Alongside EC7 two further standards EN 1537 and prEN ISO 22477-5 have been developed to provide rules for the execution of anchors and the testing of anchors respectively. Whilst EN 1537 has been published for

some time and is now the subject of systematic review, prEN ISO 22477-5 has yet to be published.

## 2 DESIGN REQUIREMENTS OF EC7

The limit state framework adopted by EC7 requires that anchors are designed to ensure that:-

- Neither an ultimate limit state (ULS) nor a serviceability limit state (SLS) occur within the anchored structure or other supported structures.
- That an anchor has the required ULS and SLS resistance corresponding to these limit states.

The requirements of the new draft of Section 8 which are designed to satisfy these limit states for the anchor and structure are discussed in the following section.

### 2.1 Ultimate limit state (ULS) design force

Anchors are required to have an ULS design capacity ( $R_{ULS,d}$ ) to resist not only the force required to prevent an ULS in the anchored structure and supported structure ( $F_{ULS,d}$ ), but also must have the capacity to resist the maximum force that could be transferred to the anchor during its service life ( $F_{serv,k}$ ), with an adequate margin of safety. Thus the design of the anchor must consider the prestress or lock-off force applied and also any additional force attracted to the anchor during its design life. These safety requirements are expressed as Eq. 1 to 3 where  $\gamma_{serv}$  is a partial factor.

$$E_{ULS,d} \leq R_{ULS,d} \quad (1)$$

$$\text{where } E_{ULS,d} = \text{Max}(F_{ULS,d}; F_{serv,d}) \quad (2)$$

$$F_{serv,d} = \gamma_{serv} F_{serv,k} \quad (3)$$

### 2.2 Serviceability limit state (SLS) design force

Anchors are required to have the design capacity ( $R_{SLS,d}$ ) to resist the  $F_{serv,k}$  such that the limiting creep or load loss for a SLS are not exceeded. This requirement is not explicitly stated in all countries and may be covered in a ULS requirement. Assuming that the appropriate partial factor for this SLS is unity, this requirement is expressed as Eq. 4.

$$F_{serv,k} \leq R_{SLS,d} \quad (4)$$

### 2.3 Geotechnical ULS anchor resistance

EC7 requires that anchor tests be carried out to confirm that they have the resistance to satisfy Eq. 1. The value of the ULS resistance,  $R_{ULS}$ , is defined as the "value of the resistance of an anchor complying with ultimate limit state criteria". This means that tests must demonstrate that an anchor can provide a certain resistance while satisfying specified criteria of creep or load loss. The pull-out resistance will be greater than the value determined from the test. The design value of  $R_{ULS,d}$  and the characteristic resistance ( $R_{ULS,k}$ ) are determined from the minimum ( $R_{ULS,m}$ )<sub>min</sub> of measured values ( $R_{ULS,m}$ ) in investigation and suitability tests using the partial factor ( $\gamma_{a,ULS}$ ) and correlation factor ( $\xi_{ULS}$ ) and Eqs. 5 & 6.

$$R_{ULS,k} = \frac{(R_{ULS,m})_{min}}{\xi_{ULS}} \quad (5)$$

$$R_{ULS,d} = \frac{R_{ULS,k}}{\gamma_{a,ULS}} \quad (6)$$

### 2.4 Geotechnical SLS anchor resistance

In those countries which require that SLS of the anchor resistance be considered, it is necessary to verify that the anchors have at least the capacity to satisfy Eq. 4, satisfying SLS criteria of creep or load loss. Using the same symbols as in 2.3 but with SLS replacing ULS and a correlation factor of

unity, the design SLS resistance ( $R_{SLS,d}$ ) and characteristic SLS resistance are given by Eqs. 7 & 8.

$$R_{SLS,k} = (R_{SLS,m})_{min} \quad (7)$$

$$R_{SLS,d} = \frac{R_{SLS,k}}{\gamma_{a,SLS}} \quad (8)$$

## 3 CURRENT DESIGN PRACTICE

The amended Section 8 of EC7 only covers the design of anchors from load tests, hence only this aspect of anchor design is covered in this paper. Calculations using parameters derived from ground tests are considered to be for the estimation of the bond length only, and the design is then verified by load tests.

The discussion on current design practice is not as straightforward as it might appear due to the way anchor forces are determined for particular design situations in some countries and to the current lack of agreement on what precisely constitutes ULS and SLS failure criteria of an anchor. The design aspects include not only whether the SLS or ULS resistance of the anchor is verified but also whether the force used in this verification process is derived from analyses using factored ground properties or using characteristic values.

The derivation of ULS anchor forces is well developed and, for embedded walls, typically involves some type of Limit Equilibrium Analysis, although the use of finite elements is becoming more common. However the design of anchors in some countries is related to the 'working load'. This practice arose from the fact that earth pressures in the SLS condition (unfactored and considering compaction and at rest pressures) are greater than those at failure when the soil strength is fully mobilised, consequently can give rise to greater anchor force. Furthermore, as these are 'working loads', the anchor would be required to satisfy more onerous creep criteria at such loads. However, EC7 requires that in ULS design a more conservative view is taken of the ground strength and resistance, together with unexpected excavations and higher surcharges than considered for SLS and this situation must also be considered.

The methods used in the past to determine SLS forces, which are also called working forces, were very approximate for embedded walls. Typically the length required for ULS was derived by considering the wall as a beam with a length required for ULS, supported at the anchor and by passive earth pressure, on which act the active earth pressures determined using characteristic actions and soil parameters. Other approaches for simple walls were to calculate the anchor force using the characteristic actions and parameters but with the shortened pile length that is required for equilibrium. The advent of finite elements and other methods of analysis has allowed deformations to be considered more realistically thus providing a more reliable estimate of  $F_{serv,k}$ . The forces required to limit the movement of the structure and the supported ground are considered, including those forces attracted to the anchor after lock-off.

France has perhaps a design practice that can be most easily related to the proposed amendments of EC7 in that a  $F_{ULS,d}$  is determined from an ULS analysis of the structure and a 'service load', similar to  $F_{serv,k}$ , is also derived using characteristic values of actions and soil parameters. The testing is required to verify that the anchors have the required 'pull-out' resistance to satisfy the ULS requirements, including the required ULS resistance to ensure safety under  $F_{ULS,d}$  and that the creep requirements are satisfied under the service load.

Germany also calculates a value of  $F_{ULS,d}$ , however this value is calculated from characteristic values of the effects of permanent and variable actions, which are termed  $F_{Gk}$  and  $F_{Qk}$ . The anchor force for proof testing is related to  $F_{ULS,d}$  which is the maximum of  $1,35 F_{Gk} + 1,5 F_{Qk}$ , or 1,35 times the anchor force after lock-off if that is greater. The proof load has to satisfy a limiting creep criterion which is discussed in the

following section. The creep criterion is selected to represent a ULS anchor resistance.

The UK currently excludes Section 8 of EC7 from use in that country in its National Annex and requires anchors to be designed to BS8081 'Ground Anchorages'. The design of anchors in that standard is based on the 'working load',  $T_w$ , which is defined as 'The safe load of the anchorage'. No guidance is given in the standard as to whether  $T_w$  is determined using a ULS calculation or using characteristic values, however the terminology would suggest that it was originally considered to be similar to  $F_{Serv;k}$ . In practice, it is considered that for embedded walls,  $T_w$  is taken as the higher of that obtained using either a limit equilibrium or a bending moment and displacement analysis using appropriate pressure distributions. The proof load is related to  $T_w$ , as discussed in the following section, with different creep criteria to be satisfied which can be related to a SLS and to a ULS resistance.

Section 8 has not been specifically excluded in Ireland, nevertheless the practice is generally to adopt the BS8081 testing criteria with  $T_w$  based on a calculation using characteristic actions and parameters. However, given the general lack of specific guidance in this area prior to the publication of the amended Section 8, some designers also considered the value of  $F_{ULS;d}$  in the selection of  $T_w$  if that gave a greater value.

Denmark uses the present EC7, section 8. The anchor force is based on a ULS design force found from a calculation of the anchored structure with factored soil parameters. Some Danish designers compute a service load ( $F_{Serv;k}$ ), which considers prestress/lockoff of the anchor. This force is such as to resist a ULS if  $F_{Serv;k}$  is greater than  $F_{ULS;d}$ . This means that  $E_{ULS;d} = F_{Serv;k}$  if  $F_{Serv;k} > F_{ULS;d}$ . The Proof load is then based on  $E_{ULS;d}$  and must satisfy a limiting creep criterion. Previously Denmark used the German test method as described in DIN 4125. However, with the introduction of EN 1537:1999 Denmark has accommodated the incomplete test specifications stated in the informative annex E of EN 1537:1999. Test method 1 (TM1) is preferred because of the relationship to the former DIN 4125, but the creep rate limit measured in the acceptance test using TM1 in EN1537:1999 is so strict (0,8 mm), that often Test Method 3 (TM3) is adopted because of the more moderate creep rate limit (1,2 mm). Temporary anchors may be loaded to a lower proof load than permanent anchors, provided the consequence of failure justifies that. Similarly the effect of high or serious consequences of failure are governed by the reliability class concept as described in EC0, Annex B by introducing a  $K_{Ff}$  factor applied to the partial safety factor on the load or on the resistance.

#### 4 TESTING OF ANCHORS

Load testing of anchors has historically been an intrinsic part of the design and execution of anchors – in particular grouted ground anchors - and the mandatory acceptance testing of all grouted anchors is required in EN 1997-1:2004/prA1:2012 and in EN 1537:1999. The anchors are loaded to a proof load ( $P_p$ ) to verify limit state design requirements. The tests are categorised as:

1. Investigation Tests undertaken to establish the geotechnical ultimate resistance,  $R_{ULS;m}$ , of the anchor at the grout/ground interface and to determine the characteristics of the anchor within the working load range.
2. Suitability tests – carried out on site on anchors identical to those to be used in the works – to investigate some characteristics of the anchor and how the anchor performs under working conditions.
3. Acceptance tests – carried out on every anchor installed in the permanent works – to ensure that each anchor will perform as designed.

For Investigation and Suitability tests  $P_p$  is derived from:

$$P_p \geq \xi_{ULS} \times \gamma_{a;ULS} \times E_{ULS;d} \quad (8)$$

For Acceptance tests  $P_p$  is derived from  $E_{ULS;d}$  or  $F_{Serv;k}$ :

$$P_p \geq \gamma_{a;acc;ULS} \times E_{ULS;d} \quad (9)$$

or

$$P_p \geq \gamma_{a;acc;SLS} \times F_{Serv;k} \quad (10)$$

The method is to be stated in the National Annex of each country.

Table 1 - Limiting Criteria for investigation, suitability and acceptance tests for persistent and transient design situations at the ultimate and serviceability limit states (from EN 1997-1:2004/prA1:2012)

Test Method <sup>a</sup>	Limiting criterion	Investigation and Suitability tests	
		ULS	SLS
1	$\alpha_1$	2 mm	$0.01\Delta_e^b$
2	$k_1$ (per log cycle of time)	2%	2%
3	$\alpha_3$	5 mm	NA (use $P_c$ )
Test Method <sup>a</sup>	Limiting criterion	Acceptance tests	
		ULS	SLS
1	$\alpha_1$	2 mm	$0.01\Delta_e$
2	$k_1$ (per log cycle of time)	2%	2%
3	$\alpha_3$	NA	1.5 mm <sup>c</sup>

Note: NA = Not applicable

<sup>a</sup> Test methods are in accordance with Draft EN ISO 22477-5 Geotechnical investigation and testing - Testing of geotechnical structures - Part 5: Testing of anchorages

<sup>b</sup>  $\Delta_e = (F_{serv;k} \times \text{tendon free length}) / (\text{area of tendon} \times \text{elastic modulus of tendon})$

<sup>c</sup> Value given is for permanent anchors; for temporary anchors,  $\alpha_3 = 1.8$  mm

EN 1537:1999 provides for three methods to undertake the suite of tests, essentially following the traditions in testing developed and maintained in Germany, the UK and France. As stated in section 3, these test methods are referred to as Test Method 1, 2 and 3. This approach and test designation has been implemented in EN 1997-1:2004/prA1:2012 and Draft EN ISO 22477-5 expected to be published in 2013.

The provisional limiting criteria for ULS and SLS resistance for these tests to EN 1997-1:2004/prA1:2012 are given in Table 1. The methods of execution and interpretation of the tests are to be found in Draft EN ISO 22477-5. This standard makes no specific reference to testing for either SLS or ULS stating that proof loads are to be set in accordance with EN1997-1. Not all countries have the requirement to determine the limiting criteria for SLS of the anchor as this is considered to be satisfied if the test results meet the ULS criteria.

The test methods currently adopted in Germany, Denmark, France, Ireland and the UK are summarised below. It should be noted that some countries already use partial factors whilst others still adopt a more global safety factor approach.

#### Germany.

1. Follow Test Method 1
2. For all categories of test (investigation, suitability and acceptance), proof load is:
 
$$P_p = 1,1 \times 1,35 \times F_{Serv;k} \quad (11)$$
 or
 
$$P_p = 1,1 \times F_{ULS;d} \quad (12)$$
3. Limiting criteria based on value of  $\alpha_1$  for investigation, suitability and acceptance tests. Acceptance tests are required to satisfy the  $\alpha_1$  criterion, but the test is shorter than that required for suitability tests.

Denmark

1. Follow Test Method 1 and 3.
2. For all categories of test, proof load:

$$P_p = \xi (\gamma_a)^\alpha F_{ad} \quad (13)$$

where

$$F_{ad} = \max(F_{ULS;d}; F_{Serv;d}) \quad (14)$$

where all anchors are tested,  $\xi = 1,1$  and  $\gamma_a = 1,3$ .

$\alpha$  is a factor used to control reduced safety in temporary situations, provided the risk of the consequence justifies it. It may range from 0 to 1. For permanent anchors  $\alpha = 1$ . For temporary anchors – with small or no risk to human life or important infrastructure  $\alpha$  is typically set to 0,5. Thus for permanent anchors:

$$P_p = 1,1 \times 1,3 F_{ad} = 1,43 F_{ad} \quad (15)$$

For temporary anchors with less severe consequence of failure:

$$P_p = 1,1 \times (1,3)^{0,5} F_{ad} = 1,25 \times F_{ad} \quad (16)$$

3. Limiting criteria are based on a value of the creep rate according to (informative) values in EN 1537:1999

France

1. Follow Test Method 3
2. Proof load for Investigation and Suitability tests

$$P_p = 1,50 \times F_{serv;k} \quad (17)$$

where  $F_{serv;k}$  is derived from calculation.

3. Suitability tests should demonstrate that the critical creep load  $P_c \geq 1,2 \times F_{serv;k}$  (for permanent anchors) and  $P_c \geq 1,1 \times F_{serv;k}$  (for temporary anchors) where  $P_c$  is derived from the load corresponding to the end of the first pseudo-linear part of the creep rate versus anchor load plot found from an investigation or suitability test.
4. Proof load for Acceptance tests:

$$P_p = 1,25 \times F_{serv;k} \text{ (permanent anchors)} \quad (18)$$

or

$$P_p = 1,15 \times F_{serv;k} \text{ (temporary anchors)} \quad (19)$$

Given the limits on  $F_{serv;k}$  with respect to the critical creep load, at these proof loads the ratio between test load and creep load is independent of the application of the anchor. It will be constant and approximately 1,04.

5. Limiting criteria based on the value of  $\alpha_3$  at Proof load  $P_p$  and the value of  $P_c$  to check that  $P_c / F_{serv;k} > 1,2$ .

UK and Ireland

1. Follow Test Method 2 but also use Test Method 1.
2. Investigation tests - the anchor is normally loaded to the point where the vertical asymptote of the cumulative load loss  $k_l$  vs load relationship may be determined. An estimate of the anchor pull-out capacity may also be made.
3. Proof Load for the suitability and acceptance tests  $P_p = 1,5 \times T_w$  (20) where  $T_w$  is derived from the stability and serviceability requirements of the structure.
4. In both suitability and acceptance tests the limiting criteria are based on the values of  $k_l$  at a)  $P_p = 1,5 \times T_w$  and b)  $P_p = T_w$
5. Where Test Method 1 is adopted the limiting criterion  $k_l$  is translated into a creep displacement as shown in Table 1, note b.

5 CONCLUSIONS

The aim in developing a new Section 8 for EC7 has been to provide a rational framework for the design of ground anchors as elements within an overall ground-structure design, while accommodating the diverse practices of different countries. In the opinion of the group responsible for the drafting, which included the authors, this has been achieved. Some of the values of factors and criteria will probably be refined during the development of national annexes, though it is likely that national practices will remain distinct for the time being. Nevertheless, as with other aspects of Eurocodes, the existence of a single agreed text gives the possibility of clearer comparisons between national approaches, and so will hopefully contribute to the development of a more unified approach in the future.

6 ACKNOWLEDGEMENTS

The authors would like to acknowledge the contributions made by their fellow members of TC250/SC7/EG1, Klaus Dietz, Yves Legendre, Pierre Schmitt, Bernd Schuppener, Arne Schram Simonsen, in the development of the new draft of Section 8 of EC7.

# Harmonising safety and profit: ethical issues in the geotechnical activity of major consulting companies

Harmoniser sécurité et profit: problèmes éthiques dans l'activité géotechnique de grosses entreprises de génie conseil

Redaelli M.  
*Halcrow (a CH2M Hill Company)*

**ABSTRACT:** Industrial enterprises aim at committing the lowest amount of resources and time to deliver a satisfactory product to the client. In the civil engineering industry failure to deliver a satisfactory product, in the form of structures and infrastructures which meet the required performance, may result in huge costs and loss of life. Conversely large uncertainties on the performance may also result in an unnecessarily safe and wasteful design. In the present time, considering the environmental impact of construction activities and the rapid depletion of finished resources, wasteful design is becoming ethically unacceptable. This paper discusses some issues that are specific of geotechnical engineering, where uncertainties are larger and the use of subjective engineering judgement and personal experience is more important than in other disciplines. Particular attention is given to problematic aspects of major projects, like the fragmentation of tasks in many sub-packages and the ensuing difficulty in managing the flow of information at the many interfaces. Practical suggestions are given to improve the compliance to ethical requirements in the geotechnical activity of large consulting companies.

**RÉSUMÉ :** Les entreprises industrielles désirent minimiser l'usage de ressources et de temps qui est nécessaire à obtenir un produit satisfaisant pour le client. Dans l'«industrie» du génie civil n'obtenir pas un produit satisfaisant, sous forme de structures ou infrastructures qui parviennent au comportement spécifiée, peut résulter en coûts énormes et même faire de victimes. Réciproquement, grandes incertitudes sur le résultat peuvent aussi produire un projet excessivement sûre et gaspilleuse. Aujourd'hui, à raison de l'impact de les activités de construction sur l'environnement et de l'épuisement rapide de ressources finies, les projets gaspilleurs deviennent éthiquement inacceptables. Ce papier discute des problèmes qui sont spécifiques de la géotechnique, où les incertitudes sont plus grandes, et l'usage du jugement subjectif et de l'expérience personnelle est plus important, que dans autres disciplines. Un' attention particulière est ici donnée aux aspects problématiques de gros projets, comme la fragmentation des actions dans beaucoup des sous-activités et la difficulté de gérer le flux d'informations a les nombreuses interfaces. Des suggestions pratiques pour améliorer la conformité aux critères éthiques de l'activité géotechnique dans les grosses sociétés de génie conseil sont, enfin, proposée.

**KEYWORDS:** ethics, decision making, risk, uncertainty, trust, communication, education, engineering judgement.

## 1 INTRODUCTION

This paper examines some ethical issues which are relevant to the practice of geotechnical engineering, with special attention to the activity of large, multidisciplinary consulting companies. The relevance of the subject arises from the peculiar nature of geotechnical engineering, which – in comparison with most other civil engineering disciplines – operates under higher levels of uncertainty and, necessarily, incorporates a remarkable amount of subjective judgement in the decision making process.

Moreover, the recent evolution of civil engineering, in its technical and commercial aspects, and the fast-paced changes our planet is experiencing, demand a constant re-evaluation and discussion of the principles of ethics applied to the civil engineering profession.

The content of this paper expresses the views of the author; it does not necessarily represent the position of the author's employer.

## 2 CODES OF CONDUCT, CORPORATE REPUTATION AND BEYOND

### 2.1 *Codes of professional conduct*

The “code of professional conduct” or “code of professional ethics” is generally the first - and often only - point of contact that civil engineering students and practitioners consciously have with their professional ethics. A code of conduct contains a set of rules of behaviour for civil engineers, established at national level by the relevant professional body. Such documents are essential cornerstones in the civil engineering ethical debate. However, due to the variety and complexity of the civil engineering profession, as well as its dynamic nature, the codes of conduct cannot be expected to always provide readily applicable rules for each and every real-life situation.

The review and discussion of specific national codes of conduct go beyond the scope of this paper. Since these documents are nowadays very accessible, the interested readers can easily expand their knowledge and understanding; for example the ICE Code of Professional Conduct (Institution of Civil Engineers 2008) and the ASCE Code of Ethics (American Society of Civil Engineers 2006) are freely available on-line.

The codes of conduct mentioned above regulate the practice of civil engineering in its entirety, as a macro-discipline. To the author's knowledge no specific code of conduct for specialist

disciplines, like geotechnical engineering, exists. The only exceptions apply to even more specific activities within a specialist discipline; for example the AGS Code of Conduct for Site Investigation (Association of Geotechnical Specialists 2007).

## 2.2 *Trustworthy corporation*

One of the functions of ethical behaviour is to protect the reputation of civil engineering professionals and corporations. This aspect is powerfully captured in the “Little Yellow Book” by Jim Howland (1982), whose *test to determine if a contemplated action is ethical is to ask: “Would I want to see it in the headlines tomorrow morning?”*. Although such an approach to ethics emphasises appearance over substance, the importance of corporate reputation and trustworthiness in the relationship with clients, contractors, third parties and society as a whole should not be underestimated. It is, in fact a key ingredient in developing successful projects which are capable of bringing benefits to the full range of stakeholders, as further discussed in Section 3.2.

## 2.3 *Full meaning of civil engineering ethics*

The full and deepest meaning of civil engineering ethics goes well beyond the straightforward application of the rules of behaviour contained in a code of conduct and the attempt to build and preserve corporate reputation.

Ethics involves the systematic study of moral norms and standards of behaviour, together with their underlying values and justifications (Armstrong *et al.* 1999). Applied ethics deals with the formulation of morally good decisions which can be made in a particular area of interest, for instance various professions (e.g. medical ethics, legal ethics, etc.) or particular issues of private and public interest (e.g. environmental ethics, bioethics, etc.). Part of the complexity of civil engineering ethics – which is one of the many branches of professional ethics – derives from the involvement of several ethical subjects and many different competing views of what is morally right or wrong. Those affected by the ethical decision-making of a geotechnical engineer for good or bad may include, for example:

- i the geotechnical engineer (and, where appropriate, their family and associates);
- ii the engineer’s colleagues (from the same discipline or from other disciplines);
- iii the engineer’s employer (in the present case a large engineering company);
- iv the engineer’s professional community (at national or international level);
- v the client;
- vi the society at large (ranging from a local community affected by a particular project, to larger groups of stakeholders at national and international level);
- vii the environment (the biosphere and its interaction with lithosphere, hydrosphere and atmosphere).

An extensive discussion of the philosophical theories of ethics is beyond the scope of this paper. The author agrees with Armstrong, Dixon and Robinson when they suggest that practical, real-life decision making requires a combination of the three main ethical theories: (a) deontological - to do with duty, (b) consequentialist - concerned with outcomes, (c) virtue ethics - concerned with moral excellence.

## 3 CIVIL ENGINEERING IN CONTEXT

### 3.1 *The intrinsic conflict between performance and profit*

Industrial enterprises aim at committing the lowest amount of resources and time to deliver a satisfactory product to their

clients. In the civil engineering industry failure to deliver a satisfactory product, in the form of a structure or infrastructure which meets the required performance, may result in huge costs and even loss of life.

In practice there is the need to strike the correct balance between a quick, cheap, approximate design of uncertain performance - on the one extreme - and slow, expensive, accurate design with much reduced uncertainty on the performance - on the other extreme. In a consulting company the “right” balance has to be satisfactory from both a commercial and an ethical point of view. Uncertainty in performance may result in either safer-than-required design (not dangerous but wasteful) or less-safe-than-required design, which is observed more rarely but may have extremely severe consequences.

In civil engineering, and particularly in geotechnics, a great deal of uncertainty in the final performance is associated with the human factor. Assigning tasks (including checking, reviewing and approving the design) to individuals with the appropriate level of competence and experience is of paramount importance. From a purely economic point of view a project manager or a project director wishes to see each task completed as quickly as possible by the available team member with the lowest hourly cost rate and therefore, most likely, level of experience. However, pushing tasks too far down the chain of competence/cost, has unacceptable implications on the quality of the design process and on the resulting uncertainty in the performance of the finished product.

There are no easy recipes to resolve this tension between cost control and profit, on one side, and quality in the form of performance of limited uncertainty (which avoids waste or lack of safety) on the other side. A useful strategy, however, consists of resisting short term pressures and “narrow framing” to embrace a long term view. Considering an oversimplified example, there is little use in containing the cost of project delivery if the final product is non-satisfactory and the client will therefore not be inclined to assign future commissions to the company. This elementary consideration can easily be suffocated by the pressure of working against tight programmes and budgets. More generally, whenever it is possible to avoid narrow framing and short term planning, commercial needs and quality assurance tend to become more compatible in an ethically satisfactory way.

### 3.2 *The problem of fragmentation*

A similar, often deleterious, tension between commercial and technical needs is connected to the problem of fragmentation, which affects the design process at many levels. From a purely technical point of view there is an obvious benefit in achieving continuity through the many phases of design and construction and in ensuring the same subject – same company and, ideally, same personnel – develops a project from inception to completion. This approach limits the need for knowledge transfer between different teams and individuals, thus minimising repetition and possible misunderstandings or loss of information. However, in some situations and in some forms of contract the continuity is discouraged or even prohibited. Such a choice is based on the principle of efficiency through competition and specialisation, which, in theory, should result in optimised cost and outcome. In practice there are other considerations which should complement, and in some cases overrule, these aspects. In a nutshell, commercial competition and specialisation push toward ever further fragmentation, while technical efficiency would require unity of vision and continuity of knowledge.

The author argues that, currently, the way major civil engineering projects are delivered is grossly unbalanced toward an excessive fragmentation which arises from the prevalence of commercially inspired principles over technical criteria. Often clients, and society at large, pay additional costs at the end of a

project due to mistakes or inefficiencies associated with this misguided approach.

It is here suggested that, without neglecting the value that project management and commercial specialists add to the delivery process, it is extremely important that high level decision-making incorporates sufficient input from technical experts. The subject deserves a richer and broader discussion than what is possible in this conference paper. The author agrees with Muir Wood (2004) on the detrimental role of discontinuity – sometimes deliberately enforced – between the functions of design and construction, and of the fragmentation of responsibility. Without reasonable continuity and unity a project is unlikely to meet satisfactory ethical standards with respect to impact on the society and the environment. Even the success in strictly engineering terms is endangered. In Muir Wood's words a successful engineering project comprises *a Client whose requirements have been understood and fulfilled; a Contractor who has been adequately reimbursed for a job well done; an Engineer who has fully understood the Client's need and has applied competence and creativity to a well-engineered project.* The final sign of success is *the rarity of unresolved dispute and litigation.* It is worth highlighting how this last point is largely dependent on the trustworthiness of the Engineer and all other parties. It is also strongly linked to the Engineers' reputation (see Section 2.2) and their conduct (Section 2.1).

A useful concept to inform the current and future discussion on successful forms of contract and procurement strategies is the Intelligent Market discussed by Muir Wood and Duffy (1991). This approach focuses on a holistic approach which avoids fragmentation and neglect of synergy, in summary taking generated value, not cost, as the main criterion for decision making.

## 4 SPECIFICITY OF GEOTECHNICS

### 4.1 *Uncertainty and judgement*

In geotechnical engineering uncertainties are typically larger than in other branches of civil engineering (structural engineering in particular). The analysis of geotechnical systems and the decision making associated with planning, designing and maintaining them often contains an unavoidable and significant component of engineering judgement. This can (and, when possible at all, should) be based on and informed by the existing literature, which condenses valuable and selected experience from others. However, in many circumstances individuals or teams of engineers have to introduce a considerable amount of subjective opinions in to the design process in order to achieve practical and usable solutions.

This consideration reveals how ethics, intended as good decision-making under uncertainty, bears particular relevance to the geotechnical discipline. The consequences of large uncertainty and reliance on judgement are numerous. On the one hand, geotechnical engineers willing to deliberately distort design outcomes for their own interests or for the interest of their direct employer can easily do so, when dealing with a client who is not familiar with ground behaviour and geotechnical works, by cherry-picking the most convenient results within the often large uncertainty band associated with different interpretations of site data and the selection of different models. On the other hand, the honest and scrupulous engineer in a consulting company may meet with resistance externally – with clients – and internally – with project managers and colleagues from other disciplines – when correctly trying to incorporate in to the design in a transparent way large levels of uncertainty which others may wish to ignore.

In this context helpful ethical behaviours from the geotechnical engineer include building trust by avoiding over-conservatism and by communicating risk accurately, also

highlighting which assumptions and hypotheses are judgement based. At the same time experienced geotechnical engineers need to hold their ground when unreasonably pressed to under-represent and under-communicate uncertainty. The author believes that in a discipline so closely associated with quantification of judgement a basic knowledge of the principles of cognitive psychology which are relevant to this task (Kahneman *et al.* 1982) should be more widespread.

Considering that large uncertainty on the performance of even very common geotechnical structures is not unusual, it is here suggested that national and international professional bodies and institutions should start recording statistical data on the key performance indicators for large numbers of structures.

### 4.2 *New challenges*

The constant evolution of geotechnics, and of the perception that mankind has of its own role and position on the planet, bring to light new ethical issues which should be incorporated in to the daily activity of geotechnical engineers. For example, the necessity of limiting greenhouse gasses emissions and of containing, as much as possible, the consumption of energy and other finite resources have never been so clear. These concepts need to become part of the basic consideration a geotechnical designer goes through when selecting and developing technical solutions (see for example Inui *et al.* 2011). Most importantly, the tendency to regard a large uncertainty in the performance of structures as tolerable and the inclination to deal with it by overdesigning, which implies producing a safer but potentially very wasteful structure, is becoming increasingly unacceptable. In fact such an approach cannot continue in the face of the new perception that the current generation must preserve the health of the environment and avoid resources depletion as much as reasonably practicable. Avoiding wasteful design is becoming an ethical imperative which cannot be achieved without credible understanding, accurate management and effective communication of uncertainties.

One more challenge currently presented to geotechnical engineers is the adoption of new, more complex and potentially more powerful, design codes. An obvious example is the suite of Eurocodes adopted by the European Union and other countries in recent years. The complexity of these codes requires particular attention to the communication between specialists of different disciplines if mistakes are to be avoided. Currently, in most consulting companies, the design of geotechnical structures (for example retaining walls) is jointly carried out by a geotechnical specialist and a structural specialist. The former verifies the geotechnical stability and provides structural actions from geotechnical considerations (for instance a soil-structure interaction analysis), whilst the latter provides the loading combinations to be studied and checks the structural safety on the basis of the geotechnical analysis results. This interaction, often iterative in its nature, requires particular attention to the communication across discipline boundaries. For example geotechnical engineers designing a structure according to Eurocode 7 – EN 1997 – will have to check and double check that they are fully understanding and using correctly the numerous load combinations that they receive from their structural colleagues. Similarly, when providing results in terms of structural actions, the geotechnical engineers need to carefully communicate to their structural colleagues the relevant explanations and clarifications about how the geotechnical calculations have been developed. A typically delicate situation is, for example, the incorporation of partial factors for the STR/GEO ultimate limit states (ULS) in soil-structure interaction analysis (for instance with the finite element method). In this specific circumstance the ULS partial factors from EN 1997-1 need to be rearranged (see for example Bond & Harris 2008) in a way which may be confusing. A discussion of such aspects and an additional effort to ensure the

correct understanding of the specific results communicated across the design team therefore becomes necessary.

## 5 CONCLUSIONS

In the process of civil engineering design there is an intrinsic tension between cost control, on one side, and quality - intended as confidence on the performance - on the other side. An excessive and uncontrolled effort to reduce costs would result in an unacceptably large uncertainty in the performance of engineering systems. Larger-than-expected uncertainty may produce an excessively safe and wasteful design or an unsafe design. Instances of unsafe design are relatively rare in civil engineering but the severity of the consequences of failure is often dramatic. In a world where we should be increasingly concerned with the human impact on the environment and with the rapid and irreversible depletion of finite resources a wasteful design is becoming increasingly unacceptable from the ethical point of view. A strategy to encourage an ethically balanced design is the avoidance of "narrow framing" and short term thinking, in favour of a long term view.

Fragmentation and discontinuity in civil engineering projects is detrimental to ethical choices and, in many cases, even to the basic success of the project in strict engineering terms (Muir Wood 2004). Procurement strategies and forms of contract should be discussed by the civil engineering community and rebalanced for a better harmony between commercial and technical needs.

The uncertainty affecting decision making in geotechnics is much higher than in other civil engineering disciplines. For this reason many ethical issues in geotechnics can be seen as ethical problems of uncertainty and risk communication. In the parts of codes of conduct concerned with communication the main focus and current interpretation is on restraining inappropriate communication. It is here argued that, still maintaining the integrity, objectivity, accuracy and sobriety requested by the codes of conduct, a new, urgent need to encourage the positive side of communication is emerging. This need for increased and improved communication acts at several levels:

- between geotechnical specialist and colleagues from other disciplines; to avoid misunderstandings (e.g. in the application of complex design codes)
- between design team and project management, to convey a realistic perception of uncertainty in the prediction of performance and programme;
- between Designer (or Engineer, depending on contract terminology), Contractor and Client (or Employer), in the various types of contractual arrangements (possibly including other parties, like checker, regulator, etc.), to maximise the probability of project success;
- between geotechnical as well as – more generally – civil engineers and multiple stakeholders and decision makers in the larger society; to ensure technical issues are understood by the public and rational decisions are made on the basis of credible and serious arguments.

The recognition of the key role that uncertainty plays in geotechnical engineering should result in practical steps being made to improve the capability of technical professionals in assessing and communicating risk. This paper suggests that the creation of databases recording the geotechnical performance of structures and infrastructures would offer valuable information, providing "base rates" to the professionals to support decision making during design.

Since a considerable amount of engineering judgement is integral to the activity of the geotechnical engineer it is here argued that the basic cognitive psychology principles associated with the quantification of expert opinion (Kahneman *et al.* 1982) should be taught to students enrolled in geotechnical engineering courses and offered to experienced engineers in continuous professional development training events.

Finally, the promotion of a culture of trust (Muir Wood 2004) is a fundamental ingredient for the success of civil engineering projects both in terms of commercial reward of the parties which are involved directly and in terms of benefit to society and the environment.

## 6 ACKNOWLEDGMENTS

The author is grateful to his employer for allowing this paper to be written. The content of this work is, in any case, an expression of the author's thoughts; it is not meant to represent the position of the author's employer. The author wishes to thank his colleague Dr Iain Tromans for the constructive discussion and the factual help which facilitated the preparation of this paper.

# La norme sur les missions d'ingénierie géotechnique, clé de voûte du management des risques géotechniques de tout projet

Geotechnical missions standard, the foundation of risk management for a project

Robert J.  
Arcadis France

**RÉSUMÉ :** Des ouvrages à construire de plus en plus complexes, des terrains disponibles de moins bonne qualité géotechnique, dans la Zone d'Influence Géotechnique (ZIG) une forte occupation du sol et du sous-sol par des ouvrages de plus en plus vulnérables, un voisinage plus sensible, tels sont les défis auxquels doit faire face l'ingénierie géotechnique pour satisfaire l'objectif fondamental du maître d'ouvrage qui est de réduire les risques techniques. Depuis 2000, la norme sur les missions d'ingénierie géotechnique a permis de définir une méthodologie d'intervention aussi bien pour la conception du projet que sa réalisation : ses révisions en 2006 et 2013 ont eu pour objectif de faciliter son application lors du déroulement d'un projet, condition indispensable pour assurer un bon management des risques géotechniques.

**ABSTRACT:** New constructions are more and more sophisticated, in a geotechnical context usually unfavourable and in an environment more and more sensitive. So, for the success of a project, it is necessary to reduce the geotechnical risk. As the soil conditions are not visible, complex and with a possibility of time-dependant modifications, the geotechnical risk reduction needs a geotechnical engineer intervention at each step of the design and during the construction to insure a good adaptation of the project to the actual soil conditions : it is the main aim of the geotechnical missions standard.

**MOTS-CLÉS :** norme, missions, zone d'influence géotechnique, maîtrise des risques

**KEY WORDS:** standard, geotechnical mission, risk management

## 1 INTRODUCTION

Tout projet de construction ou d'aménagement comporte des risques qui se sont amplifiés au fil des années. Ces risques, synonymes d'une maîtrise souvent difficile du délai de réalisation et du coût final de l'ouvrage, résultent de l'évolution défavorable de plusieurs facteurs : délais de conception et de réalisation de plus en plus courts, ouvrage de plus en plus complexe mettant en jeu des méthodes de construction sophistiquées qui s'adaptent mal aux incertitudes et aléas, environnement de plus en plus sensible à toute perturbation. Ce constat justifie l'intervention d'un nombre croissant de spécialistes, d'où des problèmes d'interfaces plus nombreux et une coordination plus difficile.

Devant cette complexité croissante des projets, le rôle joué par la géotechnique devient primordial car les exigences requises sur la qualité du sous-sol sont de plus en plus importantes notamment pour les fouilles profondes et les conditions de fondations. Le sous-sol étant non visible, complexe et évolutif dans le temps, la géotechnique permet de maîtriser au mieux l'inconnu en accompagnant le projet tout au long de sa conception et de sa réalisation par un enchaînement pertinent des missions conforme à la norme NF P 94-500.

## 2 SPÉCIFICITÉS DE LA GÉOTECHNIQUE

La géotechnique, discipline complexe qui étudie le comportement des terrains en relation ou non avec des ouvrages, s'appuie sur différentes sciences de la terre : géologie, hydrogéologie, mécanique des roches et des sols, géodynamique, rhéologie des géomatériaux, géochimie.

Sa première spécificité est d'étudier un milieu naturel non visible, donc mal connu : quelle que soit l'importance des investigations réalisées, la part du connu sera toujours faible par rapport au non reconnu. Ainsi, les observations et relevés faits lors de la réalisation de l'ouvrage sont capitaux car bien plus nombreux et mieux répartis que les investigations faites lors de sa conception. Sa deuxième spécificité est d'étudier un

milieu complexe. Le sous-sol est constitué de formations ni homogènes, ni isotropes, ni élastiques : elles sont nombreuses et de disposition spatiale aléatoire, une même formation pouvant présenter des lithologies très différenciées (voir Figure 1). Le resserrement du maillage des sondages permet de mieux approcher la complexité de la structure du sous-sol qui se prête mal à une modélisation toujours simplificatrice et réductrice, alors que le problème qui survient lors des travaux est souvent dû à une hétérogénéité locale non décelée à temps.

Figure 1 : Hétérogénéité à l'échelle de l'échantillon et du tunnel

Sa troisième spécificité est l'évolution possible de la constitution du sous-sol au fil du temps, évolution difficile à appréhender lors d'une étude limitée dans le temps. Les principaux facteurs d'évolution dans le temps sont :

- les perturbations apportées par l'homme : exploitation de matériaux, réalisation d'ouvrages souterrains, pollution de certaines formations, remblaiement de fouilles ultérieurement non détectables ;

- les phénomènes naturels liés à l'érosion et aux circulations d'eau, mettant en jeu la stabilité de versants (voir Figure 2) ;
- les secousses sismiques dont les effets sur certains terrains peuvent provoquer la perte de consistance ;
- la fluctuation des nappes contenues dans les formations, qu'elle soit naturelle (influence de la pluviométrie) ou artificielle (pompages industriels, création de barrages) ;
- le gonflement ou le retrait des terrains argileux ;
- la dissolution par l'eau de certaines formations (gypse, calcaire ...), créant un réseau karstique évolutif ;
- les entrainements de fines sous l'effet d'écoulements naturels ou non.

Figure 2 : Instabilité de versant due aux circulations d'eau

Face à cette complexité, le géotechnicien a pour principale arme les investigations ponctuelles, d'où le danger des interpolations entre sondages face aux anomalies locales difficilement détectables tels le puits perdu, le talweg fossile, la carrière.

### 3 SPÉCIFICITÉS DE L'OUVRAGE À CONSTRUIRE

Les principales spécificités de l'ouvrage à construire qui influent sur sa conception et l'interaction sol-structure sont :

- son emprise au sol et les charges qu'il apporte ;
- la sensibilité de sa structure vis à vis des incertitudes géotechniques (poussées, tassements différentiels par exemples) ;
- son implantation et sa profondeur dans le terrain ;
- ses phasages de construction qui imposeront des études d'interaction à chaque étape, même de courte durée.

L'optimisation des méthodes de construction nécessite l'étude de l'influence des incertitudes géotechniques, principalement en termes de délais de réalisation et de coût final de l'ouvrage : il faut choisir les méthodes les moins sensibles à ces incertitudes pour éviter des situations de crise. La méthode sophistiquée qui serait mise en échec par une variation de certains paramètres géotechniques est à proscrire si cette incertitude n'a pas pu être levée.

La méthode de construction elle-même peut avoir une influence sur les caractéristiques géotechniques du site : par exemples amélioration de sols, remontée de la nappe phréatique par effet de barrage, passage aux caractéristiques résiduelles par apparition de grandes déformations. Quelle que soit la méthode de construction retenue, les possibilités d'adaptations en cours de travaux doivent être étudiées, ainsi que leurs conditions de mise en œuvre : observations à faire, moyens de contrôle, dispositions conservatoires. La bonne maîtrise des méthodes de construction retenues suppose une vérification en continu de la bonne concordance entre prévision et réalité du comportement de l'ouvrage (auscultations), ainsi que de l'efficacité des procédés utilisés (pompages, soutènements, terrassements, améliorations de sol)

### 4 SENSIBILITÉ DE L'ENVIRONNEMENT

Pour mieux cerner les conséquences potentielles de la construction d'un ouvrage sur son environnement tant en surface qu'en sous-sol, la première étape est de définir sa zone d'influence géotechnique (ZIG). Sa ZIG correspond au volume du massif au sein duquel il y a interaction entre d'une part le sol et les avoisinants, d'autre part l'ouvrage du fait de sa réalisation et de son exploitation. Sa forme et son extension sont spécifiques à chaque site (contexte géotechnique, avoisinants) et à chaque ouvrage à construire (géométrie, phasage et méthodes d'exécution, conditions d'exploitation). Par exemple, un parking souterrain qui coupe un talweg fossile aquifère a une ZIG très étendue dans la direction du talweg (effet barrage).

La deuxième étape est l'identification de chaque avoisinant implanté dans la ZIG et l'analyse de sa vulnérabilité qui dépend des caractéristiques géotechniques des formations qu'il mobilise et de sa nature (structure, fondations). Cette analyse peut conduire à concevoir des dispositions préventives concernant l'avoisinant (reprises en sous œuvre, amélioration des sols) ou l'ouvrage à construire (adaptation locale de la méthode de construction), et éventuellement des dispositions correctives si le comportement réel du massif ou de l'avoisinant n'est pas conforme aux prévisions.

La vulnérabilité de l'environnement est de plus en plus importante au fil des années car d'une part il est de plus en plus dense et d'autre part il est constitué par des ouvrages vétustes (défauts de maintenance) ou complexes (nombreux sous-sols, grandes portées, fortes charges concentrées). Il est donc primordial de mettre en place une démarche conduisant à une maîtrise des risques géotechniques afin de limiter leurs conséquences potentielles sur l'environnement.

### 5 CARACTÉRISTIQUES PRINCIPALES DE LA NORME VERSION 2013

Face aux risques évoqués précédemment, la meilleure réponse est l'application rigoureuse de la norme NF P 94-500 sur la classification des missions types d'ingénierie géotechnique. Le reconnu en géotechnique est toujours modeste et les risques géotechniques dépendent non seulement des caractéristiques des terrains mais également de celles de l'ouvrage, de sa méthode de construction et de son environnement. Le projet sans risque n'existant pas, la maîtrise des risques géotechniques s'obtient par un enchaînement des missions d'ingénierie géotechnique tout au long des étapes de conception et de réalisation du projet, en coordination avec les missions de maîtrise d'œuvre générale.

Le retour d'expérience sur l'application de cette norme depuis 2000 permet de dégager quelques dysfonctionnements :

- Le non enchaînement des missions alors qu'il est obligatoire ;
- La réalisation d'une mission partielle sans que son complément soit fait ultérieurement ;
- Le contenu de la mission non adapté à l'état d'avancement du projet, parfois dû à une correspondance non évidente entre missions d'ingénierie géotechnique et phases de conception de la maîtrise d'œuvre générale.

L'objectif de la révision 2013 de la norme a été de faciliter son application en réduisant le nombre de missions pour faciliter leur enchaînement et en les calant au plus près des phases de maîtrise d'œuvre générale. Côté maître d'ouvrage et sa maîtrise d'œuvre, il y a trois missions à enchaîner de préférence par la même ingénierie géotechnique pour une plus forte valeur ajoutée dans la recherche des optimisations du projet tout en assurant une bonne maîtrise des risques.

L'étude géotechnique préalable G1, qui comprend deux phases :

- La phase étude de site ES, qui définit un modèle géologique préliminaire du site et ses principales caractéristiques géotechniques à partir de données pertinentes (investigations à réaliser si besoin), et établit une première identification des risques géotechniques majeurs du site (risques pouvant mettre en cause la faisabilité d'un projet non encore figé) ;
- La phase Principes Généraux de Construction PGC, qui contribue à la mise au point de l'étude préliminaire (ou APS) de l'ouvrage. Elle définit les données géotechniques à prendre en compte à ce stade (investigations à réaliser si besoin) et propose certains principes généraux de construction envisageables. Elle permet d'une part de compléter le modèle géologique et le contexte géotechnique, d'autre part de mieux identifier et hiérarchiser, en fonction de l'ouvrage projeté, les risques géotechniques majeurs afin d'en réduire les conséquences en cas de survenance ;

L'étude géotechnique de conception G2, qui comprend trois phases :

- La phase avant-projet AVP, qui contribue à la mise au point de l'AVP (ou avant-projet Détaillé APD) de l'ouvrage. Elle permet d'une part de compléter le modèle géologique et le contexte géotechnique (investigations en fonction du site et de la complexité de l'ouvrage projeté), d'autre part de mieux identifier les risques géotechniques importants et d'en réduire les conséquences en cas de survenance (risques pouvant nécessiter des mesures appropriées en phase conception et/ou un suivi spécifique en phase réalisation par mise en œuvre de mesures prédéfinies si besoin). Elle définit les hypothèses géotechniques à prendre en compte au stade AVP et les principes de construction des ouvrages géotechniques (terrassements, soutènements, pentes et talus, fondations, assises des dallages et des voiries, améliorations de sols, dispositions générales vis-à-vis des nappes et des avoisinants). Elle fournit une ébauche dimensionnelle par type d'ouvrage géotechnique, une première approche des quantités et conclut sur la pertinence d'application de la méthode observationnelle pour une meilleure gestion des risques résiduels.
- La phase projet PRO, qui contribue à la mise au point du projet de l'ouvrage. Elle définit les hypothèses géotechniques à prendre en compte au stade du projet, en particulier les valeurs caractéristiques des paramètres géotechniques (investigations en fonction de la complexité de l'ouvrage). Elle établit les notes techniques donnant les choix constructifs des ouvrages géotechniques (terrassements, soutènements, pentes et talus, fondations, assises des dallages et des voiries, améliorations de sols, dispositions vis-à-vis des nappes et des avoisinants), certaines notes de calcul de dimensionnement niveau projet, une approche des quantités et les valeurs seuils si l'application de la méthode observationnelle est conseillée. Si nécessaire, elle donne les principes de maintenance des ouvrages géotechniques.
- La phase DCE/ACT, qui contribue d'une part à l'établissement du Dossier de Consultation des Entreprises de l'ouvrage, d'autre part à l'Assistance pour l'établissement des Contrats de Travaux avec le ou les entrepreneurs retenus pour réaliser les ouvrages géotechniques. Elle participe à la rédaction des documents techniques nécessaires aux entreprises pour leurs études de réalisation des ouvrages géotechniques (dossier de la phase PRO avec plans, notices techniques, cahier des charges techniques particulières, cadre de bordereau des prix et d'estimatif, planning prévisionnel). Elle assiste le maître d'ouvrage ou la maîtrise d'œuvre pour la sélection des entreprises, analyse les offres techniques (projet de base et variantes éventuelles) et

participe à la finalisation des pièces techniques définitives des contrats de travaux concernés par les ouvrages géotechniques.

La supervision géotechnique d'exécution G4, réalisée en collaboration avec la maîtrise d'œuvre ou intégrée à cette dernière, qui comprend deux phases lors de la réalisation de l'ouvrage :

- La phase Supervision de l'étude géotechnique d'exécution, qui émet un avis pour le visa donné par la maîtrise d'œuvre. Elle donne un avis sur la pertinence des hypothèses géotechniques de l'étude géotechnique d'exécution, des dimensionnements et des méthodes d'exécution, des adaptations ou des optimisations des ouvrages géotechniques proposées par l'entrepreneur, du programme d'auscultation et des valeurs seuils en cas d'application de la méthode observationnelle.
- La phase Supervision du suivi géotechnique d'exécution. Par interventions ponctuelles sur le chantier, elle donne un avis sur la pertinence du contexte géotechnique et du comportement tels qu'observés par l'entrepreneur de l'ouvrage et des avoisinants concernés ainsi que de l'adaptation ou de l'optimisation éventuelle de l'ouvrage géotechnique proposée par l'entrepreneur. Elle permet de donner un avis sur le dossier des ouvrages exécutés (DOE) et sur le dossier d'interventions ultérieures sur l'ouvrage (DIUO) établis par l'entrepreneur.

Côté entrepreneur en charge de la réalisation d'un ouvrage géotechnique, la mission d'étude et suivi géotechniques d'exécution G3 est à réaliser par une ingénierie géotechnique (éventuellement intégrée à l'entreprise) : elle comprend deux phases interactives et indissociables :

- La phase Etude, qui contribue à l'étude d'exécution de l'ouvrage pour la part des ouvrages géotechniques. Elle établit la note d'hypothèses géotechniques sur la base des données fournies par la G2 phase Projet et des résultats d'investigations complémentaires si besoin. Elle donne le dimensionnement des ouvrages géotechniques, leur méthode et conditions d'exécution, leurs phasages généraux. Elle définit les suivis, les auscultations et les contrôles à prévoir, les valeurs seuils en cas d'application de la méthode observationnelle. Elle définit les moyens à mettre en œuvre pour sécuriser l'ouvrage et les avoisinants concernés ainsi que les adaptations du projet vis-à-vis des risques géotechniques identifiés en cas de survenance en cours de réalisation. Elle participe à l'établissement du dossier géotechnique d'exécution des ouvrages géotechniques provisoires et définitifs avec plans d'exécution, de phasage et de suivi.
- La phase Suivi, qui contribue fortement à la maîtrise des risques géotechniques résiduels pendant la réalisation des ouvrages géotechniques. Par un suivi en continu des travaux géotechniques (relevés) et des auscultations, elle permet d'une part de valider ou de mettre à jour le modèle géologique et les hypothèses géotechniques du site, d'autre part de s'assurer que le comportement en cours d'exécution de l'ouvrage et des avoisinants est conforme aux prévisions ou de mettre en œuvre à temps les adaptations nécessaires (mesures correctives prédéfinies) ou les optimisations possibles en cas d'application de la méthode observationnelle. Dans le cas de survenance d'un risque non identifié, elle permet de prendre les mesures sécuritaires qui s'imposent et d'alerter la maîtrise d'œuvre pour lancer en urgence un diagnostic géotechnique avec si besoin des investigations géotechniques pertinentes, et adapter en conséquence l'étude géotechnique d'exécution. Elle participe à l'établissement par l'entrepreneur du DOE et du DIUO.

## 6 MANAGEMENT DES RISQUES GEOTECHNIQUES

Dans le cadre de l'enchaînement des missions types d'ingénierie géotechnique, des risques géotechniques sont identifiés en fonction des données collectées et des spécificités de l'ouvrage géotechnique projeté, puis font l'objet d'une évaluation pour hiérarchisation et d'un traitement. Les risques géotechniques sont liés à une connaissance partielle des caractéristiques géotechniques du site susceptibles d'avoir des conséquences sur le comportement des ouvrages. Ils dépendent donc des incertitudes résiduelles (degré de connaissance limité malgré des investigations réalisées par étapes successives pendant les différentes phases de conception et un suivi géotechnique en phase de travaux), de la variabilité naturelle des paramètres et des accidents géologiques.

Les risques géotechniques identifiés sont classés selon une échelle de gravité pour apprécier leur impact sur le projet : les risques majeurs peuvent remettre en cause le projet, les risques importants peuvent nécessiter des mesures appropriées en phase conception et/ou un suivi spécifique en phase réalisation pour décider si nécessaire de la mise en œuvre d'adaptations ou de mesures prédéfinies, les risques mineurs peuvent justifier une optimisation en phase conception ou un suivi spécifique en phase réalisation pour aboutir à un faible impact en termes de qualité, sécurité, coût et délai.

Face à chaque risque identifié, il convient de définir les actions préventives possibles pour le réduire (réduction des incertitudes ou de l'impact potentiel de ces incertitudes), les dispositions à mettre en œuvre pour détecter sa survenance le plus tôt possible (programme de suivi et de contrôle avec valeurs seuils associées) et les actions correctives pour en minimiser l'impact s'il se réalise (adaptation du projet).

Le traitement des risques est adapté à chaque phase de déroulement du projet. Le canevas de traitement habituel est le suivant :

- le risque majeur identifié est réduit ou annulé par des recommandations appropriées pour le futur ouvrage dès la G1 ;
- le risque important identifié est réduit ou annulé par des mesures appropriées au stade de la G2 : adaptation du projet, suivi spécifique avec des mesures prédéfinies et des valeurs seuils associées, adaptations possibles en phase de réalisation ;
- le risque mineur identifié a un faible impact et peut justifier une solution d'optimisation au stade de la réalisation.

La gestion des risques (et donc de leur coût potentiel) est axée sur leur détection le plus tôt possible et sur le contrôle de l'efficacité des solutions correctives prédéfinies. Elle s'appuie sur les actions suivantes :

Au stade de la conception de l'ouvrage :

- évaluation des incertitudes et de la variabilité des paramètres influents, avec réalisation d'investigations géotechniques pour les réduire ;
- reconnaissance des avoisinants concernés (ZIG) ;
- définition des éventuelles dispositions constructives complémentaires à mettre en œuvre si le contexte géotechnique ou le comportement de l'ouvrage observé n'est pas conforme aux prévisions ;
- définition des adaptations possibles avec recherche d'opportunités ;
- prise en compte des risques inhérents par leur budgétisation et leur incidence sur les délais ;
- prise en compte de la maintenance inhérente à certains types d'ouvrages géotechniques (drains, tirants...).

Pendant la réalisation de l'ouvrage : suivi et contrôle géotechnique en continu (valeurs seuils associées).

Pendant l'exploitation de l'ouvrage : mise en œuvre de la maintenance inhérente à certains types d'ouvrages géotechniques.

## 7 CONCLUSION

L'application de la norme NF P 94-500 sur les missions types d'ingénierie géotechnique à réaliser dans le cadre de la conception puis de la réalisation d'un ouvrage est la clé de voûte du management des risques géotechniques. Le retour d'expérience montre que tout investissement fait par le maître d'ouvrage en phase conception pour la maîtrise des risques liés au site et aux sols est hautement rentable, l'approche quantitative faite pour les ouvrages souterrains en est une illustration (voir Figure 3). Comme disait Francis BACON, philosophe de la fin du 16<sup>ème</sup> siècle : « On ne commande à la nature qu'en lui obéissant ».

Les assureurs, qui mettent en place les polices d'assurance des intervenants pour couvrir les risques résiduels, sont les garants de l'application effective de cette norme qui consacre le rôle majeur joué par l'ingénierie géotechnique dans le management des risques. L'application de cette norme est une condition nécessaire pour répondre aux attentes du maître d'ouvrage qui recherche un ouvrage de qualité sans dépassement de délai et de coût.

# Embedding Geo Risk Management. The Geo-Impuls Approach

## L'implantation du management des risques géotechniques. L'approche Geo-Impuls

Staveren van M.Th.  
VSRM

Litjens P.P.T., Cools P.M.C.B.M.  
*Rijkswaterstaat Dienst Infrastructuur*

**ABSTRACT:** Geo-Impuls is a Dutch and industry wide geotechnical development programme. It aims to strengthen the geotechnical community by substantially reducing geotechnical failures in all types of construction projects. Over 40 Dutch organizations, including client organizations, contractors, engineering firms and knowledge institutes, work closely together in this programme that runs from 2009 up to 2015. All Geo-Impuls participants embraced geotechnical risk management (GeoRM) as leading working method to realize projects within budget and planning, as well as according to actual safety and quality standards. However, routinely applying GeoRM in projects requires embedding GeoRM in its organizations. This paper aims to present how the Dutch geotechnical community is currently embedding geotechnical risk management in its organizations. First, the Geo-Impuls program is introduced. The remaining part of this paper summarizes the four pillars of the Geo-Impuls program: (1) the process of geo risk management, (2) geo risk management principles, (3) geo risk management tools, and (4) geo risk management implementation. Finally, the main conclusions are drawn.

**RÉSUMÉ :** Geo-Impuls est un programme hollandais de développement géotechnique au niveau de l'ensemble de la profession. Son objectif est de renforcer la communauté géotechnique en réduisant les accidents géotechniques dans tous types les projets. Ce programme mis en œuvre de 2009 à 2015 regroupe plus de 40 organisations hollandaises (clients, entreprises, bureaux d'ingénieurs conseils et instituts d'enseignement et de recherche). Tous les participants au projet Geo-Impuls ont adopté le management des risques géotechniques (GeoRM) comme méthode principale pour réaliser des projets conformes aux budget et planning, et respectant les normes de sécurité et de qualité en vigueur. cependant, l'application routinière du GeoRM dans les projets exige son implantation dans les organisations. L'article vise à présenter de quel façon la communauté géotechnique hollandaise est en train d'implanter ce management des risques géotechniques. Tout d'abord, on présente le programme Geo-Impuls. Ensuite l'article fait une synthèse des quatre piliers du programme Geo-Impuls: (1) la processus de management des risques géotechniques, (2) les principes du management des risques géotechniques, (3) les outils du management des risques géotechniques, (4) l'implantation du management des risques géotechniques. Enfin, les conclusions les plus importantes sont tirées.

**KEYWORDS:** geotechnical risk, geotechnical risk management, project risk management, risk management implementation, tool box

### 1 INTRODUCTION

Building in, on, or with ground is risky. According to several assessments, on average geotechnical problems during engineering, construction, and operation of civil engineering projects result in cost increases of 5% of the original budgets. In the Netherlands only, this adds up to hundreds of millions of Euros, annually. So action within the geotechnical community is needed, which resulted in a major geotechnical development program in The Netherlands: Geo-Impuls.

First, the GeoImpuls program will be described, including three top geotechnical risks that drive the program, six dilemma's related to these top risks and three resulting research and development themes for providing effective and cost efficient risk remediation.

Next, the concept of geotechnical risk management or GeoRM will be presented, including an explanation what GeoRM is about and why GeoRM should be embraced by all geotechnical professionals.

An important element of GeoRM is provided by eight so-called Geo-Principles. These principles are derived from the generic risk management principles of the ISO 31000 risk management guideline (ISO 2009). By adopting these principles, Geo-Impuls decided to apply a modern principle-based risk management approach, rather than a more traditional rule-based one. The main advantage of a principle-based

approach is that any type of organization, in any type of construction project, is able to design its own tailor-made risk management activities and processes. This avoids a well known "one size fits nobody" situation. The Geo-Principles are introduced in the paper by a checklist, which is ready to be used in practice by any reader.

In addition to the principles, risk management tools are welcome and useful. Therefore, a Geo-Impuls risk management toolbox is in development. Together with already available techniques, this toolbox will be filled with the results of 12 working groups. It contains sub boxes for contractual matters, for geotechnical design and construction, as well as for dealing with the many project stakeholders and its environment. The latter is particular important for the growing number of complex underground projects in densely populated and sensitive build environments.

While having the risk management processes, principles, and tools, a fourth element proves to be of paramount importance: the organizations that have to deal with geotechnics. These are either client organizations, contractors, or engineers. Adapting geotechnical risk management activities to existing working procedures and process in these organizations is a key success factor for continuous GeoRM application. Rijkswaterstaat, executive agency of the Ministry of Infrastructure and the Environment and the largest Dutch

public client organization for construction projects, provides a pioneering role in embedding GeoRM in its entire organization. Their recent experiences with the GeoRM implementation will be shared.

Finally, the paper will draw some conclusions about the main experiences within the Geo-Impuls development programme with embedding geotechnical risk management in organizations. Any reader is invited to reflect on these experiences, and to use them for the benefits of his or her own geotechnical challenges.

## 2 GEO-IMPULS PROGRAM

Geo-Impuls is a Dutch and industry wide geotechnical development programme (Cools 2011). It aims to strengthen the geotechnical community, by substantially reducing geotechnical failures in all types of construction projects. Over 40 Dutch organizations, including client organizations, contractors, engineering firms and knowledge institutes, work closely together in this programme that runs from 2009 up to 2015. The two key objectives of the Geo-Impuls program are (1) a completed GeoRM toolbox, including guidelines and best-practices, and (2) a number of 100 projects that demonstrate GeoRM adoption by 2015. This requires embedding GeoRM principles and practices in organizations. Therefore, the implementation of GeoRM in (project) organizations is a key issue in the Geo-Impuls program.

During several sessions with program participants a number of infrastructural projects were analyzed regarding their geotechnical risks. The overall conclusion is that three top risks can be identified, which are related to Contracts, Geo-Engineering and Project Communication:

1. Top risk of Contracts: unforeseen soil conditions
2. Top risk of Geo-engineering: failure due to settlements or collapse
3. Top risk of Project communication: loss of public support

Managing these top risks involves dealing with several dilemmas, which are related to each specific top risk:

Ad 1 Contracts:

- A small or extensive scope of ground investigations during tendering?
- Do or don't apply contractual geotechnical risk allocation?

Ad 2 Geo-engineering:

- A robust design or flexibility during construction?
- Do or don't apply on site quality measurements?

Ad 3 Project communication:

- Do or don't inform the public on risks?
- Do or don't inform the public on nuisance?

So, there are three central development themes: Contracts for dealing with legal issues, Geo-engineering for dealing with technical issues, and Project communication for paying attention to the human factor. For each theme, the by the Dutch geotechnical community perceived most important topics are worked out in Working Groups.

Theme 1: Contracts

- Geotechnical risk allocation in projects by the geotechnical baseline approach
- Risk-based soil investigation planning, including tendering issues
- Process specifications for geo-engineering in contracts and contract management
- Geotechnical risk checklists for non-geotechnical decision makers

Theme 2: Geo-engineering

- Quality control for timely tracing imperfections of cast-in-place concrete elements

- Observational Method by using risk-based scenarios in combination with monitoring
- Reliable geotechnical modelling by revealing and presenting geological and geotechnical uncertainties and using sensitivity analysis
- Long-term geotechnical monitoring for better understanding of time-dependent geotechnical behaviour, by comparing monitoring results with predictive models

Theme 3: Project communication

- Communication of geotechnical risk to communities in project environments
- Closing the gap of misunderstanding between design and construction professionals
- International knowledge exchange on reduction of geotechnical failures and geotechnical risk management
- Geotechnical risk management education and training for students and professionals

Since 2009, an industry-wide Steering Committee takes responsibility for the Geo-Impuls programme. The day-to-day execution of the programme has been assigned to the Core Team comprising the leaders of the Working Groups. The Geo-Impuls Programme Office coordinates all administrative aspects and a program advisor focuses specifically on GeoRM and its implementation in (project) organizations.

## 3 GEO RISK MANAGEMENT

All Geo-Impuls participants embraced Geotechnical Risk Management (GeoRM) as the leading working method to realize projects within budget and planning, as well as according to pre-set safety and quality standards. Before explaining GeoRM, it helps to define the term geotechnical risk. According to ISO31000 (2009), a risk is the effect of uncertainty on realizing objectives.

Similarly, a geotechnical risk can be defined as the effect of geotechnical uncertainty on realizing objectives, such as settlements or horizontal deformations within pre-set limits. Geotechnical uncertainty may result from randomness, fuzziness, incompleteness or simply incorrect geotechnical information (Van Staveren 2006). A geotechnical risk has a probability of occurrence, one or more causes, and usually a number of effects when happening, such as damage, cost overruns and delay.

Geotechnical risk management or GeoRM is an explicit, structured, communicated, and continuous way of dealing with geotechnical risk, in order to achieve project objectives effectively and cost-efficiently. The process of geotechnical risk management is similar to the process of project risk management and involves the same sequence of steps.

Therefore, GeoRM fits well in any sort of project risk management. The difference is that GeoRM is a more detailed and in-depth approach of project risk management, for giving geotechnical risk the attention it requires in all phases of engineering and construction projects. Figure 1 presents the six GeoRM steps.

Figure 1. The GeoRM process in six steps.

While these six GeoRM steps are quite straightforward, it helps to take them according to so-called GeoRM principles. These are presented in the next section.

#### 4 GEO RISK MANAGEMENT PRINCIPLES

Basically, there are two main routes of doing risk management: rule-based and principle-based. The rule-based approach is using rules and results into one best way for managing risk. This is not appropriate for GeoRM, because of the large diversity of engineering and construction projects in complexity, size, location, and ground conditions.

For these reasons the Geo-Impuls takes the principle-based route for allowing fit-for-purpose geotechnical risk management. Based on the eleven generic risk management principles from ISO31000 (2009), eight specific geotechnical or GeoRM principles have been defined by a number of Geo-Impuls participants.

By definition, principles are abstract and need a translation into activities. Such a translation can be done for specific projects and even for specific project phases, again in a fit-for-purpose way. By this approach GeoRM is a mean for realizing project objectives and not an end in itself. Table 1 presents the eight GeoRM interrelated principles and a number of examples of related actions in the format of a simple checklist.

Table 1. GeoRM principles in a checklist format.

GeoRM Principles	GeoRM Actions	Done	
		Yes	No
1. Generate and protect value	Make all geotechnical risks in each project explicit, including all risk effects and the selected risk remediation measures.		
2. Participate in decision making in all project phases	Make a geotechnical risk file from the start if the project and use it for decision making.		
3. Make geotechnical uncertainty explicit	Include geotechnical sensitivity analyses with margins in project reports Use the geotechnical risk file for managing the consequences of any geotechnical changes during the project		
4. Work systematically, structured and in time	Include GeoRM explicitly in the project planning and reserve resources for it.		
5. Use all available information	Use all available historical and other relevant project information, right from the start of the project  Work from a general level to a detailed level, from		

		using geological maps to geotechnical monitoring
6. Work transparently together with all stakeholders	Asses the influence of the ground conditions on the critical success factors of the project stakeholders	Communicate clear about geotechnical risk with all parties involved
		Indicate and communicate any dependencies of geotechnics with other disciplines in the project
7. Include the role of the human factor	Make any differences in organizational culture of all involved project parties visible and feasible	
8. Use experiences and lessons for continuous improvement	Use all available and relevant project evaluations	Organize that geotechnical professionals participate in GeoRM courses and communities of practice

Table 1 can be used as a checklist, by simply tick boxing whether the principle-driven GeoRM actions have been executed in a project or not.

In summary, the main advantage of a principle-based approach is that any type of organization, in any type of construction project, is able to design its own tailor-made risk management activities and processes. This avoids a well known “one size fits nobody” situation.

#### 5 GEO RISK MANAGEMENT TOOLS

In addition to the GeoRM process and the GeoRM principles, a set of GeoRM tools is of great help for facilitating geotechnical risk management. Therefore, the Geo-Impuls program aims to provide a toolbox with tools for the three themes of contracts, geo-engineering and project communication. As a result of the Geo-Impuls program, the following tools examples become ready:

##### Theme 1: Contracts:

- Geotechnical Risk Allocation Reports, comparable to the concept of Geotechnical Baseline Report (GBR) from the United States. Recent project evaluations demonstrated that this concept is also beneficial to Dutch projects.
- Guideline for defining Risk-based Site Investigation programmes that provides explicit information and data for quantification of geotechnical risk
- Ground Risk Identification Checklists

##### Theme 2: Geo-Engineering

- Guideline with best practices for monitoring based design & construction by the Observational Method
- Long Term Subsoil Monitoring results for validation of existing numerical ground deformation models
- Techniques for checking the integrity of diaphragm-walls and in-situ made piled foundations. By using these techniques, weak spots can be detected and repaired before excavation

##### Theme 3: Project communication

- Communication strategies for managing expectations of the project stakeholders
- Intervention models for risk-based subsoil communication with in particular the public living and

working around projects in cities, by using tailor-made workshops

- Intervention models for effective communication from geotechnical designers to construction crews.

Together with already available techniques, these tools are part of the GeoRM toolbox. A study of 40 recent geotechnical failures shows that 90 % of these failures was caused by the fact that right knowledge and tools are available in the Dutch geotechnical community, but not used by the right engineer in the right way and at the right time (van Tol 2007).

## 6 GEO RISK MANAGEMENT IMPLEMENTATION

Routinely applying GeoRM in projects requires embedding GeoRM in its organizations. This implementation of risk management in general, and of GeoRM in particular, is not a spontaneous process (Van Staveren 2009). Organizational conditions, like the organizational structure and the organizational culture should facilitate, rather than frustrate, the routine application of GeoRM.

For this reason specific working sessions have been organized with the Geo-Impuls, for clients, contractors, and engineers. During these working sessions it has been made explicit to which degree four key conditions for GeoRM were available in the participating organizations. These key conditions are (1) shared GeoRM understanding, (2) GeoRM is formally embedded in existing procedures, (3) interdisciplinary application of GeoRM within the organizations, and (4) GeoRM cooperation with external parties and stakeholders. During the sessions it became clear that for most organizations considerable steps for optimizing these GeoRM conditions can be made. Therefore, each participant defined at least one specific GeoRM embedment action to be executed in his or her organization. This exercise provided in total 44 concrete actions for embedding GeoRM in client, contractor, and engineering organizations of the Dutch construction industry.

Regarding the development of a shared GeoRM understanding, examples of actions are including GeoRM in internal project management courses and explicitly discussing the main geotechnical risk in regular project meetings.

Examples of formally embedding GeoRM is providing a clear internal procedure GeoRM procedure and applying GeoRM products in projects.

Concerning the interdisciplinary application of GeoRM, it was for instance decided to involve a geotechnical engineer in tender-kick off and subsequent meetings and to integrate risk-based geotechnical engineering during tenders with design, quality, contracts and safety. With regard to the GeoRM cooperation with external parties, demonstrating to project stakeholders how to deal explicitly with geotechnical risk and embedding geotechnical risk in contracts were some of the actions. All of these actions are straightforward, concrete and relatively easy to execute in the going concern of projects. These activities demonstrate that implementing GeoRM in organizations is merely a matter of a lot of relatively small steps towards an explicit way of risk-based geotechnical engineering, than one major change management jump.

Rijkswaterstaat, the executive agency of the Ministry of Infrastructure and the Environment and the largest Dutch public client organization for construction projects, provides a pioneering role in embedding GeoRM in its entire organization. They work parallel on developing all of the four key conditions for implementing GeoRM in their organization. Developing a shared GeoRM understanding is ongoing by regular meetings of the geotechnical experts, where they exchange experiences and lessons how to apply their geotechnical activities in a risk-based way by taking the GeoRM process steps. Furthermore, a formal GeoRM procedure that fits in their project process is in

development. This GeoRM procedure is communicated to the project managers, contract managers and environment managers, in order to become accepted and used in an interdisciplinary way. Finally, Rijkswaterstaat is going to subscribe the application of GeoRM to the engineering consultancies and contractors, which involves the application of GeoRM together with external parties.

## 7 CONCLUSIONS

Due to the inherently uncertain nature of the subsoil, building in, on, or with ground remains risky. Nevertheless, modern risk management approaches are readily available for more explicitly and well-structured dealing with inherent ground uncertainty. Therefore, the Dutch industry wide geotechnical development programme Geo-Impuls has been started. It aims to substantially reduce geotechnical failures in all types of construction projects. Geotechnical risk management or GeoRM has been adopted as the main approach to achieve this objective by the forty organizations participating in Geo-Impuls.

The Geo-Impuls program is founded on four pillars: (1) the geo risk management process, (2) georisk management principles, (3) geo risk management tools, and (4) geo risk management implementation.

The process of geotechnical risk management is similar to the process of project risk management. Because it involves the same sequence of the similar risk management steps, GeoRM fits excellently in any sort of project risk management. By being geotechnically driven, GeoRM is simply a more detailed and in-depth approach of project risk management.

Geo-Impuls takes the principle-based route for allowing fit-for-purpose geotechnical risk management, which is worked out in eight specific GeoRM principles. These are based on generic ISO31000 risk management principles and translated into straightforward actions for geotechnical risk remediation. In addition to developing GeoRM tools, GeoImpuls dedicates considerable attention to routinely applying these tools by implementing the GeoRM processes and principles in organizations. These organizations are clients, contractors and engineering firms. This requires embedding GeoRM in the existing processes of organizations. Implementing GeoRM in (project) organizations is therefore considered the key success factor for effectively and cost-efficiently managing geotechnical risk. In final conclusion, applying GeoRM gives geotechnical risk the attention it requires, in all phases of engineering and construction projects, in order to realize project success.

## 8 ACKNOWLEDGEMENTS

The authors would like to thank all participants of the Geo-Impuls development program for sharing their knowledge and experience in the program, on which this paper is founded.

# General Report for TC206 Interactive Design

## Rapport général du TC206 Le dimensionnement géotechnique interactif

Ho A.  
*Ove Arup & Partners Hong Kong Ltd*

**ABSTRACT:** This General Report is to summarise the all papers submitted for TC206 – Interactive Design. A total of 15 papers were received and 6 papers were recommended for oral presentation and the rest for recommended for panel presentation at the 18<sup>th</sup> ICSMGE Paris, 2-6 September 2013. The submitted papers gave a general picture of the interactive design works around the Globe ranging from experimental and theoretical works from SWOT analysis to geoenvironmental application and potential risk detection for Slope failure to case report on some successful practical works from excavation of diaphragm wall to fibre optic instrumentation in reusing deep foundations. The papers are of good quality and will generate opportunities for the academia and practitioners to discuss and question on various different techniques and approaches to implement interactive design to their works.

**RÉSUMÉ :** Ce rapport général présente une synthèse des communications correspondant au TC206 – Dimensionnement géotechnique interactif. Un total de 15 articles ont été reçus, 6 ont été recommandés pour une présentation orale et les autres seront présentés lors de la conférence correspondant à ce rapport général au 18<sup>ème</sup> CIMSG Paris, 2-6 septembre 2013. Les communications donnent une description générale des travaux en dimensionnement interactif de par le monde, depuis les travaux expérimentaux et théoriques jusqu'aux analyses SWOT, aux applications géoenvironnementales et à la détection des risques potentiels dans la réutilisation des fondations profondes. La bonne qualité des communications créera des opportunités pour les universitaires et les praticiens de discuter et échanger sur les différentes techniques et approches permettant de mettre en œuvre le dimensionnement interactif dans leurs réalisations.

**KEYWORDS:** Observational method, SWOT analysis, monitoring, risk of slope failure, small-strain, fibre-optic sensing technology.

### 1 INTRODUCTION

A total of 15 papers were received by the TC 206 – Interactive design and 6 papers were selected for oral presentation and the other for panel presentation at the 18<sup>th</sup> ICSMGE, Paris, 2-6 September 2013. The submitted papers gave a general picture of the interactive design works around the Globe ranging from experimental and theoretical works from SWOT analysis to geoenvironmental application and potential risk detection for Slope failure to case report on some successful practical works from excavation of diaphragm wall to fibre optic instrumentation in reusing deep foundations.

The following section will highlight some keys in the various papers submitted.

#### 1.1 *Papers recommended for oral presentation*

Paper 1907 “Comparison of monitoring techniques for measuring deformations in an excavation” by DeVos, Van Alboon, Haelterman from Belgium. An online monitoring test set-up was realized in a railway-infrastructure project site in Anderlecht (Belgium). Both advanced and traditional monitoring equipment were installed to measure the deformation of a soil nailed jet grout wall, deformations behind the jet grout wall (on the railway tracks) and forces in the soil nails. The paper presents the results of the measurements in and behind the jet grout wall and on the comparison between the different techniques: FBGS; SAAF (in place inclinometer); Optical strands OSMOS; Traditional inclinometer; Draw Tower Grating; and BOTDR. It concluded that both new and traditional techniques can lead to the same result, when sufficient care is taken in the installation and interpretation. A significant advantage can be seen when continuous monitoring is applied, as the link with execution phases can be made.

The paper is clearly set out and well written and presents a real site monitoring case and compares predicted with actual deformation and bending moment results.

Paper 2397 “SWOT analysis Observational Method applications” by Korf, de Jong and Bles from Holland. A well set out account of Strengths, Weaknesses, Opportunities and Strengths of Observational Method and draws on a wide range of published work. This research is performed as part of “Geoimpuls” in the Netherlands; a joint industry programme, with the ambitious goal to half the occurrence of geotechnical failure in Dutch civil engineering projects by 2015. The Conclusion are given in the form of “Go”, “No Go” listed in terms of importance and “To be Overcome” items.

Paper 2029 “Experimental analyses on detection of potential risk of slope failure by monitoring of shear strain in the shallow section” by Tamate & Hori from Japan. The paper consider monitoring locations at shallow depth of slope and introduces a mean to monitor the failure of shallow portion of slope which is particularly important during temporary cut. It may attract discussions in how to bring this into practice so as to enhance safety control measures to safeguard the workers during actual construction stage. It would be good to have a paragraph summarizing their findings from the experiment and / or any further study that may be worthwhile, e.g. any suggested alert, alarm and action shear strain to quantify the potential risk level.

Paper 3059 “The role of fibre optic instrumentation in the re-use of deep foundations” by Bell, Soga, Ouyang, Yan and Wang from UK & China. This paper provided details of a recent project in London to further develop the understanding of foundation reuse by installing fibre optic sensors in both existing piles and a borehole to observe the impact of the demolition process on the changes in piles behavior and ground response. It explained how optical fibre instrumentation was used to monitor pile and ground response under demolition and presented the data captured by the fibre optic instrumentation during the demolition process. It also showed how the use of such instrumentation was fundamental to the successful reuse of the existing piles on this project. It would be good to include the limitations of fibre optic instrumentation; such as can it quantify the vertical extent of section changes or the lateral position of defects; the presence of vertical cracks. And percentage of

existing pile to be instrumented to assess the integrity of existing piles for reuse can also be discussed.

Paper 2971 "New Sensing Technology and New Applications in Geotechnical Engineering" by Wang, Ooi & Gao from Hong Kong. The paper described that soils are inherently a particulate medium, and relevant physical principles behind the macro-scale engineering properties originate from particle interactions. However, it is difficult in general to conduct measurements which can monitor soil particle movement and even characterize micromechanics behind different soil behaviour. The paper presented two examples of advancement of sensing technologies. The first is on using the tactile pressure sensor (film-like sensor) to monitor the evolution of contact normal forces among particles in aged sand. The measurement reveals that the contact forces are continuously redistributed during aging. This ultimately strengthens the soil structure and therefore increases the associated small-strain shear modulus. The second is on using the miniature 3D Micro-Electro-Mechanical-Systems (MEMS) accelerometer to characterize the soil movement in a laboratory flow landslide. The MEMS sensors demonstrate promising results in describing the rich features of local responses of soil movement in the shear zone, e.g. liquefaction, deceleration, contraction and dilation. Some comments on the paper: Are the sensors insensitive to any other property likely to be encountered in its application and to what extent the sensors influence the measured property? Are the sensors designed to be linear or linear to some simple mathematical function of the measurement, typically logarithmic? What is the dynamic error of MEMS accelerometer? A very relevant paper on application of the small-strain theory on flow slides.

Paper 1965 "Monitoring earthwork foundations by fibre optic sensors" by Artières from France. The paper presented that strain in earthworks is now easier to measure by using fibre optic sensing technologies combined with geotextile properties, such as very good soil friction interface enhancing the transfer of soil displacement to the sensors. More accurate measurements can be obtained due to their smaller and less intrusive size than those of the usual electro-mechanical strain gages. They have high sensing sensitiveness below 0.01% on strain measurement, but also temperature measurement with 0.1°C accuracy, that is combined with a high spatial resolution in the range of 1 m or less and a good durability of the sensors into soil. And they can be used to monitor either local earthworks such as walls and slopes or long infrastructures of several tenths of kilometers such as roads, railways and dikes, all with the same accuracy. Several tenths of earthworks are now monitored globally with this solution for more than 8 years demonstrating its durability. The detection of cavities in the foundation of a large polluted water storage basin was also described. Some comments on the paper: Are the sensors insensitive to any other property likely to be encountered in its application and to what extent the sensors influence the measured property? And are the sensors designed to be linear or linear to some simple mathematical function of the measurement, typically logarithmic? The paper was selected for oral presentation on its relevancy in the application of sensor technology in practical works.

## 1.2 Papers recommended for panel presentation

Paper 2253 "Development of Method for Evaluating and Visualizing 3-dimensional Deformation of Earth Retaining Wall for Excavation" by Matsumaru and Kojima from Japan. The paper described a System to evaluate and visualize retaining wall as three-dimensional curved surface. The validity was confirmed by the simulation of the loading test on the model wall and actual monitoring from the on-site measurement. It proposed to conduct monitoring of retaining walls using this analytical method and simple inclinometers. The paper

describes original research/application and would be interested to most researchers.

Paper 2669 "Geotechnical protection of engineering infrastructure objects in large cities under intense anthropogenic impact and long term operation" by Perminov, Zentsov, Perminov, Russia. This article describes more than 30-year experience of scientific and technical support, design, construction and reconstruction of water supply and sewage facilities in St. Petersburg, Sochi, etc. It includes experience of sinking of large diameter shaft/caisson and long term loadings on tunnels in urban areas. Could do with a thorough proof reading and some of the terms used are unfamiliar. It is recommended for Panel presentation as it will be of interest to those who would like to practice in Russia.

Paper 2535 "A geoenvironmental application of an optimisation model" by Azimi, Merrifield, Gallagher & Smith from UK. The paper summaries a network of monitoring wells installed in and around a refinery in mid 1990s as part of a research project aiming to investigate the impact of local groundwater on corrosion of buried foundations and underground storage facilities. A second research project was started in 2000 to delineate the extent of the oil contamination mound(s) beneath the refinery and devise appropriate remedial measures. This paper presented an optimisation technique which assisted with augmentation of the monitoring network, thereby the cost-effective delineation of the oil mounds beneath the refinery. An optimisation model, The Maximal Covering Location Problem (MCLP), was modified and applied to find the optimum number and locations of additional monitoring wells to assist with the cost-effective delineation of the oil contamination mound beneath the refinery.

It is recommended for panel presentation as it may provide further discussions on the degree of confidence in selection of the value of maximal service distance (S) in the order of 100m without consideration of field, laboratory and theoretical investigations.

Paper 2460 "Evaluation of diaphragm wall as-built data to determine the risk of leakage for the Kruisplein car park excavation in Rotterdam, The Netherlands" by Hannink & Thumann from Netherlands. This paper should give the geological profile of the site to let readers have a better understanding of the ground conditions. Representative pumping test results may be included to demonstrate the critical or potential locations of leakage and the contingency measures which shall be required. It is recommended for Panel presentation.

Papers 3083 "Preventive maintenance of water retaining structures based on fiber optic systems" by Fry, Courivaud, Beck & Pinettes from France. The Pare described that EDF develops the concept of preventive maintenance. It means design, building and operation of an early warning monitoring system (leakage and strains), plus model of interpretation and portfolio of technical or legal alarm and interventions. In that framework, EDF has been working since 1994 on the development of the use of the distributed measurements with fiber optic, to improve the monitoring of dykes and flood embankments. The fiber optic technology provides a remote control measurement of the distributed temperature and strain every meter along the embankment. This new technology strategically placed in the fill, allows to reinforce the hydraulic and mechanical behavior monitoring, which is provided to date by conventional instrumentation (leveling, piezometer, discharge rate), with simultaneously a global and detailed surveillance and an early warning system for extreme loadings and crisis (floods, earthquakes, vandalism). It introduces the principle of dikes monitoring using fiber optic and the validation results of this technology from both trial test sites and on EDF's real sites.

# Auscultation des fondations d'un ouvrage en terre par des capteurs à fibre optique

## Monitoring earthwork foundations by fibre optic sensors

Artières O.

TENCATE GEOSYNTHETICS, Bezons, France

**RÉSUMÉ :** La mesure des déformations dans un ouvrage en terre est maintenant plus facile à réaliser en utilisant la technologie des capteurs à fibres optiques, qui associée aux propriétés des géotextiles, comme par exemple leur excellent frottement d'interface avec les sols, permet un bon transfert des mouvements du sol vers le capteur. Leur faible taille moins intrusive que celle des capteurs électromécaniques classiques donne l'accès à des mesures plus fines. Ils ont une sensibilité élevée, inférieure à 0,01% en déformation, mais aussi de 0,1°C en température, combinée avec une haute résolution spatiale de l'ordre du mètre et une bonne durabilité des capteurs dans le sol. Ils sont polyvalents tant pour ausculter des ouvrages locaux, comme des murs ou des talus, que des infrastructures linéaires de plusieurs dizaines de kilomètres, comme les routes, les voies ferrées ou les digues avec la même résolution. Plusieurs dizaines d'ouvrages sont maintenant auscultés depuis plus de 8 ans, preuve de la durabilité de ces capteurs, comme des remblais sur cavité ou sur inclusions. La détection de cavités en fond d'un grand bassin de stockage d'eau industrielle est décrite

**ABSTRACT:** Strain in earthworks is now easier to measure by using fibre optic sensing technologies combined with geotextile properties, such as very good soil friction interface enhancing the transfer of soil displacement to the sensors. More accurate measurements can be obtained due to their smaller and less intrusive size than those of the usual electro-mechanical strain gages. They have high sensing sensitiveness below 0.01% on strain measurement, but also temperature measurement with 0.1°C accuracy, that is combined with a high spatial resolution in the range of 1 m or less and a good durability of the sensors into soil. ## 1 INTRODUCTION

Les capteurs ponctuels de mesure des déformations des ouvrages en terre sont difficiles à installer et occasionnent parfois des problèmes de fiabilité à long terme. Les capteurs à fibre optique solutionnent ces inconvénients. Ils associent les propriétés des géotextiles, comme par exemple un frottement d'interface avec le sol élevé, avec plusieurs technologies de capteurs utilisant les fibres optiques pour mesurer des paramètres importants comme la déformation et la température. Les avantages principaux de cette solution sont sa sensibilité élevée, sa résolution spatiale de l'ordre du mètre voire moins, la durabilité des capteurs dans le sol, leur capacité à mesurer soit des ouvrages ponctuels comme des murs ou des talus, ou de longues infrastructures de plusieurs dizaines de kilomètres comme les routes, les voies ferrées ou les digues, toutes avec la même précision.

Plusieurs dizaines d'ouvrages sont auscultés dans le monde avec cette solution depuis plus de 8 ans, démontrant ainsi sa durabilité. Par exemple, une pile de pont renforcée est auscultée avec succès depuis juillet 2004. A côté des ouvrages en terre, plusieurs ouvrages en terre, tels que bassins, barrages, digues et levées ont été auscultés pour détecter des problèmes de stabilité et de fuite.

Après avoir introduit les principes de la solution d'auscultation et les principaux résultats obtenus sur plusieurs projets anciens, cet article se concentrera sur son emploi pour ausculter les fondations de remblais sur cavités : seront décrits en premier lieu, une section de voie ferrée auscultée en continu

depuis octobre 2004, puis la fondation d'un grand bassin de stockage d'eau ausculté depuis 2011.

## 2 LA SOLUTION D'AUSCULTATION

Les capteurs à fibre optique ont été largement utilisés depuis plusieurs années dans les applications de génie civil, en particulier pour la surveillance des conduites d'hydrocarbure, dans des systèmes de surveillance de l'état de structure, ou des applications hydrauliques comme des barrages ou des digues en béton ou en terre. En associant des fibres optiques sur un géotextile (Figure 1), TenCate GeoDetect<sup>®</sup> est un capteur géotextile innovant qui améliore les performances des fibres optiques lorsqu'elles sont utilisées en contact avec le sol, du béton ou du bitume : le géotextile crée une excellente interface d'ancrage avec le milieu environnant. Grâce au très bon ancrage du géotextile dans le sol et à la bonne liaison des câbles optiques sur le géotextile, de très faibles déformations du sol peuvent être détectées. Cette interface de frottement améliore également le transfert des mouvements de géotextile vers la ligne optique. De plus, et quand cela est nécessaire, des propriétés de renforcement et raideurs en traction élevées peuvent être associées au capteur comme cela est indiqué au §3.

Différentes technologies de capteurs par fibre optique peuvent être utilisées : les réseaux de Bragg (Fiber Bragg Gratings ou FBG) employés dans le premier exemple d'application au §3, ou la mesure répartie décrite dans le deuxième exemple d'application au §4.

Les réseaux de Bragg sont des modifications locales de l'indice optique à l'intérieur de la fibre optique sous forme d'une série de petits miroirs inscrits sur une distance de quelques millimètres de long et réfléchissant une longueur d'onde donnée, proportionnelle à la température et à la déformation. A l'inverse des réseaux de Bragg qui sont des mesures ponctuelles, les technologies réparties Brillouin ou Raman mesurent tout point le long de la fibre sur des distances de plusieurs dizaines de kilomètres. Ces deux technologies permettent une mesure très précise de paramètres comme la température ou la déformation, avec des fréquences de mesure soit statiques (< 1 Hz) soit dynamiques (de 1Hz à 2 kHz).

La solution d'auscultation comprend le capteur géotextile à fibres optiques, l'instrumentation et le logiciel d'acquisition de données (Figure 1). Différentes stratégies d'auscultation peuvent être prévues lors du dimensionnement, comme une auscultation périodique ou continue à des fins d'alerte précoce.

En comparaison avec des techniques d'auscultation existantes constituées de capteurs ponctuels câblés individuellement, cette solution mesure en continu jusqu'à plusieurs dizaines de milliers de points avec une seule instrumentation sur toute la longueur de la structure. La résolution spatiale peut être dans certains cas de 0,5 m. Dès son installation, le capteur géotextile à fibre optique peut acquérir des valeurs de déformation et de température : la résolution en déformation est inférieure à 0,01% et des variations de température inférieures à 0,1°C peuvent être mesurées avec les logiciels correspondants. La technologie de mesure par fibres optiques ne nécessite aucune calibration avant mesure, seulement une compensation de la température peut être nécessaire pour des amplitudes supérieures à 10°C.

Figure 1. Composants du système d'auscultation

### 3 SYSTÈME D'ALERTE SOUS VOIE FERRÉE

A la suite de la détection de failles perpendiculaires à la voie ferrée entre Mouchard et Bourg dans la région d'Arbois (France), la SNCF a décidé de renforcer la zone suspectée active avec un système de renforcement et d'alerte par fibres optiques, à la fois pour éviter tout effondrement et rupture dommageable au niveau de la voie, et d'autre part pour détecter et éviter tout passage de train au-dessus d'une cavité de taille supérieure à 1,5 m. La surface couverte est une section à voie unique de 50 m de long et de 5 m de large. La plateforme est construite avec 25 cm de ballast sur 50 cm de sol.

Le capteur géotextile à fibre optique qui a été installé sur cette section en 2004 combine à la fois des câbles optiques et des câbles de renforcement pour augmenter la résistance et la raideur en traction, et réduire la déflexion à la surface du remblai (Figure 2). La technologie optique utilisée est celle des réseaux de Bragg (FBG) inscrits dans la fibre qui mesurent directement les modifications de déformation en renvoyant une variation de longueur d'onde. Ce sont 297 FBG qui quadrillent la zone et qui permettent de localiser des cavités de 1.2 m de diamètre avec deux FBG différents. Une armoire étanche est

placée à proximité de la zone renforcée pour protéger l'interrogateur et les systèmes de communication à distance utilisés pour ausculter la zone en continu (Briançon et al., 2006).

Malgré des conditions de mise en place difficiles (pluie, zone de travail exigüe, travail de nuit), le panneau de capteur a été installé dans les délais impartis. L'association du système de capteur avec le géotextile de renforcement améliore la facilité d'installation qui pourrait difficilement être atteinte avec des capteurs locaux conventionnels.

Les déformations mesurées lors de la construction du remblai sont inférieures à 0,5%. Le système d'alerte est installé depuis plus de 8 ans. Les mesures sont stables depuis la remise en service de la voie. La valeur seuil fixée à 2% de déformation, correspondant à une déflexion de 2 cm au niveau du rail n'a pas encore été atteinte. Aussi, le branchement d'un interrogateur dynamique permet d'acquérir des données avec une fréquence élevée (1 kHz), ce qui permet de mesurer des variations de déformation d'environ 0.3% lors du passage d'un train.

## 4 L'AUSCULTATION DES FONDATIONS D'UN BASSIN

### 4.1 Description

L'objectif de ce bassin est le stockage d'eau salée industrielle pendant environ 6 mois sur 12 pour pouvoir la relarguer dans la rivière voisine lorsque celle-ci est en crue (en hiver) afin d'obtenir un taux de dilution suffisant. La surface totale du bassin est de 30 ha et a une capacité de stockage de 300 000 m<sup>3</sup> pour une hauteur d'eau maximum de 10,7 m. Il est construit à l'endroit d'une ancienne gravière à proximité d'une rivière et est délimité par une digue périphérique de 2 km fondée sur le sol naturel en dehors de la gravière. Le fond du bassin est à 4 m en-dessous du sol naturel. Il est sous le niveau de la nappe et pour cette raison étanché en fond et sur les talus par une structure d'étanchéité incluant une géomembrane PEHD de 2 mm protégée par des géotextiles et un tapis drainant granulaire en fond. Les conditions géologiques et hydrologiques, ainsi que la conception de ce bassin sont décrites en détail dans une autre publication (Artières et al. 2013).

### 4.2 Observations

Une augmentation des concentrations de produits salés correspondant au même type que ceux stockés a été détectée en 2008 dans l'eau de pompage de rabattement de nappe sous le bassin. Après vidange du bassin, des tassements ont été

observés dans les casiers E1 et D1 le long de la ligne de collecte des sources (Figure 4). Le contexte hydrogéologique de cette zone est très complexe. On a supposé une dissolution du chapeau sulfaté de la dolomie profonde par des eaux salées. Ces tassements étaient visibles sur la géomembrane sous la forme d'une déchirure de 15 cm par 3 cm et étaient dus à un fontis de 6 m<sup>2</sup> et de 3 m de profondeur. Ceci a expliqué les raisons des fuites. Sur trois autres endroits, le substratum argileux était décomprimé. A partir d'une analyse topographique, la surface totale d'effondrement a été estimée à environ 1500 m<sup>3</sup> autour des sources.

#### 4.3 Travaux de réparation

Il a été décidé une réparation du fond de la zone du bassin présentant un risque élevé de tassement en installant une structure de renforcement de la fondation par géotextile, associée à un système de détection et de localisation des fontis par capteur géotextile à fibre optique. Dans ce projet, la fonction renforcement a été dissociée de la fonction auscultation.

Le géotextile de renforcement évite à la fois que le fontis atteigne de façon soudaine la structure d'étanchéité et que la géomembrane s'allonge au-dessus d'une valeur seuil permettant de maintenir la fonction étanchéité jusqu'à ce que la cavité soit traitée. Il est dimensionné selon l'Eurocode 7 (2005). Aux états limites ultimes (ELU), les justifications sont menées en utilisant l'approche de calcul 2, avec les coefficients partiels définis dans l'Annexe Nationale [NF EN 1997-1 /NA] de l'Eurocode 7.

Figure 4. Numérotation des casiers et sortie des sources

La méthode de dimensionnement est une méthode simplifiée (Blivet et al. 2001) développée après le programme de recherche RAFAEL. Le dimensionnement du géotextile a été conduit en appliquant les trois états limites : un de service et deux ultimes à court et long terme (Artières et al. 2013). Le calcul aboutit à une raideur élevée ( $J=11000$  kN/m). Le géotextile mis en place est un tissu polyester TenCate Geolon PET 1600 avec une résistance en traction de 1600 kN/m selon la méthode d'essai EN ISO 10319.

Le capteur de déformation est installé sous le géotextile de renforcement pour détecter de façon précoce, localiser et suivre les mouvements du sol sur cette zone, et enfin, estimer la taille des fontis pour vérifier la compatibilité avec la taille de cavité utilisée dans les hypothèses de dimensionnement du géotextile de renforcement.

La structure reconstruite sous la structure d'étanchéité par géomembrane comprend de haut en bas : 60 cm de gravier 0/20 mm (tapis drainant), le géotextile de renforcement, 20 cm de gravier 0/16 mm et le système d'auscultation.

#### 4.4 Le capteur géotextile à fibre optique

Le capteur se présente sous forme de bandes géotextile de 76 cm de large portant 2 câbles optiques pour la mesure des déformations, la première étant la ligne principale, la deuxième

étant une ligne redondante de sécurité. La distance entre les deux câbles de déformation est de 0.6 m (Figure 4). Ces capteurs sont reliés par un câble de liaison de 200 m de long à un interrogateur optoélectronique Brillouin installé dans une cabine en tête de digue. Il n'y a donc aucun appareil électromécanique ni de source électrique dans le bassin. Cette solution est décrite plus en détail dans d'autres publications (Artières et al. 2011, Artières et Dortmund 2011).

L'interrogateur connecté à une extrémité de la fibre optique envoie un pulse laser de quelques nanosecondes qui parcourt toute la longueur de la fibre optique. En chaque point de la fibre optique, le pulse laser interfère avec la structure moléculaire de la matière en rétrodiffusant en sens inverse un spectre de lumière schématisé en figure 5. La longueur d'onde des pics secondaires Brillouin dépend notamment de l'état de déformation de la fibre optique. La résolution spatiale de la fibre est d'environ 1 m et la résolution sur la mesure de la déformation est inférieure 0,01 %.

L'interrogateur optique connecté à une extrémité de la fibre optique envoie un pulse laser que quelques nanosecondes qui est guidé tout au long de la fibre optique. A tout point de la fibre, le pulse laser interfère avec la structure moléculaire du matériau en rétrodiffusant un spectre de lumière (Figure 5). Les pics de longueur d'onde secondaires Brillouin dépendent de la déformation de la fibre et de sa température. La résolution spatiale le long de la fibre est d'environ 1, ce qui signifie que le système génère un point de mesure tous les mètres. La résolution de la mesure de la déformation est de moins de 0,01%.

Figure 5. Spectre de lumière rétrodiffusé lors de la mesure répartie sur fibre optique ( $\lambda_0$  est la longueur d'onde de la lumière incidente)

#### 4.5 Conception et mise en œuvre de l'auscultation

Une surface d'environ 10.000 m<sup>2</sup> présente un risque de tassements liés à la remontée aléatoire de cavités souterraines. La solution d'auscultation est implantée sur une zone particulière d'environ 165 m x 20 m incurvée couvrant les casiers E1, D1 et C1 (Figure 6).

Sur cette surface, 18 bandes du capteur géotextile à fibres optiques ont été installées en 5 boucles optiques distinctes permettant de lire l'une indépendamment des autres. Les bandes sont espacées l'une de l'autre de 1,2 m correspondant à la taille minimale de cavité à détecter. Les deux câbles optiques de déformation portés par chaque bande sont raccordés séparément, ce qui constitue un total de 5 boucles principales et de 5 boucles redondantes de sécurité. Ces dix boucles sont raccordées à un câble optique de liaison de 200 m de long vers l'instrumentation. Ce sont environ 6.000 points de mesures qui couvrent la surface totale avec un pas de 0.6 m x 1 m.

Les bandes de capteur composite géotextile à fibres optiques sont déroulées sur le site selon un plan de calepinage approuvé par le Maître d'Ouvrage. Les bandes sont immédiatement lestées temporairement jusqu'à la fin de l'installation du système d'auscultation (Figure 7). La continuité des lignes optiques est contrôlée avant la pose du gravier de couverture 0/16 et du géotextile de renforcement (Figure 8).

Figure 6. Vue depuis la crête de digue du bassin et de la zone instrumentée (en clair au centre).

Figure 7. Pose de bandes capteur en fond de bassin.

Figure 8 : Installation du géotextile de renforcement.

#### 4.6 Mesures

Le bassin a été ausculté dès la fin de l'installation du système géotextile à fibre optique en mai 2011 mettant en évidence l'effet de la mise en place de la couche de remblai de 80 cm puis du remplissage en eau du bassin.

Les déformations principales ont été enregistrées lors de la mise en place du remblai qui s'explique par la rugosité importante du fond de forme et la mise sous tension des bandes capteur. Un évènement pluvieux intervenu lors de la pose des capteurs avait en effet érodé la surface du fond de forme. La moyenne des déformations est de l'ordre de 0,2% avec des pointes autour de 1% et une forte irrégularité. Un remblaiement sur support plan créé généralement des déformations initiales inférieures à 0,1%. Cette mesure a été choisie comme ligne de référence par le Maître de l'Ouvrage pour le suivi du bassin.

Le remplissage du bassin à 6 m d'eau en décembre 2011 et en novembre 2012 ne montrent pas d'accroissement sensible des déformations, en moyenne inférieures à 0,1% avec quelques points très localisés entre 0,1 et 0,4 %, ceux-ci étant encore certainement liés à la mise en place des capteurs sur le fond de forme (Figure 9).

Figure 9. Evolution des déformations entre mai 2011 et novembre 2012

## 5 CONCLUSION

L'association d'une structure de renforcement par géotextile avec un système d'auscultation pour détecter les mouvements du sous-sol est une solution utilisée avec succès depuis plus de huit ans sous un remblai ferré sujet à des risques de remonté de fontis.

Cette solution a également été utilisée pour stabiliser la fondation d'un bassin industriel étanché par une géomembrane après que des tassements aient été constatés. Une structure de renforcement par géotextile a été conçue sous la structure d'étanchéité pour réduire les déformations de la géomembrane pour des tailles de cavité de 3 m. En complément, un système d'auscultation basé sur des capteurs composites géotextile à fibres optiques a été positionné en-dessous pour détecter de façon précoce et localiser les effondrements, suivre l'évolution de la taille des cavités et éventuellement planifier une opération de maintenance si leur taille dépasse les hypothèses de dimensionnement du géotextile de renforcement. La solution d'auscultation a indiqué le développement de déformations lors des réparations à cause de la rugosité élevée du fond de forme, mais aucune déformation liée à un fontis n'est apparu depuis un an et demi après son installation.

**ABSTRACT:** A network of monitoring wells was installed in and around a refinery in mid 1990s as part of a research project aiming to investigate the impact of local groundwater on corrosion of buried foundations and underground storage facilities. Oil contaminated groundwater was evident in some of the monitoring wells. A second research project was started in 2000 to delineate the extent of the oil contamination mound(s) beneath the refinery and devise appropriate remedial measures. Of 30 initial monitoring wells, 15 were found operational inside the refinery in 2000. An optimisation technique is presented herein which assisted with augmentation of the monitoring network, thereby the cost-effective delineation of the oil mounds beneath the refinery. The Maximal Covering Location Problem (MCLP) was adapted and utilised to find the optimum number and locations of additional monitoring wells. The contamination results obtained from the augmented and optimised network of monitoring wells were analysed using a geostatistical tool and the oil contamination hot spots beneath the refinery were delineated cost-effectively.

**RÉSUMÉ :** Au milieu des années 1990, un réseau de puits de surveillance a été installé à l'intérieur et autour d'une raffinerie de pétrole pour étudier l'action des eaux souterraines sur la corrosion des fondations enterrées et des structures de stockages souterrains de la raffinerie. Une contamination par le pétrole a été détectée dans certains de ces puits. Un second projet de recherche a été lancé en 2000 pour suivre l'étendue de la contamination sous la raffinerie et concevoir des solutions appropriées pour y remédier. 15 des 30 puits fonctionnaient encore à l'intérieur de la raffinerie en 2000. Cet article présente, une technique d'optimisation du réseau de puits de surveillance afin de cartographier l'évolution de la tache de pétrole sous la raffinerie pour un coût limité. Les auteurs ont modifié le modèle d'optimisation 'Maximal Covering Location Problem' (MCLP) pour trouver le nombre optimal de puits de surveillance supplémentaires et leurs emplacements. L'analyse de ces résultats en utilisant une méthode statistique a permis de confirmer le contour de la contamination sous la raffinerie pour un coût bien défini.

### 1 INTRODUCTION

An oil refinery constructed in the early 1970s and operated ever since caused groundwater contamination. A research project was conducted at the refinery in mid 1990s to investigate the impact of local groundwater flow on corrosion of buried foundations and underground storage facilities inside the refinery. As part of that project, a network of 30 monitoring wells was installed in and around the refinery. Oil contamination of groundwater was evident in some of the monitoring wells. A second research project was started in 2000 to delineate the extent of the oil contamination mound beneath the refinery and devise appropriate remedial solution(s). Of 30 initial monitoring wells, 15 were found to be operational inside the refinery at the beginning of the second research project. Monitoring of these wells demonstrated that free phase of oil contamination was present in groundwater at least at two separate locations inside the refinery. However, the contamination data obtained from the existing monitoring network of 15 wells were too sparse for the purpose of oil contamination delineation. Therefore, it was decided to add monitoring wells to the network within the refinery. The two major engineering challenges were identified as:

- How many monitoring wells should be added to the existing network?
- In which locations should these wells be installed?

There is substantial evidence in the literature on the application of Operations Research (OR)-based optimisation

methods in different civil and environmental engineering practices (ReVelle et al. 1997). Fields of practice such as transport engineering, urban planning and water resources management are examples where successful applications of OR methods including optimisation techniques have been demonstrated. The Maximal Covering Location Problem (MCLP) is an optimisation model proposed in the literature, primarily devised to find the optimum locations for public facilities, such as ambulance dispatch centres, on a network of demand nodes (Church and ReVelle 1974). The model was modified and applied to the groundwater contamination problem in this study to assist with the cost-effective delineation of the oil contamination mound beneath the refinery.

### 2 MAXIMAL COVERING LOCATION PROBLEM (MCLP) – CONCEPT, THEORY AND APPLICATION

An example where the MCLP can be used for the optimum usage of the resources is the requirement to add a certain number of a public facility (e.g. ambulance dispatch centres) to an existing network in a city. The city is discretized to a set of demand nodes where additional dispatch centres can be situated. Each demand node is assigned a weight representing its population with the existing dispatch centres being attributed to the nearest nodes. From the network operator's point of view, coverage of the demand nodes (i.e. population nodes in this example) on the network is the key objective with demand nodes not being located farther than a threshold distance (i.e. maximal service distance,  $S$ ) from an ambulance dispatch

centre. In other words, a node is covered if at least one facility is located within the maximal service distance of that node. Otherwise, the node is uncovered. If a network operator instinctively places all the available resources on the nodes with the greatest nodal weight (e.g. population), the outcome will not necessarily be maximum coverage of the population by the public facilities because of the likely overlaps and gaps in the coverage of the demand nodes.

In reality, the 100% coverage target is not always achievable due to limitations in the availability of supply units. If the resources are insufficient to cover all the demand nodes, the objective changes to cover as many nodes as possible within  $S$  using the limited resources. Figure 1 represents a typical discretized network of demand nodes which could be considered as the potential locations for accommodating the additional facilities. With a sufficiently large maximal service distance, for example, a single facility can cover all the demand nodes on the network; hence  $S$  is a key decision parameter.

Figure 1. The concept of maximal service distance.

The MCLP is expressed as: Maximize coverage (population covered) within a desired service distance by locating a fixed number of facilities (Church and ReVelle, 1974).

The mathematical formulation of the MCLP in the context of augmentation of a groundwater monitoring network is presented in Hudak & Loaiciga (1992). Groundwater monitoring network augmentation incorporates the following stages:

- Discretize the model domain into a network of potential detection monitoring sites (nodes).
- Assign weighting to each node to quantify its relative importance for coverage by a monitoring well.
- Solve MCLP with successive values of  $S$  until target areal plume coverage is achieved.
- Determine the corresponding configuration of the added wells on the network.

### 2.1 Geometry of the grid (problem domain discretization)

An irregular grid of 188 nodes was defined within the oil refinery area taking into account the local hydrogeology as compared to similar cases where groundwater monitoring networks has been augmented, the limitations against excavation of wells on site, the spacing between the existing wells and the computational limitations for a plausible nodal weight estimation. Each of the 15 existing wells was assigned to the nearest node.

### 2.2 Nodal weight estimation

Due to the complex hydrogeological setting of the site and presence of a large number of potential sources of oil

contamination within the refinery, using physical / numerical models to calculate the nodal concentrations (weights) was considered impractical. Kriging as a stochastic interpolator was employed instead to estimate the weights. The groundwater chemical data obtained from all 22 available monitoring wells located within and around the refinery were utilised in this nodal weight estimation.

### 2.3 Results

The budget allocated for additional monitoring wells included the addition of a maximum 10 number to the existing network. Therefore, the MCLP model was solved for different values of  $P$  from 20 to 25, noting  $P$  is the total number of existing and additional wells on the network and there were 15 existing wells. There were three key decision parameters; areal plume coverage which corresponds to the vertical axis on Figure 2 and is defined as the percentage of the nodes with weight values above zero covered by one or more wells (i.e. located within distance  $S$  of one or more wells), the total number of existing and added wells ( $P$ ), and the maximal service distance  $S$  (horizontal axis on Figure 2). The marked increase in the slope of the curves on Figure 2 in two particular regions demonstrated that with a moderate increase in the value of  $S$ , the areal plume coverage would increase considerably compared to the other regions on the curves. If the values of  $S$  and the number of covered nodes (i.e. areal plume coverage) within these regions (intervals) were reasonable for decision making, then it would be possible to focus on these two regions for taking the next steps towards the final decision. The maximal service distance ( $S$ ) plays the most important role in dictating the final configuration of the added facilities. This parameter should ideally be calculated through field, laboratory and theoretical investigations. Considering the grid size of the study area, values of  $S$  in the order of 100m were justified in this study.

Figure 2. The coverage trend curves.

Figure 3 demonstrates that within the maximal service distance of 76m, it was possible to achieve a maximum areal plume coverage of 60% (i.e. 113 covered nodes out of total 188 nodes could be covered). This amount of coverage was not considered satisfactory. Therefore, the first interval on Figure 2 was not considered further and the second interval was selected. Figure 4 illustrates the variation of maximal service distance  $S$  versus  $P'$  (number of monitoring stations to be added). Points with unjustified values of  $S$  were not depicted on the graph. Figure 4 demonstrated that augmenting the network with 10 additional monitoring wells was somewhat insensitive to the magnitude of  $S$ , i.e. selection of 10 additional monitoring stations would result in a considerable increase in the areal plume coverage with minimum change in  $S$ . Hence, the network was augmented with 10 additional boreholes, corresponding to the areal plume coverage of 85% and  $S \sim 108$  m. The pattern of additional wells showed no clustering at the areas of high

estimated chemical concentration (weights). This model located the additional stations (i.e. monitoring wells) at regions with high concentration of contaminant and at the same time prevented clustering of the wells (See the layout in Figures 5 and 6).

Figure 3. Cost-effectiveness curves for two distinct values of  $S$  derived from Figure 2.

Figure 4. Variation of maximal service distance ( $S$ ) versus the number of added wells ( $P'=P-15$ ).

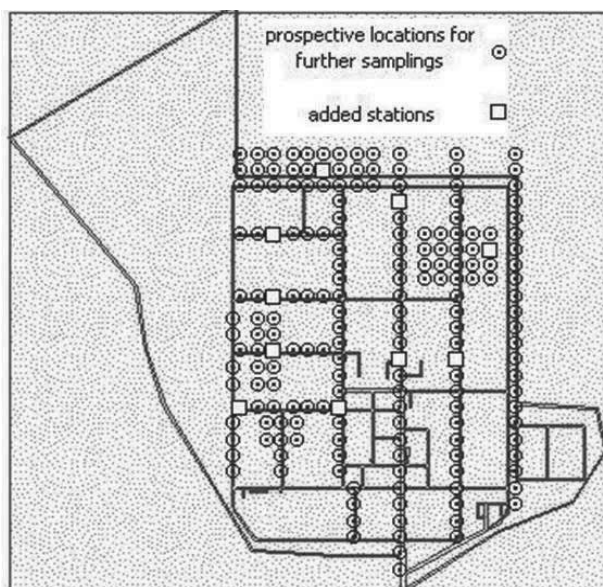

Figure 5. Added wells on the discretized network.

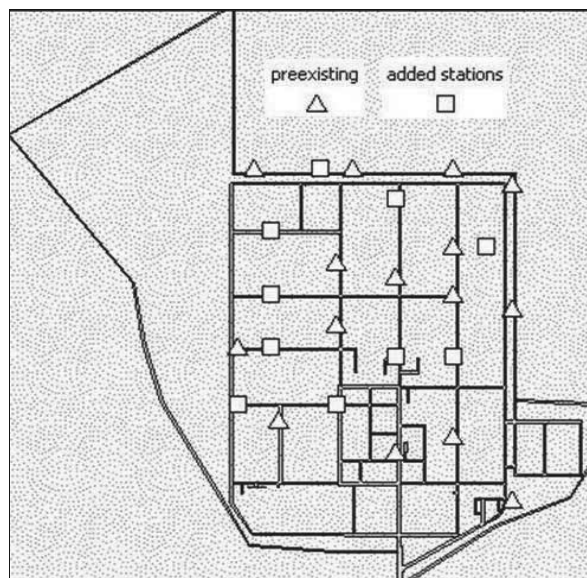

Figure 6. Added and existing wells.

### 3 GEOSTATISTICAL ANALYSES ON THE AUGMENTED DATA SET

A geostatistical analysis, using the same geostatistical tool which was used in nodal weight estimation (i.e. estimation of chemical concentrations at different nodes), was conducted on the extended data set to assist with delineating the locations and the extent of hot spots of oil contamination beneath the refinery. Three different hot spots were identified at three distinct areas. Figure 7 shows the location and the extent of the hot spots.

### 4 CONCLUSIONS

A geoenvironmental case history of applying an optimisation model in practice is illustrated in this paper. The Maximal Covering Location Problem (MCLP) was employed to enhance the efficiency of an existing network of monitoring wells in an oil refinery in order to assist with delineating the mounds of oil contamination beneath the refinery. After installation of the added monitoring wells at the locations predicted by the model (i.e. monitoring network augmentation), the results obtained from the augmented network demonstrated the robustness of the method. The model helped to prevent clustering of the added monitoring wells in the areas with high estimated values of the attribute (i.e. concentration) and at the same time helped to benefit the monitoring from further sampling at these areas. Using the data from the augmented network of monitoring wells

and a geostatistical tool, the oil contamination hot spots were delineated cost-effectively.

**ABSTRACT:** The re-use of existing foundations, in particular piled foundations has increased in recent years due to the significant environmental and commercial benefits. However, there has been limited progress in assessing the condition of such piles by considering the effect of initial use and the impact from the subsequent demolition process which often requires a detailed study. This paper will provide details of a recent project in London that successfully reused all existing piles beneath the site and optical fibre sensors were instrumented to the existing foundations in order to monitor the behavior of piles during the demolition of the existing building. The use of optical fibre instrumentation is believed to be the first of such an approach in observing the behavior of reuse piles during demolition in the UK and as urban environments become more congested particularly below ground, the approach discussed in this paper will become increasingly valuable. The monitoring data is presented and discussed in detail and the role of using these sets of data in assessing the reuse strategy is also highlighted in this paper.

**RÉSUMÉ :** La réutilisation de fondations existantes, en particulier de fondations sur pieux, a augmenté ces dernières années en raison des avantages environnementaux et commerciaux significatifs. Cependant, l'état des pieux suite à leur première utilisation et le processus de démolition sont souvent négligés. Ce document présente un projet récent à Londres où les pieux ont été instrumentés avec des capteurs en fibre optique, avant la campagne de démolition. Les fibres optiques permettent de mesurer des déplacements le long des pieux lors de la démolition. L'utilisation d'une telle instrumentation est une première au Royaume-Uni. Les données de la campagne de surveillance sont présentées et discutées en détail. Une stratégie de réutilisation des fondations sur pieux est également proposée dans ce document.

## 1 INTRODUCTION

Foundation re-use can generate significant environmental and commercial benefits, and is becoming a popular engineering option, particularly in congested urban environments. Due to the many practical constraints, most redevelopments need to be constructed on the existing foundations together with a new pile system; therefore it is crucial to understand the geotechnical behaviour of reused piles and their compatibility with the new structure. This is often difficult without removal of significant parts of the substructure. Previous researches (Leung et al., 2011; Begaj-Qerimi&McNamara, 2010) have shown that pile behavior may change with time, due to consolidation and ageing, residual stress at the pile base and increased soil stiffness; hence reused piles are often stiffer than new piles. On the other hand, the building demolition process could potentially introduce ground heaving and the physical unloading of the reused piles can also generate tension cracks. These differences in pile responses need to be properly assessed in the design of a new pile system.

A recent project in London provided the opportunity to further develop the understanding of foundation reuse by installing fibre optic sensors in both existing piles and a borehole to observe the impact of the demolition process on the changes in piles behavior and ground response. The site is located at 6 Bevis Marks and near to Liverpool Street, London, UK, and it was proposed to reuse all existing foundation piles and the majority of the basement substructure on this project.

This approach produced significant commercial and environmental benefits.

The existing piled foundations are large diameter under-ream piles, and there was a concern that these piles would be damaged during the demolition process. Such damage is usually caused either by the forces generated by the removal of significant load as the building is demolished, the tensile forces within the piles and surrounding soil, or physical damage caused by demolition of the substructure, pile caps and pile breaking down. This can lead to the reuse being questioned and ultimately being discounted.

This paper explains how optical fibre instrumentation was used to monitor pile and ground response under demolition and will present the data captured by the fibre optic instrumentation during the demolition process. It will show how the use of such sophisticated instrumentation was fundamental to the successful reuse of the existing piles on this project.

## 2 SITE DESCRIPTION

### 2.1 Existing site and proposed redevelopment

The existing building at 6 Bevis Marks was constructed in the early 1980's and comprised eight superstructure floors and two basements. The existing foundations system includes (i) piles located inside the basement, which is approximately 7.0m below pavement level, and (ii) piles constructed in the Bevis Marks pavement, which is approximately 3.5m below pavement

level as shown in Figure 1. All existing piles were designed and constructed by Cementation Skanska as under-ream piles.

The local geology comprises made ground overlying Terrace Gravels, which in turn rests on London Clay. The top of the London Clay is within 2m of the existing basement level and all piles, both existing and new, are founded within this stratum. The existing piles were designed to carry total building loads of 350,100kN and 33,900kN for those inside and outside the basement, respectively. There are a series of heavily reinforced pile caps and ground beams, and their thickness varies across the site. Typically the ground beams are around 1000mm to 1500mm deep at pile positions, and the pile caps vary from 1500mm to 4150mm deep. This complex pile foundation system practically constrains the available physical space for designing new piles.

The scheme design was developed with the existing building arrangement and existing foundation arrangement in mind. However, with the proposed building being taller (sixteen floors in lieu of eight) and the main stability systems located in slightly different areas, the existing foundations proved to be inadequate as a whole. The result of technical studies demonstrated that the existing piles were overloaded by some 85,000 kN when compared to actual load carried originally.

To enhance the existing piles where they were found to have inadequate capacity, supplementary piles needed to be installed. Figure 2 shows the significant subsurface congestion beneath the site when new piles were installed.

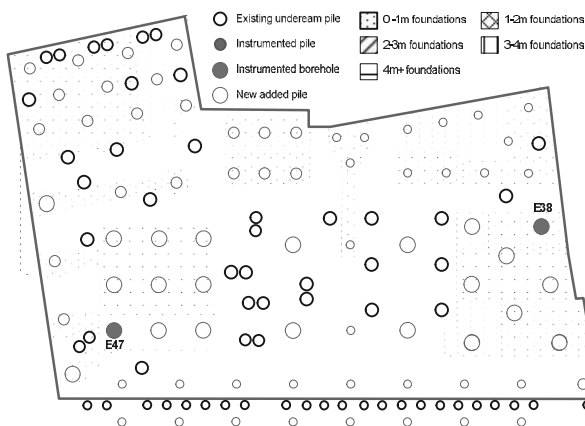

Figure 1. Pile layout and physical constraints to substructure.

Figure 2. Foundation system including the existing and new piles.

## 2.2 BOTDR sensing principle

Brillouin Optical Time Domain Reflectometer (BOTDR) was adopted for this project. It provides sensitive strain measurement from the reflected light that travels along the standard single mode fibre optic cable. The entire fibre cable can be considered as the sensor itself. When the light travels in

the optical fibre sensor, the majority of it travels through but a small fraction is back scattered as shown in Figure 3. In the back scattered spectrum, where only Brillouin spectrums are temperature and strain dependent, the frequency shift of the Brillouin spectrum indicates the local change in the fibre properties induced by the change of strain and temperature. Hence, the change in strain and temperature along the fibre optic sensor is proportional to the frequency shift, which can be detected by the BOTDR analyzer. The analyzer used in this study is capable to sample 1 m averaged strain or temperature at every 5 cm with an accuracy of 50  $\mu\epsilon$  and up to a distance of 10km.

Figure 3. The spectrum of backscattered light.

Due to the principle of Brillouin backscattered sensing, the system registers strain induced by the elongation of the optical fibre itself and the strain resulted from temperature change. Therefore it is necessary to incorporate two different types of optical fibre sensing cables to compensate for temperature effect. Figure 4 shows two types of cables which have been carefully calibrated and widely used for infrastructure sensing (Klar et al., 2006; Mohammed, 2012). Figure 4a shows the strain sensing cable, which consists of four optical fibre members tightly bonded by strong nylon material. This is to ensure the strain can be fully transferred from the nylon coating to the optical fibre itself. Two steel wires at both ends reinforce the cable and make it robust enough to survive in the harsh construction environment. The temperature cable shown in Figure 4b consists of several optical fibres in a gel filled tube, so that it can contract and expand only under temperature effects, independent of mechanical strain.

The use of optical fibre technology has numerous advantages over conventional monitoring systems, it is capable of providing a continuous and full length strain profile and this makes it possible to monitor for cracking of the pile along its full depth. The continuous strain profile also provides a picture of what is happening over the full pile shaft; this would not be possible with traditional single point based system such as vibrating strain gauges or extensometers.

Figure 4. a) strain sensing, b) temperature sensing cable.

## 2.3 Instrumentations and field installation

Prior to demolishing the building, an under-ream pile (E47, see Fig. 1) was selected on site to be cored to full depth for

inspecting and assessing concrete quality. Fibre optic cables were attached to a flexible pipe and installed to the full depth of the cored hole. Table 1 lists the detailed level of the under ream pile. In addition, a new borehole was drilled to 35.5m adjacent to an instrumented pile in the basement and also instrumented to full depth to capture potential ground heave during the demolition process.

This paper will present the data recorded during the demolition process and summarise the results to highlighting the role of the instrumentation in the successful reuse of the deep foundations on this project. It will also include details of challenges faced in using the fibre optic sensors to instrument existing deep foundations, which is believed to be the first of such use in the UK.

Table 1. Summary of instrumented pile

	PileE47
Core length [m]	20.16
Coring length [mAOD]	7.46
Toe Level [mAOD]	-13.70
Original Design Toe Level	-13.00
Shaft Diameter [mm]	1500
Bell Diameter [mm]	3300

### 3 FIELD DATA ANALYSIS

There are ten sets of strain data that have been collected on five dates from 15/08/2011 to 05/10/2011 up to building level 3 of the demolition programme. All optical fibre strain sensing cables and optical fibre temperature sensing cables, installed in the pile and the borehole close to one of the piles, were monitored as close as possible to the removal of each floor. The data from 15/08/2011 taken when the 6th floor had been demolished and 05/10/2011 when the 3rd floor was demolished is presented in this paper to evaluate the pile and borehole performance. The original geotechnical design load on the pile was around 7,250 kN to 7,500 kN, but the structure takedown load on these piles (i.e. the load they experienced under use) is more likely to be around 65 percent of this at around 4,700 kN to 4,900 kN.

#### 3.1 Pile E47

The first set of data was taken on 15/08/2012 and has been considered as the reference for comparing with the dataset collected on 05/10/2012. The profile of strain change between the two periods is shown in Figure 5(a). In general, the axial strain is reducing from the top to the middle part of the pile (0-9m) in the range between 0 and 100 micro-strain, and the axial strain change becomes reasonably small in the base part of the pile (9-17m). After integration of the strain profile, the calculated overall vertical heave between the two periods is less than 1mm at the pile head as shown in Figure (b).

Pile E47 was initially constructed with a design concrete strength  $f_{cu}$  of 30  $N/mm^2$ , with a corresponding modulus of elasticity varying from 20 to 32  $GPa$  as suggested by BS 8110-2:1985. The concrete strength data taken from the tests on the full length cores in pile indicates that the concrete strength in-situ is between 47  $N/mm^2$  to 56  $N/mm^2$ . The modulus of elasticity of this concrete can be calculated, allowing for creep and degradation, as ranging from 26  $GPa$  to 43 $GPa$ . Figure 5(c) shows the load profile by assuming the pile Young's modulus is 26 $GPa$ . Hence, the axial force reduction at the top of pile can be estimated to be around 3,830 kN, which roughly corresponds well to the load removed between the two periods.

It is believed that nominal starter cages were installed into all of the original under-ream piles on this site and are likely to be between 9m and 12m in lengths. Reinforcement details for the existing piles were not available, as is often the case with reuse projects. The cage toes were observed in the strain

measurements at 10m to 13m as a change in the strain profile, which indicates the pile is experiencing tension forces around the base of the reinforced section. It is suspected that this is as a result of the different Young's modulus between the reinforced and unreinforced sections of the pile.

Figure 5. The calculated pile performance due to the demolition activities: a) axial strain along the pile; b) vertical heave; c) pile load.

#### 3.2 Borehole

In comparison to the pile reaction to the demolition of the substructure, the magnitude of change in strain along the borehole is less pronounced than the results observed from the pile, which ranges within 50 micro-strain and within the accuracy range of the BOTDR system. The calculated strain profiles are shown in 6 including the strain profile along the borehole and the interpreted vertical heave is about 0.4 mm at the top. Due to the limitation of the BOTDR system, it is difficult to obtain the accurate vertical displacement profile from such small strain measurement, and the data shown in Figure 6 are the best approximation of the ground movement from the borehole measurements.

Figure 6. Strain profile along the borehole with interpreted ground heave profile.

### 3.3 Discussion

The magnitude of vertical movement measured from pile E47 during the demolition is smaller than 1mm. The resulting force generated at the top section of the pile is estimated to be around 3,800 kN by assuming the pile Young's modulus is 26GPa, and this is relatively large for a pile reinforced with only a nominal steel cage and justifies the concern towards the integrity of the pile post demolition. The significant advantage of using optical fibre instrumentation is that a continuous and full length strain profile is measured, which allows assessment of the potential for cracking of the pile as a result of the demolition induced (load removal) strains. This would be visible as localized sharp peaks within the strain profile and from such data it would even be possible to calculate potential crack thickness. There are no signs of cracking along pile E47 throughout the whole depth and as such there appears to be no visible signs of any detrimental effect of the demolition process up to the 05/10/2011.

With regard to the instrumented borehole, very small strain variation was observed during the monitored demolition process. Such small strains are indicative of small heave forces generated. This could be as a result of both the location of the borehole, which was close to the edge of the basement, and almost certainly as a result of the confining effect of the existing piles and basement slab.

There remain a large number of exiting piles that have not been instrumented and will be reused. Nevertheless, the monitored piles and borehole gave a good indication of the typical response of the existing piles beneath 6 Bevis Marks to the removal of building load during demolition. The results were an essential part of the proofing process and validated the reuse strategy.

## 4 CONCLUSIONS

Currently the primary source of information available for considering foundation reuse are limited to "as built" design and installation records. Although in the future these may be more comprehensive than what are currently available on development sites, the extent of re-use will be limited to the quality of such records. This will in turn constrain the future development options for such sites and is likely to influence the asset values of the site and the existing development, and the viability of redevelopment.

There are developments taking place continuously where more piles are being added to those installed previously, either re-using the existing piles, but more often than not, ignoring the

capacity of existing piles, further restricting the future development potential. In the UK high capacity bored piles have been widely used since the 1950s and it is not unusual for a site to be on its second or even third set of piles, all of which will obstruct and constrain further developments.

Traditionally, low strain pile integrity testing is carried out to confirm that new piles have been constructed correctly and no discontinuities exist. It is also used to assess the integrity of existing piles for reuse, usually with mixed success. Such testing is often not appropriate for pile reuse as,

- To carry out a low strain integrity test, the top of the pile needs to be exposed and structurally separated from other foundations. This is not possible where pile caps, slabs and basement substructures are to remain in place for reuse.
- Such testing only confirms if there is a crack, not how big it is or what is below it. When demolishing an existing building, the expected ground heave may crack the piles to some degree, such cracks are expected to be small and to close up upon pile reload but these tests cannot confirm this.

An alternative solution is to install fibre optic strain measuring devices into existing piles that have been cored full depth and into future piles on installation, producing a smart foundation system. Making this provision for the future will not only increase the potential for re-use and increase its asset value, but is also likely to make the asset more valuable when compared to other properties where such "future proofing" has not been incorporated. Such an approach will allow monitoring of how the piles actually perform under loading, unloading, reload and during the life cycle of the building. Results could be used to further advance our understanding of actual foundation response during the construction phase and operation of such buildings.

## 5 ACKNOWLEDGEMENTS

The authors would like to thank Waterman Structures Ltd for their initial foresight in assessing the re-use potential of the foundations on the Bevis Marks project and their considerable involvement in developing and implementing the pile reuse strategy and associated instrumentation and monitoring works.

# Comparison of monitoring techniques for measuring deformations in an excavation

## Comparaison de techniques d'auscultation pour la mesure de déformations dans une excavation

De Vos L., Van Alboom G., Haelterman K.  
*Geotechnics Division, Flemish Government, Ghent, Belgium*

Maekelberg W.  
*TUC RAIL, Brussels, Belgium*

**ABSTRACT:** Active monitoring is often suggested as a method to decrease the required safety coefficients in the design stage of a construction. In order to apply active monitoring precise, reliable and interpretable measurements of the actual behaviour of the structure and soil-structure interaction are required. To obtain this data, accurate and robust monitoring tools should be available at an acceptable cost. An online monitoring test set-up was realized in a railway-infrastructure project site in Anderlecht (Belgium). The braced excavation consists of a nailed jet grout wall with HEB profiles, installed immediately next to a railway track. Both advanced and traditional monitoring equipment is installed to measure the deformation of the jet grout wall, deformations behind the jet grout wall (on the railway tracks) and forces in the nails. The present paper focuses on the results of the measurements in and behind the jet grout wall and on the comparison between the different techniques.

**RÉSUMÉ :** L'auscultation active est souvent suggérée comme une méthode permettant de réduire le coefficient de sécurité du dimensionnement d'un ouvrage. Afin d'appliquer une auscultation active, des mesures précises, fiables et interprétables du comportement réel des ouvrages et de l'interaction sol-structure sont requises. Afin d'obtenir ces données, des outils d'auscultation précis et robustes doivent être disponibles à un coût acceptable. Un essai de surveillance en ligne a été réalisé sur le site d'un projet d'infrastructure ferroviaire à Anderlecht (Belgique). L'excavation consiste en un mur d'étanchéité cloué, avec des profils HEB, installé à proximité immédiate de la voie ferrée. Des technologies aussi bien avancées que traditionnelles ont été utilisées pour mesurer les déformations du mur d'étanchéité, les déformations derrière le mur (sur les voies ferrées) et les forces dans les clous. Le présent article vise à comparer les résultats des mesures dans et derrière le mur et à comparer les différentes techniques de mesure.

**MOTS-CLÉS:** auscultation active, outils d'auscultation avancés, site d'essai d'auscultation

## 1 INTRODUCTION.

The Geotechnics Division of the Flemish Government (GEO) realised an online monitoring test set-up to extend the experience with new monitoring techniques and to make a step forward in the application of active monitoring on construction sites. The project was partially funded by the Agency for Innovation by Science and Technology (IWT), allowing 3 firms to develop and perform online monitoring for an excavation. Verification measurements were made by several parties, using both more traditional as well as new monitoring techniques.

### 1.1 Main objective

The main goal of the project is to evaluate different monitoring results and suitability of proposed monitoring schemes for application in interactive design. This implies that accuracy, installation possibilities, reliability and cost are important aspects to be considered.

The monitoring scheme consists of measuring and logging:

- deformation of a vertical wall ( $x,y,z$ )
- maximum bending moment in a vertical wall
- deformation of the soil ( $z$ ) behind a vertical wall
- anchorage forces in nails

### 1.2 Site description and applied equipment

The monitoring site is located in Belgium, Anderlecht (Brussels), where an extra railway track will be constructed alongside the existing tracks. For the foundation of the new bridge, a nailed jet grout wall was installed next to the existing railway. By doing so, the soil could be excavated vertically and

the foundation could be realised in an open construction pit. The excavation depth is 12.5m starting from the railways. The jet grout wall starts 4m below the railway level and has a total length of 21m. HEB profiles with a length of 21m are inserted in the jet grout wall. Five rows of nails are installed over the excavated depth. Figure 1 shows pictures before excavation and after excavation. The excavation is executed in different phases. Each time 2m is excavated and consecutively, a row of nails is installed. After installation of the nails, the contractor waits at least 2 weeks before excavating the consecutive part. More information on the site can be found in Van Alboom et al. 2012 and Verstraelen et al. 2013.

Figure 1. Picture of initial situation (left) and picture of the jet grout wall after excavation (right).

### 1.2.1 Deformation of and bending moments in the jet grout wall

To measure the deformation of the jet grout wall, both advanced and traditional monitoring equipment is installed:

- Fiber Bragg Grating (fiber optics, FBGS)
- SAAF (In-place inclinometer, Inventec)

- Optical strands (fiber optics, OSMOS)
- Traditional inclinometer (GEO)
- Draw Tower Grating (fiber optics, Belgian Building Research Institute (BBRI))
- BOTDR (fiber optics, Cambridge University)

The equipment for measuring the deformation of the wall or stresses in the wall, is placed on 4 HEB profiles which are lowered over their full length in the jet grout wall. Figure 2 shows a front view of the excavation site and the location of the instrumented profiles is indicated in red. Figure 3 shows a drawing and some pictures of the FBG and BOTDR fibers which are fixed to the HEB profile. The FBG fibers are fixed in small anchor blocks which are welded to the HEB profile (size of the anchor blocks is 18mm x 18mm). Those anchors are placed every 0.5m in the upper 8m of the profile and every 2m for the lower part. The BOTDR fibers measure the strain continuously, but are locally glued to the HEB-profile (every 0.5m and 2m) for better comparison with the FBG data. To measure deformations and moments perpendicular to the wall, fibers are placed on the top and bottom flange. To measure possible deformations parallel to the wall, two extra fibers are placed at the sides of the bottom flange. Extra L-profiles, placed above all fibers, are used as a protection during installation.

The other instrumentation was similarly fixed on the HEB profiles by welding or gluing.

Figure 2. Front view of excavation with indication of instrumented HEB profiles.

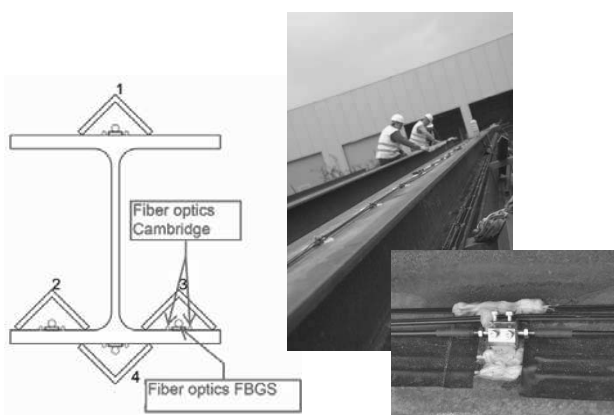

Figure 3. Sketch and pictures of a HEB profile which was instrumented with two optical fiber systems.

### 1.2.2 Settlements behind the jet grout wall

As one of the main concerns during an excavation are the settlements of the soil (and inherently the infrastructure) in the vicinity of the excavation, the vertical deformation of the soil behind the wall is one of the important parameters to be monitored. In this project specifically, deformations of the railroad track are to be avoided.

The deformations behind the wall are measured:

- with two horizontal inclinometers (a traditional one and a continuous SAAF inclinometer) which are placed perpendicular to the wall in the ballast underneath the rails. The inclinometers are attached to a Berliner wall, which is located at one side of the rails. It is assumed that this creates a fixed point;
- topographically: the rails are marked with survey nails along a length of 100m and vertical deformations are measured by topographic levelling at different stages of the project;
- with electrical beam sensors placed on the railway sleepers; the beam sensor consists of an electrolytic tilt sensor attached to a rigid metal beam. The beam, one to two meters long, is mounted on anchor bolts that are set onto the sleepers. The sensors are linked end to end, as to allow displacement values to be accumulated from anchor to anchor to provide a profile of differential movements or settlement.
- with two optical strands, placed at a certain angle with the railway on the railroad tracks .

Figure 4 gives a top view of the instrumentation which is placed on or underneath the railway tracks. It also shows the different HEB profiles which were instrumented.

Figure 4. Top view of installed equipment.

A more detailed description of all installed equipment is given in Van Alboom et al. 2012.

### 1.3 Design of the jet grout wall

Calculations of the jet grout wall are implemented in FLAC2D by TUC Rail. They result in a maximum horizontal displacement of 21 mm, a maximum moment of 65KNm and a maximum settlement of 9mm behind the wall in the final excavation phase. A more detailed description of the calculations is given in Verstraelen et al. 2013.

### 1.4 Sequence of the execution phases

Table 1 gives the sequence of the execution phases, retrieved from photos made on site every hour. As continuous monitoring was performed, the influence of the executed works on the movement of the soil could be assessed.

Table 1. Execution phases.

Date	information
22-23/10/2011	Installation of the instrumented HEB profiles in the jet grout wall
3/11/2011	Excavation up to 1,25m below the top of the concrete beam
06-09/11/2011	Installation of the first row of nails
06-07/12/2011	Excavation up to 3m below the top of the jet grout wall
08-12/12/2011	Installation of the second row of nails

11/01/2012	Excavation up to 5m below the top of the concrete beam
17-20/01/2012	Installation of third row of nails
01-02/02/2012	Excavation up to 7m below the top of the concrete beam
14/02/2012	Putting in gravel for ground improvement
17-21/02/2012	Installation of fourth row of nails
27/02/2012	Installation load cells GEO
08-09/03/2012	Unspecified drilling activity
12-13/03/2012	Excavation up to 8,5m below the top of the concrete beam
13-14/03/2012	Installation of 5 <sup>th</sup> row of nails

## 2 MEASUREMENTS

The measurements made by the 3 tenderers are continuous and data is transferred over the internet. The verification measurements, both with traditional equipment and innovative techniques are performed at discrete moments in time.

### 2.1 Deformation of the jet grout wall

The instrumentation is placed on the HEB profiles which are lowered in the jet grout wall. The traditional inclinometer and the SAAF measure the inclination of the profile every 0.5m, allowing direct derivation of horizontal deformation of the wall.

Figure 5 shows the horizontal deformation of the HEB profiles, measured with the traditional inclinometer and the SAAF. These measurements are both made on the same date and are taken after the installation of the fourth row of nails. The excavation depth at that time is 7m. The data fit very well together. The data from the SAAF start above the reference zero level (which is the top of the grout wall), as the HEB profile did not reach full depth and protruded about 1.7m above the top of the grout wall.

Figure 5. Horizontal deformation of the HEB profile on 07-03-2012.

The maximum horizontal displacement, measured after full excavation, amounts to 21 mm (26/04/2012) at a depth of 6.5m below the top of the grout wall for the inclinometer and 21.6mm for the SAAF. This lies very close to the calculated value of 22mm. It is found however that the direction at which the maximum deformation is found for the SAAF deviates slightly from the expected angle (perpendicular to the wall). This is probably due to a very small twist in between the different elements of the SAAF.

The other optical fiber instrumentation measures the strains in the HEB profiles and derivation of deformations can only be achieved by integration of the measured strains. This implies knowledge of the boundary conditions. Furthermore, the stiffness of the combination jet grout wall and HEB-profile needs to be estimated to obtain the deformation. It was found that there are a lot of assumptions which need to be made to obtain a reliable result. Further analysis will be attempted in the future.

### 2.2 Moments in the jet grout wall

From the inclinometers, the bending moment can be derived as:

$$M = EI \frac{d\alpha}{dx} \quad (1)$$

with E Young's modulus, I the moment of inertia of the HEB profile and  $\alpha$  the inclination.

From the fiber optics, which measure strains at regular intervals, the bending moment can be obtained as:

$$M = \epsilon EW \quad (2)$$

with  $\epsilon$  measured strain and W the section modulus. All fiber optics are mounted on the top and bottom flange of the HEB profile. Strains resulting from temperature differences or normal forces can thus be excluded and only the bending strain is withheld.

For the optical strand, measuring only 1 strain over its full length (top 10m of the HEB profile), the moment can also be derived with Eq.2, only this will result in 1 single bending moment and not in a bending moment as a function of depth.

Figure 6 shows the bending moments derived according to Eq. 1 and Eq. 2 for the different measuring techniques (except for the optical strand, as this does not result in a bending moment as a function of depth). Unfortunately, a lot of the FBG sensors placed by FBGS failed during the first weeks after installation. For this reason, they are not included in the graph. For the stiffness of the wall, the stiffness of the HEB profiles was used, as the instrumentation is placed on these profiles.

The discontinuous and continuous measurements were not always measured on the exact same dates. However, all measurements are made after the final excavation phase.

Figure 6 shows that all derived bending moments give comparable values, except for the SAAF. This can be explained by the fact that the deformation measurements of the SAAF are less "smooth". As the bending moment is a result of the derivative of the measured inclination, this results in unexpected peak values.

A maximum bending moment of about 55 kNm is derived from the measurements. This is again in the same order of magnitude as the calculations (maximum calculated bending moment of 65 kNm). For the optical strand, the derived bending moment is about 35kNm, which is considerably lower than the other measurements. Due to the smoothing which is used for the BOTDR measurements, the peak bending moment is also reduced and has a value of 39kNm, which is also less than the value obtained by the inclinometer and the FBG technique from the BBRI. The shape of the bending moment curve however, is comparable to the other results.

Figure 6. Bending moment HEB profile after the last excavation.

### 2.3 Settlements behind the jet grout wall

The calculated settlement prior to installation is 5mm. The measurements indicate a maximum settlement varying between 50 mm and 70mm for the different measuring techniques, which is much larger than the calculated value. Figure 7 shows the evolution in time of the maximum settlement value as measured by the SAAF. It demonstrates the great advantage of measuring continuously.

Figure 7. Maximum settlement as a function of time for the horizontal SAAF.

When comparing Table 1 with Figure 7, it can be seen that the discontinuities in the settlement curve correspond each time with the installation of the nails. In Verstraelen et al. 2013, it is explained that this is due to the execution of the jet grout nails. The settlement on 25/02/2012 is caused by lifting the tracks, due to which the inclinometer was locally displaced.

Figure 8 shows the settlement measured by the horizontal inclinometer and the SAAF on two different dates. The zero settlement point corresponds with the fixed point on the Berliner wall. A significant difference between the settlements measured with the two techniques can be observed (approx. 30%). When comparing with the topographical levelling, it can be concluded that the measurements made with the horizontal SAAF are closest to the real settlements. This can be explained by the limited length of the inclinometer tubes (8m) and the fact that the stiffness of a traditional inclinometer tube is quite high for such a short distance (and large settlements).

The “bump” in the measurements of the SAAF (circled in Figure 8) is caused by the lifting of the tracks on 25/02/2012, as explained above. This “bump” has no influence on the settlement which is measured at the end of the railway tracks.

Figure 8. Settlements measured with hor. SAAF and hor. inclinometer.

The measurements made with the electrical beam sensors give comparable results to the measurement of the SAAF. The data measured with the optical strands appears to be uninterpretable. This is probably because it was in no way connected to a fixed point.

### 3 CONCLUSIONS

An extensive monitoring program was set up to compare different monitoring techniques. It appears that both new and traditional techniques can lead to the same result, when sufficient care is taken to the installation and interpretation. A significant advantage can be seen when continuous monitoring is applied, as the link with execution phases can be made.

**RÉSUMÉ :** EDF est maître d'ouvrage de plus de 500 km de digues, dont certaines qui forment une protection d'aménagements intéressant la sécurité publique. Afin d'améliorer la sûreté de son parc, EDF travaille au concept de maintenance préventive. Il s'agit de concevoir, réaliser et gérer un système de détection précoce d'anomalies (dont les principales sont les fuites et les déformations), un modèle d'interprétation et une chaîne d'interventions précises comportant alarmes techniques, administratives et travaux de réparation adaptés. Dans ce cadre, EDF travaille depuis 1994 à développer l'utilisation de mesures réparties par fibre optique pour améliorer la surveillance des digues. En effet, la technologie fibre optique permet d'avoir une mesure de température et/ou de déformation répartie tous les mètres le long de celles-ci, mesurée en continu. Cette nouvelle technologie, placée stratégiquement dans l'ouvrage, permet de compléter la surveillance habituelle du comportement hydraulique et mécanique, assurée à ce jour avec une instrumentation classique (nivellement, piézomètre, drain), par une surveillance à la fois globale, détaillée et surtout apte à la détection des phénomènes extrêmes et des états de crise (crue, séisme, vandalisme). Cet article présente le principe de la surveillance des digues de canaux par fibre optique ainsi que les résultats de validation de cette technologie tant à l'échelle de sites test que sur sites réels du parc d'EDF.

**ABSTRACT:** EDF owns more than 500 km of dikes, some of them protecting large critical structures involving public security. In order to improve the safety of its stock of power plants, EDF develops the concept of preventive maintenance. It means design, building and operation of an early warning monitoring system (leakage and strains), plus model of interpretation and portfolio of technical or legal alarm and interventions. In that framework, EDF has been working since 1994 on the development of the use of the distributed measurements with fiber optic, to improve the monitoring of dikes and flood embankments. The fiber optic technology provides a remote control measurement of the distributed temperature and strain every meter along the embankment. This new technology strategically placed in the fill, allows to reinforce the hydraulic and mechanical behavior monitoring, which is provided to date by conventional instrumentation (leveling, piezometer, discharge rate), with simultaneously a global and detailed surveillance and an early warning system for extreme loadings and crisis (floods, earthquakes, vandalism). This paper introduces the principle of dikes monitoring using fiber optic and the validation results of this technology from both trial test sites and on EDF's real sites.

### 1 INTRODUCTION

En 1995, EDF est le premier gestionnaire d'ouvrages hydrauliques à tester la technologie de mesure de température répartie par fibre optique pour la surveillance des fuites d'une digue. Sur les digues, il est courant d'observer des fuites soudaines, sans que les piézomètres ne détectent une variation de la surface libre. Cette observation, souvent répétée sur des ouvrages variés, montre à quel point le phénomène d'érosion interne, à l'origine de la fuite, est local. EDF, sensibilisé à ces manifestations d'érosion interne, lors de la mise en eau des digues d'Isère Moyenne Aval en 1991, en conclut que la détection précoce de l'érosion interne ne peut pas être envisagée avec l'espacement habituel des piézomètres, mais plutôt avec un espacement de l'ordre du mètre et un système d'acquisition marchant en continu. Dans le cadre d'un groupe de travail constitué avec la CNR en 1993, il apparaît que la méthode thermométrique de GTC, détectant les anomalies thermiques provoquées par un écoulement préférentiel dans le remblai avec des mesures de température dans des forages implantés tous les 20 m, est la méthode la plus efficace pour localiser la zone de fuite. D'autre part, Johansson propose à cette époque une interprétation des mesures de thermométriques, apte à en

extraire la perméabilité et à suivre son évolution dans le temps. EDF en déduit en 1994 que la détection de l'érosion interne par l'augmentation de la perméabilité dans le temps est possible grâce aux mesures à l'interprétation de température, comme l'écrit plus tard Johansson (1997) dans sa thèse.

Cependant, la méthode n'est pas prédictive : l'intervention est curative. Il faut un nouveau saut technologique, pour détecter l'initiation de l'érosion interne, surveiller son évolution au fil du temps et décider d'une intervention ou non. Quel système a l'aptitude de mesurer la température tous les mètres et en permanence ? En discutant avec Jürgen Dornstädter en 1994, patron de GTC, EDF met en parallèle le contrôle de l'érosion interne et le contrôle des câbles électriques enterrés. Ces derniers sont mis en place avec une fibre optique, en vue de détecter à tout moment, une éventuelle coupure accidentelle du câble. L'outil existe donc à cette époque ! Il reste à l'adapter au contexte de la surveillance des ouvrages hydrauliques. Cela nécessitera plus de 15 années d'étude... Dès le premier test avec une fibre optique d'une centaine de mètres, en juillet 1995, la détection de fuites, dans le canal de drainage en pied de la digue Cusset, montre que la détection des fuites est possible, mais qu'elle est dépendante de la technologie et exige une forte précision de la mesure. D'autre part, le diagnostic est entaché de

difficultés d'interprétation, suite aux nombreux biais physiques : changement thermique de l'eau canalisé, rayonnement, pluie, perte de signal dans les soudures ou les rayons de courbure trop courts. Ce premier bilan montre l'importance de la difficulté, du temps et des moyens qu'il faudra développer, pour aboutir à une surveillance fiable. Cependant le fort enjeu de sécurité justifie les nombreux efforts pour surmonter ces difficultés. EDF veut améliorer la sûreté des aménagements les plus sensibles, en démontrant une détection précoce, un diagnostic fiable et une intervention préventive minimisant le coût la réparation. Depuis, EDF, maître d'ouvrage, développe et valide méthodiquement cette métrologie (Fry 2004).

Cet article introduit le principe de cette maintenance préventive, montre les principaux résultats de qualification et évoque le déploiement opérationnel de cette technologie.

## 2 LA MAINTENANCE PREVENTIVE

### 2.1 La mesure par fibre optique

Le principe consiste à envoyer un rayon lumineux de laser dans une fibre optique standard, dont les défauts installés à pas régulier, souvent 1 m, vont rétrodiffuser le signal, qui sera analysé par un interrogateur optoélectronique et identifié par son temps d'aller-retour et son spectre en fréquence. Les pics du spectre, dépendant de la température et de la contrainte, mesurent d'une manière indirecte et surtout répartie la température et la déformation le long de celle-ci. Les interrogateurs optoélectroniques disponibles sur le marché actuellement permettent d'obtenir une mesure tous les mètres, avec une portée allant jusqu'à 20 à 30 km. En choisissant bien l'interrogateur et en utilisant des fibres standard télécom multimodes, la précision est de 0,1°C pour une mesure de température seule avec un interrogateur Raman et une distance inférieure à 10 km. A partir d'une fibre optique monomode contrainte dans un câble, la précision des mesures de température et de déformation par un interrogateur Brillouin est de l'ordre de 1°C et de 20µm/m.

### 2.2 Surveillance active ou passive

La méthode thermométrique initiale de GTC mesure une seule fois la température. Comme ce n'est souvent pas suffisant, GTC développe un test de convection forcée, où la température est imposée par chauffé ou réfrigération (Dornstädter J. 2010). Ce mode opératoire est appelé méthode active, en opposition à la méthode passive, consistant à mesurer les températures naturelles. Le débat, autrefois vif entre les partisans de l'une ou de l'autre approche, laisse maintenant une place à chaque méthode.

Johansson (1997) n'utilise que la méthode passive associée à une modélisation numérique des échanges thermiques. EDF montre qu'une interprétation simpliste de la méthode passive dans un milieu non saturé aboutit à un diagnostic faux. Pour surmonter cette incohérence, EDF développe d'autres modèles d'interprétation, valables quelle que soit la position de la fibre optique ou celle de la nappe. Quatre modèles sont complémentaires (Beck & al. 2010), les deux premiers sont physico-statistiques, issus de la pratique de l'auscultation, tandis que les suivants sont basés sur le traitement du signal. La méthode passive a l'avantage de permettre la surveillance permanente et d'identifier les fuites à plus d'un mètre de la fibre. Son inconvénient est de nécessiter la mesure de la température de l'eau stockée ou canalisée et celle de l'air et un modèle d'interprétation complexe à plusieurs niveaux de traitement.

Perzmaier, Aufleger et Dornstadter (2007) ont été les précurseurs de la méthode active, en entourant la fibre optique d'un câble de cuivre chauffé par effet Joule sur une courte période de temps. La puissance électrique nécessaire est de 3 à

15 W/m. Cette méthode présente l'inconvénient d'être applicable uniquement à des tronçons limités de digues (< 2 km), d'avoir un faible rayon d'action (< 20 cm autour du câble), de ne pas permettre une surveillance en continu et de nécessiter quelques précautions de conception et d'utilisation afin d'assurer la sécurité du personnel.

### 2.3 Le concept de maintenance préventive

Le choix d'un système de surveillance par fibre optique n'est pas justifié sur tous les ouvrages. Une stratégie basée sur l'évaluation du risque ne montre pas de bénéfice à équiper ni les grands barrages de bonne conception, dont la sécurité est assurée par une surveillance habituelle, ni les petits barrages de risque limité, dont la rupture aurait peu de conséquences. A l'opposé, un système de détection par fibres optiques apporte un gain justifié quand l'ouvrage est de grande longueur, sur une fondation mal connue ou édifié avec une conception non conforme à l'état de l'art actuel, dont le coût de réparation est lourd pour le maître d'ouvrage, alors que des zones de faiblesse sont suspectées sans qu'elles soient localisées, laissant un doute sur la sécurité dans le temps ou en conditions extrêmes.

Le système de surveillance par fibre optique apporte dans tous les cas un complément au réseau habituel d'auscultation. C'est un outil d'aide à la gestion de crise. Que se soit après un séisme ou une crue, il a la capacité de localiser en temps réel les zones à risque et donc d'améliorer la gestion des ressources et d'accroître l'efficacité des interventions.

Le choix de la méthode et du modèle d'interprétation est lié à la stratégie du maître d'ouvrage : surveillance long terme ou court terme, pathologies à suivre, gestion du risque sismique. La mise en place de ce système de surveillance est identique à celui de la méthode observationnelle, en réunissant quatre conditions :

1. Les limites admissibles du comportement en température et/ou en déformation sont évaluées par modélisation avant d'être mesurées;

2. Le domaine des variations possibles du comportement thermique ou cinématique est jugé acceptable. Un tel système d'auscultation n'est installé que si la marge de sécurité est jugée acceptable, dans le cas contraire il s'agit de programmer en urgence la réhabilitation;

3. Le programme de suivi est établi pour vérifier si le comportement réel reste dans les limites admises. La fréquence d'acquisition est suffisamment élevée pour que le dispositif puisse détecter l'apparition de toute fuite, vérifier par la progression du phénomène s'il s'agit d'érosion interne et laisser le temps de réparer. Le choix de la méthode passive ou active doit être justifié par rapport à la cinétique des phénomènes attendus;

4. Un programme d'interventions d'urgence est défini au cas où le suivi révèle un comportement sortant des limites admissibles.

L'avantage de la maintenance prédictive est de limiter les zones endommagées par la détection précoce des pathologies menant à n'importe quel mode de rupture. Il existe 3 modes de rupture potentiels : l'érosion externe, l'érosion interne et le glissement. Chacun de ces trois modes est intercepté par le système de surveillance à base de fibres optiques de mesure de température et de déformation. Les mesures de température repèrent le risque de rupture par érosion et les mesures de déformation détectent le risque d'instabilité générale. Cela est bien démontré par les résultats du projet IJkdijk en Hollande (Koelewijn A. 2010) et (Beck & al. 2010).

## 3 VALIDATION DE LA DÉTECTION PRÉCOCE DE LA RUPTURE

L'été 2003, en pleine canicule, la digue de Wilnis se rompt, quelques heures après une inspection visuelle. La démonstration est faite que l'inspection visuelle, souvent essentielle à la

surveillance, ne garantit pas à elle seule la sûreté. Le gouvernement hollandais en prend conscience. Il décide de lancer le projet IJdijk en vue de sélectionner les meilleures technologies de détection précoce de la rupture. EDF, associé à Tencate, Géophysconsult et au projet PAREOT, voit une opportunité hors du commun de tester son approche de la sûreté.

### 3.1 Rupture par instabilité générale

Le premier test en 2008 concerne la détection du glissement d'une digue, chargée par des containers et dont le pied est excavé. 4 fibres optiques mesurent l'élongation du parement aval (Figures 1 à 3). La surface de rupture est bien détectée.

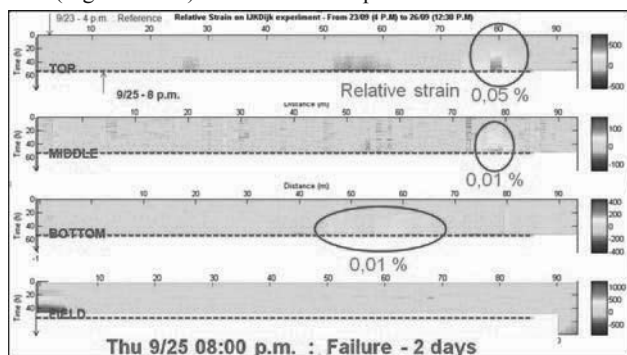

Figure 1: Elongation des 4 fibres optiques 2 jours avant la rupture

Figure 2: Détection de la surface de rupture par les 4 fibres optiques

Figure 3 : Glissement de la digue (photo Koelewijn)

### 3.2 Rupture par érosion interne

Le système de détection est de nouveau testé sur les 4 essais de détection de rupture par renard des digues expérimentales du projet IJdijk en 2009. Les remblais mesurent 3,5 m de hauteur, 15 m de longueur et ont un fruit H/V=2/1 à l'amont et aval. Les fibres optiques passives sont installées avec Tencate dans la

fondation au contact du remblai (Figure 4). La rupture est obtenue par érosion régressive en montant par palier le plan d'eau amont. La durée de l'essai varie de 4 à 6 jours. La détection visuelle et la détection par analyse de signal sont représentées respectivement sur les figures 5 et 6.

Figure 4 : Installation des fibres sous le remblai

Figure 5 : Détection visuelle du renard 2 jours avant la rupture

Figure 6 : détection du renard par analyse du signal

La Figure 5 montre que l'analyse visuelle détecte le renard en formation sans erreur deux jours avant la rupture dans le test N°2. La figure 6 illustre l'intérêt de l'analyse de signal sur le même test. Le réservoir est rempli le 19/10/2009 d'une charge d'eau de 1,9 m à 12h00. L'essai s'achève le 25/10/2009 à 10h00 par la rupture de la digue. Les données sont rapatriées à distance et analysées au pas journalier par géophysConsult du 19/10 à 9h18 au 25/10 à 9h10. La transformation des données de

température par analyse du signal détecte un clair précurseur de la rupture plusieurs jours avant l'analyse brute des données. Sur la Figure 6, l'absence d'anomalie au cours de la première journée d'essai (19-20/10) correspond bien à l'absence d'observation de fuite sur le terrain. Les jours suivants, des fuites sont observées et visualisées par un rectangle bleu, alors que l'entraînement et le dépôt de sable est représenté par un rectangle rouge. Le modèle d'analyse détecte bien une fuite croissante vers l'abscisse 9-10 m, là où la rupture va se produire 5 jours plus tard.

Pour chacun des quatre essais, le modèle d'analyse développé par EDF apparait plus performant que la visualisation des mesures brutes (tableau 1). Le temps de détection varie d'un test à l'autre, car les fibres n'ont pas pu être posées exactement aux endroits demandés par EDF. Cela montre l'importance de la localisation des fibres dans la conception du système de détection.

Tableau 1. Durée entre la détection et la rupture

Test	Durée (jours)	Détection visuelle	Détection analyse du signal
1	4	3 heures	3 jours
2	6	48 heures	5 jours
3	5	31 heures	3 jours
4	5	21 heures	1 jour

### 3.3 Bilan des tests de validation de IJkdijk

Que ce soit pour la détection du glissement ou de l'érosion interne, le système de fibres optiques accompagné d'un robuste modèle d'interprétation apparait la méthode la plus performante (robustesse et justesse) parmi les technologies de détection testées par la trentaine de participants du projet international.

Conforté par ces résultats d'inter-comparaison des pratiques internationales, EDF programme et déploie cette maintenance préventive en 2010 sur une série de travaux visant à réhabiliter certains biefs hydro-électriques et à optimiser leur maintenance.

## 4 APPLICATIONS

EDF dispose en 2012 de quatre ouvrages instrumentés et suivis par fibre optique. Ainsi, le canal de Curbans, de 5 km de longueur, est instrumenté par 11 km de fibre optique et est aujourd'hui suivi périodiquement par des mesures de température actives et passives. Des mesures de déformation sont faites à une fréquence plus faible. La surveillance par fibre optique de la remise en eau de l'ouvrage à la fin des travaux de réhabilitation contribue à détecter rapidement les zones de fuites (résultats de surveillance toute les 4 heures) et à diminuer les pertes d'exploitation remboursant son coût d'installation. La surveillance actuelle de l'ouvrage en exploitation montre une bonne corrélation entre les résultats d'analyse des données de température par fibre optique et les débits de drainage sous l'étanchéité rénovée, captés tous les 300 mètres. Ils mettent en évidence une décroissance due au phénomène de colmatage. Les mesures de déformation identifient trois secteurs de déformations différentielles à suivre de près.

## 5 CONCLUSION

La maintenance préventive par un système de fibres optiques permet une mesure en continue et répartie dans l'espace d'anomalies thermiques ou mécaniques, une détection précoce

des risques de rupture, une optimisation des ressources en situation de crise et une économie sur les durées d'indisponibilités ou le coût des travaux de réhabilitation. Elle est adaptée aux ouvrages de grand linéaire ou à ceux qui posent des difficultés de conception ou sont très sensibles au niveau de la sûreté.

## 6 REMERCIEMENTS

Nous remercions les nombreux partenaires (de Deltares, EDF R&D, GTC, Hydroresearch, Irex, Irstea, Tencate, Université de Grenoble) qui ont accompagné EDF et ont contribué à la qualification de la technologie à base de fibres optiques pour la surveillance des ouvrages hydrauliques.

# Evaluation of diaphragm wall as-built data to determine the risk of leakage for the Kruisplein car park excavation in Rotterdam, The Netherlands

Evaluation des données de fabrication des murs diaphragmes pour déterminer le risque de fuite dans le chantier du parking souterrain Kruisplein à Rotterdam, Pays-Bas

Hannink G.

*Engineering Consultancy Division, City of Rotterdam, The Netherlands*

Thumann V.M.

*Seaway Heavy Lifting Engineering B.V, The Netherlands, formerly Engineering Consultancy Division, City of Rotterdam, The Netherlands*

**ABSTRACT:** In the centre of Rotterdam, the Kruisplein car park is becoming the deepest underground parking facility in the country. It is being constructed since 2009, and will provide around 760 parking places on a total of five floors, of which the deepest is reaching to almost 20 m below ground surface. The retaining wall has been designed as a diaphragm wall reaching from ground surface to approximately 40 m depth. Because of some major leakage incidents in diaphragm wall type excavations in Rotterdam and elsewhere in The Netherlands, additional effort was raised to define and prepare mitigating measures to reduce the risk of leakage for the Kruisplein car park project. An extensive evaluation of as-built data of the diaphragm wall was made, including all available field records of process-parameters. Based on the outcome of the evaluation, it has been concluded that in general the diaphragm walls were of sufficient quality. No major leakage incidents have occurred to date.

**RÉSUMÉ :** Dans le centre de Rotterdam, le parking de la place Kruisplein est en train de devenir le plus profond garage souterrain du pays. Ce parking est en construction depuis 2009 et pourvoira 760 places de stationnement réparties sur cinq niveaux. Le plus profond d'entre eux atteint plus de 20 m de profondeur sous la surface du sol. Le mur de soutènement a été conçu comme une paroi moulée atteignant approximativement 40 m de profondeur. À cause de divers accidents majeurs de fuites d'eau survenus dans des excavations utilisant des parois moulées à Rotterdam et ailleurs dans les Pays-Bas, des efforts supplémentaires ont été fournis pour définir et préparer des mesures d'atténuation pour réduire le risque de fuite lors du projet du parking Kruisplein. Une évaluation étendue des données des parois moulées, incluant toutes les données de chantiers enregistrées lors de leur fabrication, est présentée. Il n'y a eu jusqu'à ce jour aucun incident majeur de fuite sur le chantier de Kruisplein.

**KEYWORDS:** diaphragm wall, deep excavation, risk of leakage, field records, as-built data, mitigating measures.

## 1 INTRODUCTION

In Rotterdam diaphragm walls are regularly applied since the construction of the Willem Railway tunnel in the nineties of the past century. For underground infrastructural projects, it is an appropriate building method, because it facilitates deep excavations under dry conditions. By connecting the diaphragm walls to the rather impermeable soil layers of the Formation of Waalre a dry building pit can easily be created. The geological conditions are favorable for this building method: in the centre of Rotterdam the rather impermeable layers of the Formation of Waalre are everywhere present between 35 and 40 m below sea level (this corresponds to the Dutch reference level NAP).

Diaphragm walls have been applied at several locations of the metropolitan light rail project RandstadRail in the beginning of this century. During the extension of metro station CS a major leak through the diaphragm walls arose when the excavation inside the building pit was at its maximum depth (14 m below sea level). As a result a huge amount of water and sand entered the building pit. With a lot of trouble, the leak was fortunately stopped within two days, and the construction of the metro station could be continued (Thumann et al. 2009).

In the same period the preparation of the underground car park Kruisplein was in full swing. The design consisted of 40 m deep diaphragm walls to make a 20 m deep excavation possible. A logical question at that moment was, how to minimize the possibility of a similar incident during the construction of the car park. This paper describes the mitigating measures taken in advance, the supervision during the construction, and the effectiveness of the precautionary measures in practice.

The construction of the Kruisplein car park is part of the overall project Rotterdam Centraal (Hannink & Thumann 2007). This major project comprises of the building of a large

Public Transport Terminal in the vicinity of the Rotterdam Central Railway Station. It is designed to facilitate passenger transfer between (inter)national trains including the high-speed train, and local public transport like trams, buses and underground trains. The excavation as required for the construction works of the Kruisplein car park covers about 5.000 m<sup>2</sup>.

Engineering of the car park Kruisplein, and supervision of the execution of the project is performed by the Engineering Consultancy Division of the City of Rotterdam.

Figure 1. Building pit of car park Kruisplein.

## 2 SOIL CONDITIONS

The ground level in the area is situated at about sea level. The geotechnical profile of the Rotterdam city area consists of anthropogenic layers (from ground level to about 5 m below sea level), and soft Holocene peat and organic clay layers (from about 5 to 17 m below sea level). Below this level Pleistocene coarse sand layers are encountered up to 35 to 40 m below sea level. These sand layers are underlain by the Formation of Waalre, consisting of over consolidated clay and sand layers. Figure 2 shows the result of a CPT. The phreatic groundwater level is about 2 m below sea level.

Figure 2: Results of a CPT at car park Kruisplein.

## 3 RISK ANALYSIS

In this project the principal is responsible for the design, and the contractor is responsible for the construction. The contractor is obliged to present plans about the way the risks connected to the building method are controlled, including relevant solutions and mitigating measures.

The possibility of leakage into a building pit with diaphragm walls is small, but the consequences may be very serious in case groundwater flows into the building pit. Especially in an urban environment a sand carrying leak is seen as a huge risk. Piles are founded in the sand layer with the top at 17 m below sea level. This is the same sand layer that may flow into the building pit. There are several possible causes for leakage out of this sand layer:

- the panels of the diaphragm wall are insufficiently connected;
- the base of the panel is not or insufficiently connected to the impermeable layer, for example as a result of the presence of an obstacle;
- the concrete of the panel contains intrusions of sand, peat or clay, that form weak spots in the diaphragm wall;
- the concrete of the panel contains bentonite, that forms weak spots in the diaphragm wall.

The starting point in the design stage of the car park was that the diaphragm walls would be placed at least 1.5 m into the impermeable layers of the Formation of Waalre. At the deepest point of the excavation the diaphragm wall must be able to retain a groundwater pressure difference of about 20 m.

Measures to minimize the possibility of a leaking diaphragm wall were prescribed in the contract. However, to minimize the possibility of leakage, the most was expected of measures that could facilitate the building process.

The outcome of the risk analysis indicated that to minimize the possibility of a leaking diaphragm wall:

- additional requirements should be prescribed in the contract;
- early observations of imperfections during the building process are of utmost importance;
- the execution of the project has to be monitored adequately;
- the analysis of as-built records is essential as to identify hazardous locations.

## 4 MEASURES IN THE CONTRACT

The building contract included Dutch standard RAW specifications regarding quality control of the diaphragm wall building process. The following additional contract requirements have been defined:

- the verticality of the panels shall be within 0.5% of the depth in both transverse and longitudinal directions;
- the horizontal deviations of the exposed face of a panel shall be less than 100 mm;
- 150 mm wide water-stops (rubber profiles) shall be put into every steel stop end of the diaphragm wall;
- the concrete surface of adjacent panels shall be cleaned from bentonite cake before the commencement of concreting;
- the maximum rate of concrete rising in the trench shall be 6 m/h in the Holocene clay and peat layers;
- a good connection between the floors and the diaphragm walls shall be secured. It is important not to drill unnecessary additional holes for reinforcement bars into the diaphragm walls. Zones of overlap of the reinforcement of the diaphragm wall were not allowed at the locations of the reinforcing bars;
- the maximum aggregate particle size of the concrete shall not exceed 16 mm.

Concreting records of the diaphragm wall panels had to be made to register the following possible execution imperfections:

- the time during which the trench is left open before concreting;
- the deviations of the steel stop ends;
- the deviations of the reinforcement;
- steel stop ends which are left behind;
- discontinuities in concreting.

After completing the diaphragm wall, and before starting the excavation, a check had to be made on the permeability of the building pit by means of generating a 20 m pressure difference between inside and outside of the diaphragm wall. This pumping test was meant to deliver information about the water tightness of the diaphragm wall in the sand layer with the top at 17 m below sea level, and about the water tightness of the rather impermeable layers at 40 m below sea level. A successful test however, does not exclude leakage in the execution phase, because the diaphragm wall will be excavated at one side, and will deflect. This may result into open joints between the panels.

According to the contract four boreholes for so-called sleeping wells had to be drilled around the building pit, to be able to act quickly in case of a leak. The purpose of these 'sleeping' wells was, in case of a calamity, to decrease the difference in water pressure between the inside and the outside of the building pit as soon as possible. This will make it easier to control the amount of groundwater that penetrates the building pit. The installation of pumps and mains was not required in the contract. The idea was that in case of a calamity the mobilization period would be limited.

## 5 MEASURES DURING THE EXECUTION

It was considered to be important to specify the most vulnerable processes into a number of documents that made it possible to control the processes:

- the excavation plan describes the sequence of the execution of the panels of the diaphragm wall as to minimize the possibility that a leak will occur during the night;
- the supervision plan for the construction of the diaphragm wall and for the excavation of the building pit is meant to detect imperfections in an early stage during the excavation;
- the calamity plan describes the risks connected to the construction of the diaphragm wall and the available mitigating measures at the moment of signaling a (potential) leak or a threatening calamity;
- results of monitoring activities and records give detailed information on the execution of each panel, and of possible imperfections. It is of utmost importance that the content of the documents and the point in time of handing them in are mutually agreed;

The results of the supervision by both the principal and the contractor are discussed at the building meetings, and a separate regular monitoring meeting with all persons concerned was convened.

## 6 ASSESSMENT OF DIAPHRAGM WALL QUALITY

All relevant data have been evaluated to determine potential weak-spots in the diaphragm wall along the excavation circumference.

### 6.1 Pumping test

The pumping test to check the water tightness of the diaphragm walls was executed in June 2010. The measuring results showed that the water tightness of the building pit as a whole met the requirements as formulated in the permit for water extraction. This implicated that the average quality of the diaphragm walls came up to expectations about water tightness in not excavated circumstances.

### 6.2 Field observations

Field observations by both the contractor and the supervisors of the City of Rotterdam were meant to record regular and any extraordinary circumstances during the building process of each individual panel. In practice, general data on the duration of the consecutive building stages (a.o. excavating, refreshing of bentonite suspension, lowering of steel reinforcement, concreting) and identification of excavated soil type (sand or clay) have been recorded. For some panels, underground obstacles were encountered.

### 6.3 As-built documents

Information from as-built documents has been thoroughly examined to detect any hazardous sections of the diaphragm panel. These data have been visualized as for example shown in Figures 3 to 5. Figure 3 shows amongst other things the elapsed time between:

- the start of the excavation of the trench and the start of the installation of the steel stop ends;
- the start of the installation of the steel stop ends and the end of the excavation of the trench;
- the end of the excavation of the trench and the start of the cleaning of the concrete surface;
- the start of the cleaning of the concrete surface and the start of the installation of the reinforcement cage;
- the end of the installation of the reinforcement cage and the commencement of concreting.

Long periods of elapsed time for a particular activity may indicate an increased risk of imperfections.

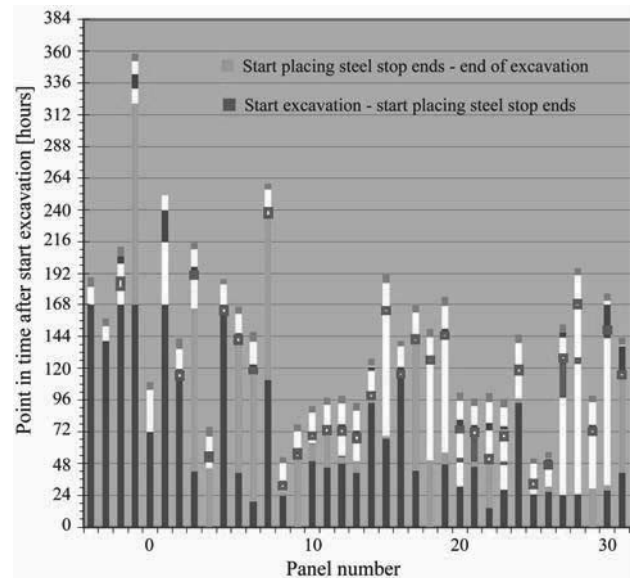

Figure 3. Continuity of the production process.

Figure 4 shows the calculated deviation of wall thickness as can be calculated from the concreting progress reports. From Figure 4 it can be identified where the panels are suspected to have a reduced thickness of more than 0.2 m. However, it is recommended to have more detailed information on the progress of the concreting process for future projects, as to increase the resolution (reliability) of this graph.

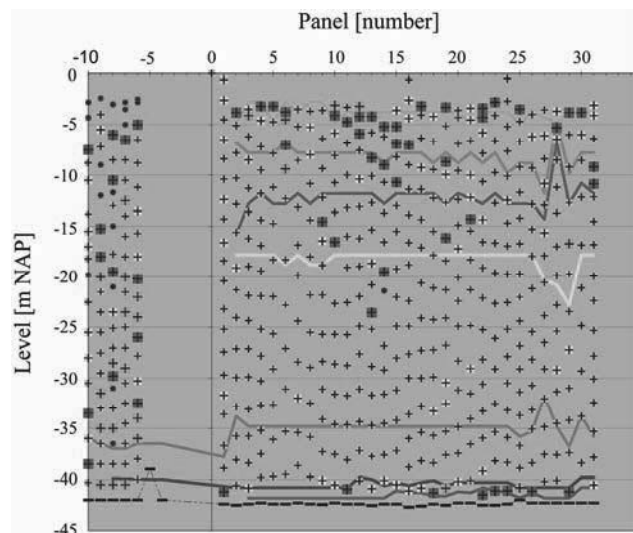

Figure 4. Deviation of panel width (data originating from leveling data and concrete consumption). The separation of the different soil layers as derived of excavation data and of geotechnical investigations is also indicated.

Figure 5 shows the position of all diaphragm wall panels at 40 m depth, as derived from crane operating monitoring equipment. Most of the panels have been excavated in two or three parts, thus giving at least two monitoring records (inclination and deviation vs. excavation depth) per panel. From Figure 5 it can be identified where the panels are suspected to have insufficient overlap. The diaphragm wall thickness as designed was 1.20 m; the allowable position with respect to overlap (zone width of 1.60 m at 40 m depth) follows from the 2% deviation of the verticality.

Figure 5. Relative position of the panels at 40 m depth. Dark represents the outside of the diaphragm wall; light the inside. The dotted red lines represent the 2% deviation of the verticality.

#### 6.4 Non-standard measurement techniques

Reference is made to Doornenbal et al. (2011) and Spruit et al. (2011) for more information on the experiments using non-standard measurement techniques to detect imperfections in diaphragm walls, which appeared to be quite successful.

#### 6.5 Increased risk of leakage

Combined interpretation of Figures 3 to 5 reveals areas where an increased risk of leakage has to be anticipated for, as compared to normal conditions. Following aspects have been evaluated using the outcome of the interpretation of the as-built records:

- a missing/damaged water-stop;
- no cleaning of the concrete surface;
- the elapsed time between refreshing of the bentonite and the commencement of concreting greater than 24 hours;
- encountered problems during the stop end removal works;
- concrete characteristics;
- wall thickness reduction > 0.20 m (Figure 4),
- reduced overlap < 0.80 m (Figure 5).

An overview of locations with an increased risk of leakage along the excavation circumference has been generated as shown in Figure 6.

Figure 6. Increased risk of leakage.

Subsequently, a number of mitigating measures has been defined for each individual panel as to compensate the increased risk. It appeared from the overall risk analysis that careful positioning of four ‘sleeping’ wells around the excavation would provide sufficient means for acting in case of leakage at any of the identified weak spots as shown in Figure 7. Additionally, for a number of panels it has been recommended to call for an intensified inspection and repair program (when necessary) during the excavation works.

## 7 CONCLUSIONS

The realized diaphragm wall panels were in general of sufficient quality. A number of hot spots along the circumference of the building pit with an increased risk of leakage were identified. The risk profile related to leakage was considered to be at an

acceptable level if a number of mitigating measures were executed. These measures were supplementary to the required measures in the contract.

A pumping test to check the water tightness of the diaphragm walls is very valuable in case the subsoil conditions are similar to those in Rotterdam.

Supervision of the construction process appeared to be an important mitigating measure, in combination with the registration of the execution data of the diaphragm wall, and the subsequent analysis of these data.

The extensive acquisition of data as such is not new for the construction of diaphragm walls, but the systematic analysis of the data, as performed for this project, has not been noticed so far. It is recommended to do so for all future projects.

The positioning of ‘sleeping’ wells can be considered as a major mitigating measure, and is a lesson learned from the construction of the (leaking) diaphragm wall at metro station CS.

Figure 7. Positioning of the four ‘sleeping’ wells east and west of the building pit. Additional wells may be installed at the north and south side in case of a calamity in the northern or southern wall.

## ACKNOWLEDGEMENTS

The work on this subject of former colleagues Edwin Dekker and Rens Servais is gratefully acknowledged. Records of the execution of the diaphragm walls have been provided by the contractor Besix BV. Colleague Arie van de Heerik collected most of the records, and Ton de Keiser prepared the illustrations in this paper.

# Optimisation of bridge approach treatment via staged construction

## Optimisation du traitement de remblais d'accès à des ponts par phasage des travaux

Hsi J.P., Carson D.J., Lee C.H.  
SMEC Australia Pty Ltd, Australia

**ABSTRACT:** This paper describes an improved approach to bridge embankment transition design and construction staging that was utilised to overcome financial and programme challenges associated with the proposed initial design solution for bridge approach embankments. An alternative staged approach was developed for construction, comprising improvement of the strength and compressibility characteristics of the soft soil foundation by surcharging techniques in combination with use of prefabricated vertical drains (PVD) and high strength geotextile. Unreinforced continuous flight auger (CFA) columns were installed after surcharging to achieve smooth transition at bridge approach embankments. During construction, the behaviour of the foundation under load was closely monitored and back analysis of the performance of the improved foundation was undertaken. Construction stage design optimisations were then made to satisfy the design criteria using actual monitoring data. This approach to bridge embankment transition design provided ability for the entire subsurface profile to accommodate the applied embankment loading. As a result, major cost, programme and environmental benefits were realised during construction by avoiding the installation of approximately 88,900 lineal metres of concrete foundation piles that were specified in the initial design.

**RÉSUMÉ :** Cet article décrit une approche améliorée pour la conception et le phasage des travaux de remblais d'accès aux ponts. Cette approche a été utilisée pour répondre aux contraintes financières et de planning associées à la solution initiale proposée. Une approche alternative en termes de phasage des travaux a été développée et comprenait l'amélioration de la résistance et de la compressibilité du sol de fondation (argile molle) par l'installation de remblais de chargement, de drains verticaux préfabriqués et de géotextiles haute performance. Des colonnes en béton ont été installées après la période de chargement pour assurer une transition en douceur au niveau des remblais d'accès au pont. En phase construction, le comportement du sol de fondation sous la charge était étroitement contrôlé et une évaluation de la performance en ce qui concerne l'amélioration actuelle du sol de fondation a été réalisée. Sur la base des mesures effectuées sur chantier, certains paramètres de conception ont été optimisés en phase travaux pour satisfaire aux exigences du projet. Cette méthode de conception des remblais d'accès aux ponts a fourni à l'ensemble du sous-sol la capacité de supporter le chargement qui s'applique sur le remblai. Ainsi, de conséquents gains financiers, de temps et environnementaux ont été réalisés en phase travaux puisque cette solution a évité l'installation d'environ 88,900 mètres de pieux en béton, spécifiés dans les études initiales.

**KEYWORDS:** Ground improvement, bridge approach transition treatment, prefabricated vertical drain, CFA column, preloading.

## 1 INTRODUCTION

As a state government initiative, the AUD \$1.88B Gateway Upgrade Project in Brisbane Australia involves the design, construction, operation and 10 year maintenance (DCOM) of a new Gateway Bridge, existing Gateway Bridge refurbishment, 12km of motorway upgrade and 7km of new motorway.

Located along Brisbane's north south arterial transportation corridor, the project provides improved connectivity to infrastructure such as Brisbane's Trade Coast region, Airport and the Port of Brisbane. Construction completion for the entire project occurred during November 2010.

Delivered by Queensland Motorways Limited (QML) in partnership with Leighton Abigroup Joint Venture (LAJV) and principal designers Maunsell SMEC Joint Venture (MSJV), the project involved construction and refurbishment of 30 bridge structures. Fourteen (14) of these bridges are located within the Brisbane Airport Interchange precinct, which is characterised by soft, compressible foundation soils up to 20 m in thickness, with road embankment heights up to 13m.

Initial design for the bridge approach treatment in this area comprised use of various forms of piled embankment supported by a mixture of approximately 4,900 continuous flight auger (CFA) piles, displacement auger piles, pre-stressed concrete piles and dynamic replacement columns.

Following cost and program analysis, an alternative staged ground treatment approach was proposed and adopted for the construction of 14 of the 28 bridge approaches within the Airport precinct. This paper focuses on one such abutment (denoted as BR25A) within this area. Site based geotechnical characteristics are identified together with key aspects of the initial and alternative design approach, summary of the alternative design methodology, comparison between predicted and actual ground settlement and outcomes successfully delivered through utilisation of a staged approach to ground treatment.

## 2 GEOTECHNICAL CHARACTERISTICS

### 2.1 *Subsurface conditions*

Geotechnical investigations indicated that the Airport Interchange is underlain by up to 20m Holocene (upper and lower) and Pleistocene alluvial deposits.

Upper Holocene alluvium within the Airport Interchange area was characterised by variable deposits of clay and silt (UH-C) and sands (UH-S). Lower Holocene alluvium (LH-C) was found to be of more uniform composition, comprising compressible silty clay to up to 20m depth.

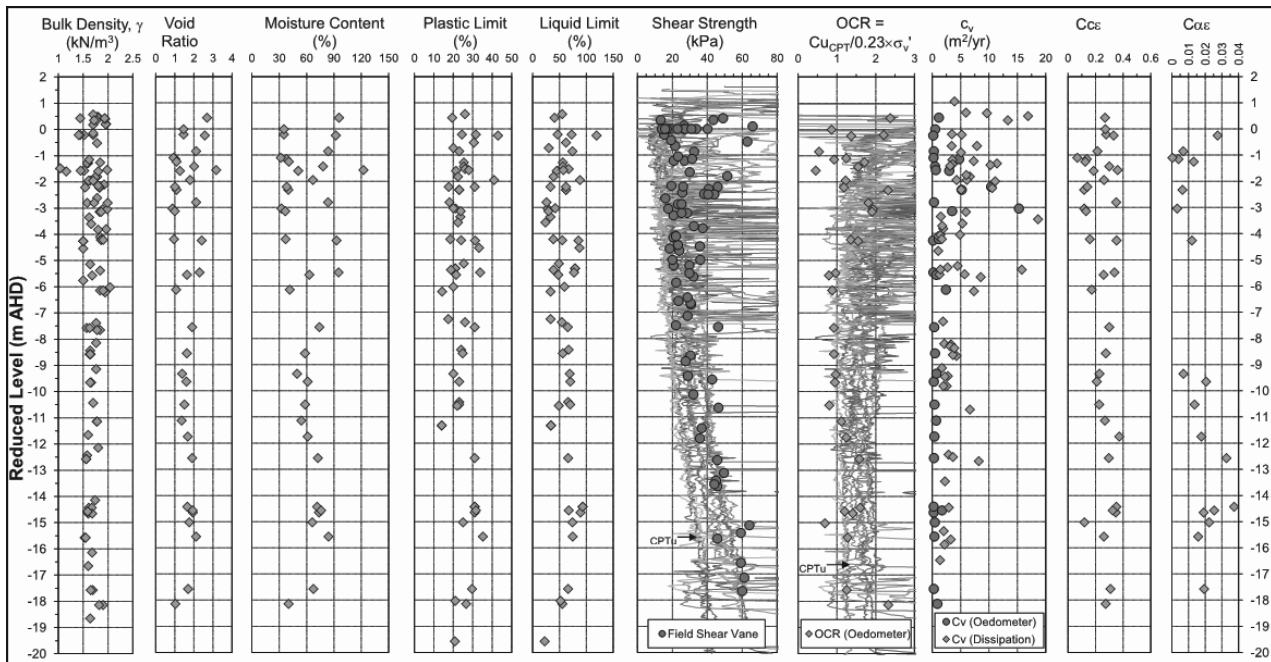

Figure 1: Soil test results - Airport Interchange precinct

Deposited during previous lower sea level, Pleistocene clay (P-C) was found to be characterised by less compressible stratum including stiff to hard clays and medium dense (or denser) sand layer. The ground water level was observed to be within 1-2m of the natural ground surface. The design ground water table was assumed at the ground surface level prior to construction (approximately RL 1.3m).

2.2 Geotechnical design parameters

The geotechnical parameters adopted for design and back-analysis of BR25A bridge approach are summarised in Table 1. Design parameters were derived taking into consideration the potential variability in the ground conditions and were calibrated against monitoring results during construction stage. The coefficient of consolidation in the horizontal direction ( $c_h$ ) was assumed to be  $2c_v$  and this ratio was found to be appropriate based on the back-analysis of field measurements.

Site investigation data indicated variation in strength, compressibility and hydraulic conductivity with depth and location within the Airport Interchange area. Field results from this vicinity indicate that the undrained shear strength ( $C_u$ ) of the compressible clay increases with depth from approximately 10kPa to 60kPa.  $C_u$  values derived from piezocone were calibrated against the shear strength determined from the field shear vane. For geotechnical design, a characteristic  $C_u$  value of  $20 + 0.6z_1$  (kPa) for UH-C and  $23.6 + 2.7z_2$  (kPa) for LH-C was selected, where  $z_1 = 0$  at RL 0 and  $z_2 = 0$  at RL -6. Over-consolidation ratios (OCR) were derived from Oedometer and piezocone data. Figure 1 shows field and laboratory test results.

3 ALTERNATIVE DESIGN DETAILS

The alternative design philosophy involved initially improving the shear strength and compressibility characteristics of the soft soil by 6 months preloading in combination with placement of 4.3m surcharge. High strength geotextile (2 layers of WX600/50) and prefabricated wick drains (1.0m triangular pattern) were utilised for stability control. Refer to Figure 2 for schematic design arrangement nominated during design stage 1.

To facilitate construction haulage, a 2m high temporary berm in the longitudinal direction was proposed and this stabilising effect was incorporated in the design. The use of temporary berm achieved a reduction in the high strength

geotextile requirement for stability control.

Following conclusion of preload, installation of final settlement transition treatment was anticipated, following review of actual performance of the embankment during preloading. The ground transition treatment for the alternative approach comprised 3 transverse rows of unreinforced concrete CFA columns (0.6m diameter on a 2.5m square grid with a UCS of 40MPa) overlain by a 20m long geotextile reinforced mattress to provide adequate pavement transition (see Figure 3). Two layers of WX1100/100 were specified in the longitudinal direction and one layer of WX200/50 in the lateral direction for the geotextile mattress. As a Stage 3 optimisation, 1m of embankment fill was excavated and replaced with lightweight fill (flyash) to increase the final over-consolidation ratio of the foundation soils and decrease preload period from 6 months to 2.4 months.

Figure 2: Typical stability and settlement control (schematic)

4 ALTERNATIVE DESIGN METHODOLOGY

The alternative design comprised a 3 staged approach to design, which occurred across the design and construction stages for the BR25A bridge approach.

4.1 Stage 1 methodology

Stage 1 involved undertaking design calculations to predict the required ground treatment to meet the settlement and stability criteria for the bridge approach transition. To meet the prescribed settlement criteria of 50mm (max) at the abutment

Table 1: Geotechnical Design Parameters

Layer	Depth (top of layer) (m)	$\gamma_t$ (kN/m <sup>3</sup> )	$c'$ (kPa)	$\Phi'$ (°)	$E'$ (MPa)	$\nu$	OCR	$C_{ce}$	$C_{re}$	$C_{ue}$	$c_v$ (m <sup>2</sup> /yr)

Figure 3: Typical operational stage bridge approach transition design arrangement proposed during Stage 1

location at the conclusion of the 10 years maintenance period in combination with 0.5% change in grade on the pavement surface, 6 months preloading with surcharge was proposed (refer section 3). Methodology for settlement assessment and calculation was undertaken in accordance with the method outlined by Hsi *et al.* (2008). Permeability numerical matching technique (Hird *et al.* 1992) was adopted to model the consolidation behaviour of wick drains in plain strain FEA using PLAXIS.

Suitability of the CFA column arrangement was evaluated using PLAXIS by comparing the predicted principal stresses with the allowable compression and tensile strength. Unreinforced CFA columns were modelled as non-porous elastic-perfectly plastic model with a tension cut-off at its tensile strength and plasticity parameters were obtained from compressive and tensile strengths.

In PLAXIS analysis, the two-dimensional stresses were converted into principal stresses ( $\sigma_1'$  and  $\sigma_3'$ ) in the two major and minor principal axis directions. The major principal stress value ( $\sigma_1'$ ) was compared with the factored unconfined compressive strength (UCS) and factored tensile capacity of concrete. A factor of safety of 2 was adopted for both compressive and tensile strengths. Structural adequacy was considered to be met if the principal stresses induced in the columns were less than the respective compressive and tensile capacities.

Soil structure interaction of bridge approach transition treatment was analysed in PLAXIS. The prescribed settlement method was used to analyse the differential settlement within the transition zone due to creep effect. Post construction creep settlement was firstly estimated. Subsequently, the ground behind the CFA columns was then prescribed to settle by an amount equal to the estimated post construction settlement. The embankment change in grade over any 4m length of pavement due to differential settlement was then calculated.

To meet the stability criteria (minimum safety factor of 1.2 in short term and 1.5 in long term), the embankment construction was constrained at a rate of 1m per week. Accordingly, strength gains due to consolidation of the UH-C and LH-C layers were able to be considered in the design. Time rate of consolidation of the UH-C and LH-C layers was further accelerated by use of PVD's. High strength geotextile in combination with lateral stability berms was utilised to provide additional stability control during construction. Stability analysis and design of soil reinforcement were carried out in accordance with the method outlined in Hsi and Martin (2005).

#### 4.2 Stage 2 methodology

Stage 2 involved constructing the embankment using the design arrangement in combination with monitoring of the actual embankment performance during the preload period based on an observational approach. The objective of Stage 2 was to validate the design assumptions and ensure the safe and economical construction of the embankment by controlling the filling rate. Two settlement plates and markers, one vibrating wire piezometer, three inclinometers and one extensometer were implemented at BR25A to monitor the embankment performance during filling and preloading.

#### 4.3 Stage 3 methodology

Conducted in parallel with Stage 2, Stage 3 involved back analysis during construction to validate the proposed transition design with respect to the settlement criteria. Additionally, the predicted date of preload removal was refined and investigation into opportunities to optimise the design from a cost and time perspective was undertaken. Back analysis was conducted using actual construction stage monitoring data.

To validate the magnitude of primary settlement, back analysis comprised initial modelling of the actual rate of

embankment construction in PLAXIS and then comparing the primary settlement obtained from the modelling to the settlement actually observed in the field (see Figure 4). Calibrations were then made to the soil model to achieve an acceptable match between observed and predicted behaviour. The magnitude of primary settlement inferred by the Asaoka (1978) method using a constant time step of 7 days was compared to the actual field data and numerical predictions as an additional validation check on the degree of consolidation achieved. A further validation was undertaken by comparing the actual degree of excess pore water pressure dissipation recorded by the piezometer against the degree of excess pore water pressure dissipation calculated by FEM during stage 3 back analysis (see Figure 4). The magnitude of creep settlement was estimated based on the methods described in Mesri and Feng (1991), Mesri *et al.* (1997) and Stewart *et al.* (1994) and compared with the design criteria. The recommended preload duration was then refined to ensure that the predicted post construction settlement met the design criteria.

## 5 RESULTS

As shown in Figure 4, the magnitude of primary settlement predicted in Stage 1 was significantly greater than the actual primary settlement recorded during Stage 2 field monitoring. Compressibility and consolidation parameters were calibrated (calibrated parameters shown bracketed in Table 1) to achieve a good agreement between Stage 2 actual settlement results and settlement back calculated at Stage 3. From iterations during the Stage 3 back calculation, the source of the difference between Stage 1 and Stage 3 settlement predictions was partly attributed to the higher modified compression index  $C_{ce}$  and modified recompression index  $C_{rc}$  adopted during Stage 1 design. As a result, the modified secondary compression index  $C_{ac}$  was also amended. As a further validation check, the primary settlement was also calculated using the Asaoka (1978) method. Using this method, primary settlement of approximately 1.79m was estimated, which compared reasonably well to the Stage 3 back calculated primary settlement estimate (1.80m).

The degree of excess pore pressure dissipated as measured by the piezometer during Stage 2 was compared against the degree of excess pore water dissipation from the Stage 3 back calculation. This comparison provided an additional validation check in relation to the estimated degree of consolidation of the compressible soils. A reasonable agreement between the measured (Stage 2) and back calculated degree of excess pore water dissipation (Stage 3) of the compressible soil was observed (see Figure 4).

## 6 CONCLUSIONS

An alternative staged approach to design and construction successfully achieved reductions of over 88,900 lineal metres of ground improvement piling that was specified in the initial design. BR25A approach has been presented as a ground treatment design case study; providing key geotechnical considerations, design methodology and a comparison of actual embankment performance with design predictions.

# SWOT analysis Observational Method applications

## Analyse FFOM à l'implémentation de la méthode observationnelle

Korff M.

*Deltares and Cambridge University*

Jong de E.

*Geobest*

Bles T.J.

*Deltares*

**ABSTRACT:** The paper analyses the strengths, weaknesses, opportunities and threats (SWOT) for the application of the Observational Method in civil engineering practice. International cases, many of which are well known in literature have been analysed along the lines of the SWOT methodology. A specific number of cases has been analysed, having typical Dutch conditions, to determine country specific aspects as well. This paper describes the evaluation of the cases. This results in conditions under which the application of the Observational Method is best suitable and conditions in which it is best to avoid the observational method.

**RÉSUMÉ :** Cet article présente les résultats d'analyses Forces, Faiblesses, Opportunités, Menaces (FFOM) effectuées pour appliquer la méthode observationnelle au domaine du génie civil. L'analyse FFOM est appliquée à des réalisations internationales, bien connues dans la littérature et pour lesquelles la méthode observationnelle a été mise en œuvre. Un certain nombre de cas est analysé sous les conditions néerlandaises, afin de déterminer les éléments spécifiques pour ce pays. Cet article décrit l'évaluation des cas. Les résultats de cette évaluation sont des situations dans laquelle l'application de la méthode observationnelle est la plus appropriée et des situations dans laquelle il est préférable d'éviter la méthode observationnelle.

**KEYWORDS:** Observational Method, SWOT, cases.

## 1 INTRODUCTION

The Observational Method (OM) can produce savings in cost and programme on engineering projects, without compromising safety, and can also benefit the geotechnical community by increasing scientific knowledge. In some countries the use of OM is common practice, see for example Britain with famous papers by Powderham (1994) and Patel et al. (2007) and the CIRIA report 185 (Nicholson et al., 1999) and France with the Irex-RGCU guideline by Allagnat (2005). In many other countries, such as The Netherlands, the method is used in specific cases only and/or more reluctantly. Many papers in literature have described procedures on implementing the OM such as Powderham and Nicholson (1996) and the guidelines mentioned above, but very little attention is usually paid to the conditions in which the OM is most adequate. With use of a SWOT analysis this papers aims to provide such an overview of hurdles and conditions.

This research is performed as part of "Geoimpuls" in the Netherlands; a joint industry programme, with the ambitious goal to half the occurrence of geotechnical failure in Dutch civil engineering projects by 2015. The measures proposed were clustered into five themes by Cools (2011): geo-engineering in contracts, implementing and sharing of existing knowledge and experience, quality of design and construction processes, new knowledge for Geo-Engineering in 2015 and managing expectations. The observational method is seen as a means to obtain robust en cost-effective projects based on measurements in combination with risk-based scenarios. The method provides projects with the possibility to benefit from uncertainties in soil conditions, which results in opportunities.

## 2 ANALYSIS OF CASE HISTORIES

The paper illustrates the results of a SWOT analysis based on various projects reported in case histories. The focus of this analysis is on the conditions in the projects that make them suitable for the application of the OM. By collecting these aspects, one can check whether for a new project the application of the OM may bring benefits. If this is the case, the authors of this paper wishes to refer to the use of Eurocode 7 and specific guidelines for the correct and optimal procedures. Those procedures are not part of this paper.

Geotechnical monitoring is an essential part of the Observational Method, and if used separately mostly aims to control the construction processes and design assumptions. As part of the OM monitoring is used for design purposes as well. If the monitoring shows that a design can/must be changed with less/more conservative assumptions this is foreseen in the OM. In the SWOT analysis monitoring is also considered, as it is part of the OM. Parts of the SWOT analysis can therefor be used for geotechnical monitoring.

It must be mentioned that for a true SWOT analysis the internal (Strength, Weaknesses) and the external (Opportunities and Threats) must be clearly distinguished. In the case of the application of the OM, this may not be so evident, especially if we consider the soil conditions. In this paper, the soil is considered an internal part of the project. Furthermore, the SWOT analysis focusses on the application of the OM from the start of the project ('ab initio') and not as the 'best way out', when unwanted events already have appeared.

### **Strengths (S)**

Some project characteristics can be seen as strengths for the application of the OM. If the following characteristics exist, OM could be considered as a serious option. .

1. Multiple stages or parts in a project, Patel et al. (2007) suggest that for a good application of the OM it is necessary

to have some sort of a variation between parts or stages of the construction. This is essential to make it possible to learn from previous behaviour, which is the essence of the OM. Both projects that are multistage or that are executed according to an incremental construction process are suitable for application of the OM.

*Multistage projects* for example include a staged excavation or staged application of loads. These provide good possibilities for the OM. Subsequent stages of loading can be based on results measured in previous stages. Examples include the excavation after collapse of the Heathrow terminal described by Hitchcock (2003) and the raising of the embankment of the Betuweroute Cargo Rail on very soft soils as described in the Geotechnet report by Huybrechts (2000). Using the multi-stage construction process, reliability can be controlled by interpreting monitoring of the previous stages and by taking subsequent actions if necessary. Also excavations that progress in depth, for which the struts can be pre-stressed according to the rate of deformation, or when additional struts or soil nails can be installed depending on the deformations, may possess good characteristics for the use of the OM.

Another strength characteristic is present in projects with an *incremental construction process*. These projects are flexible in the speed with which they progress or consist of several steps. An example may be in NATM tunnelling work, or vibratory installation of (sheet) piles, where the rate of advancing can be controlled based on the monitoring results. Also projects with a long length (in similar soil conditions) for example line infrastructure projects such as roads and rail can provide a good basis for the OM, such as for example described for the Limehouse Link by Glass and Powderham (1994).

2. Short project duration in relation with beneficial short term behaviour of soil. In some cases short term soil behaviour may be a strength, such as when the undrained strength of soils is larger than the drained strength and only short term loading conditions are applicable which have diminished before drainage takes place. Here also the NATM method could be mentioned.
3. Displacements as leading design characteristic. Projects where displacements govern the design are by nature often suitable for the use of the OM. Deformations can usually be monitored accurately and extensively and provide good indication of the mechanisms that have to be controlled. When deformations of adjacent buildings are important, projects can be suitable for the OM, but it must be mentioned that the possible measures and variations might be limited to a specific and tight range of acceptable expected impact, thus giving less space for its application. It can however be considered a strength in the sense of this SWOT if a project relates to existing structures or conditions that are difficult to assess, such as the stability of an existing embankment (Lee, 2012) or old existing structures with unknown response (Chapman and Green, 2004). The application of the OM in those cases might solve otherwise unknown response of the structure. In general projects where epistemic uncertainties, which originate from insufficient knowledge of a property, can be decreased by the use of monitoring might be suitable (Nossan, 2006).
4. Integrated responsibility for both design and construction. Cases where a strong connection exists between design and construction teams and in which good communication between parties is assured, have a strong case for the use of the OM. The OM works well with an alliance contract in which risks (and opportunities) are shared between client and contractor, see section 3 of this paper.
5. Flexible and risk based culture. It can also be considered a strength if the culture of each organization involved is open to some flexibility but also very strict with regard to risk management and monitoring. If staff members are

sufficiently experienced and had proper training, preferably related to the use of the OM, this is a main benefit. A management commitment to implementing the OM approach at all levels is also an organizational strength.

6. High ground heterogeneity and or uncertainty in failure mechanism. In cases with high uncertainty a 'standard' (non OM) design approach forces the designer to make conservative design assumptions, leading to costs that possibly are not necessary and can be avoided. This leads to a potentially high cost differences between a 'standard' design and an OM design. It is the advantage of using the OM to justify a set of more favourable assumptions leading to a more cost effective design. This for instance can be the case when a decision needs to be made between a shallow foundation and a piled foundation, as has been experienced by GeoImpuls participants for a LNG terminal with high demands for dissimilar settlements, or in geological heterogeneous areas (for instance close to rivers).

Two combinations of variability are especially suitable for the OM. First, the soil strength or stiffness is not well known or has a large spread, but the load that will be presented is relatively well known (for example in NATM tunnels or deep excavations as described by Kamp (2003) or the railway example by Lee (2012). Secondly, if the opposite is the case and the load is relatively unknown but the soil strength is well known, for example in the case of deep foundations and embankments described by Peck (1969) and many others, the method could also work well. If both are known, or both are unknown, the OM is not suitable and this should be considered a threat.

#### **Weaknesses**

Opposite to the benefits are of course also weaknesses for the application of the OM. If any of the following characteristics exist, application of the OM may result in additional challenges or may not be suitable.

1. Too little time between measurements and measures. A major weakness exists if mechanisms involved in the project reveal themselves quicker than measures can be implemented. In the case of brittle failure monitoring may not provide previous warning. Brittle failure is a no go for the OM, while late appearance may make application of the OM inefficient since savings of necessary reinforcements can not be decided early enough, such as described by (Korevaar, 2012). Examples are non-ductile failures of structural members such as struts/waling connections in multi-propped basements as described by Patel (2007) or the vertical equilibrium of deep excavations.
2. Measurements that cause failure. In some mechanisms, for example related to the pull out capacity of (micro)piles or anchors, monitoring would require failure of the system, which is not acceptable.
3. Failure mechanism/parameter can not be measured. It can also be problematic if the monitoring system is not able to capture the correct mechanism or relevant parameters. This is often the case as stiffness and strength of soils are only weakly correlated, meaning that deformation measurements do not always indicate a possible failure of the strength of a material.
4. Change of failure mechanism during construction. Other weaknesses could be that during the construction process, the failure mechanisms change, for example if shallow failures become deep failures, primary consolidation becomes creep etc.
5. Costs for changes during construction are higher than profits minus costs for monitoring. The use of OM inevitably requires usually costly continuous measurements that have to be taken, interpreted and analysed during construction. During the design more scenarios need to be calculated together with analysis of other cases/experiences in order to know what to expect. These costs need to be balanced with

expected benefits. Also sometimes measures that might be needed as an outcome of OM are inefficient during construction. This for instance is described by (Schmitt and Schlosser, 2007) for the case of an excavation in Monaco where huge stays bearing on the bottom of the excavation would have caused major consequences for the completion time of the project.

Although it might seem that OM through this weakness is more beneficial in larger projects than in smaller, this not necessarily is the case. For example small embankments lend themselves often for the use of OM.

6. Communication between site and design office. Application of OM requires direct communication between site and design office, being responsible for direct analyses of the measurements. If these different cultures do not find each other easily in a project, this may cause delays in go – no go moments or even proceeding of the work on site without commitment of the design office. However, if communication is planned carefully it can even be considered a strength of OM that is brings design and construction close to each other. Projects where the culture is based on individual profit and loss opposed to mutual benefits, with extremely low bid or difficult market conditions are not suitable for the application of the OM.

Figure 1. Example project with application of OM in Amsterdam, Rokin Station

### Opportunities

Opportunities for the use of the OM are present at projects with the following characteristics:

1. Presence of risks with low, but unacceptable a priori probability of exceedance and significant consequences. For the use of OM it is necessary that the full range of possible behaviour is assessed and that it is shown that there is an acceptable probability that the actual behaviour will be within the acceptable limits (Eurocode 7). OM is suitable if the probability is higher than acceptable for a standard design, but is small enough to still have a large chance of successfully completing the project without necessary measures. This also requires the consequences to be large enough to justify the additional costs. Examples can be the impact of vibratory installation of sheet pile nearby a pipeline or possible damage by vibrations to old monumental buildings during driving of piles. The vibrations will most likely be present, but the probability of exceedance might be low enough to use the OM, in order to avoid a priori costly measures in design.
2. Stakeholders. OM lends itself perfectly for good communication with stakeholders involved in the project. For instance a critical attitude of a project's neighbours can be addressed with a proper explanation of the project risks and the way the project is organized to react pro actively if risks seem to occur. It is shown at the North South Line in Amsterdam during the application of OM in the final

excavation of Rokin Station that the stakeholders were reassured by the extensive risk based OM approach. Also the application of OM at the A2 Maastricht proved to be a very good way for communication with the stakeholder (Grote and van Dalen, 2012) The uncertainties related to the strength of the limestone and the subsequent response of the excavation wall, see Figure 2, made application of the OM suitable for a good communication strategy. However, it should also be mentioned here that miscommunication of the use of OM is a threat for the project, since it can easily be interpreted wrongly by stakeholders as a way of window-dressing a risky project.

3. Best way out. Although the authors of this paper think OM should be used 'ab initio', OM has proven many times to be a very good opportunity in case unwanted events are (nearly) happening, for instance observed from geotechnical monitoring. Because the original design already is 'in place' and can not easily be changed, an OM approach can still save the project.

### Threats

Threats for the use of the OM are present at projects with the following characteristics:

1. Quickly changing loads. One of the major and most well known threats is the possibility of quickly changing loads (causing brittle failure) such as deterioration of soils caused by intrusion of groundwater. Also external loads such as rainfall induced ground water surges or burst water mains as well as the risk for liquefaction all are potential threats for the use of the OM.
2. Unwillingness of authorities. Another type of potential threat may be the willingness for authorities to allow the method, even though according to Eurocode 7, the method is now regulated. Use of OM almost inevitable requires efforts on communication with the authorities in order to explain what OM is, why it is used, and how is ensured that a safe and sound construction will take place. This especially is the case in countries with little experience with OM, such as the Netherlands.
3. Time restrictions. Making an OM design requires more effort in the design phase. If the design capacity is not adapted this may lead to a longer design period. Projects with high planning demands can therefore be impractical for the use of OM, especially if it is expected that OM will not lead to time savings during construction.
4. Calculation methods and tools do not always allow for proper use of OM, in this case related to the necessary inverse modelling. A large amount of data becomes available during construction and needs to be processed. For instance for settlement prediction software, modules exist in which fitting between model parameters and measurements can take place in order to make better forecasts for stages to come. However, for other mechanisms such as deformations of retaining walls or designs using finite element models this is not easily done. Many calculations may need to be performed in advance in order to use OM properly during the construction. This might lead to inefficient use of OM, causing high design costs or even (if mechanisms happen outside the design expectations) the fact that OM can not be used quickly enough during construction.

It can be concluded from all of the above SWOT conditions that the observational method is best suited for projects that are governed by the serviceability limit states. It is applicable, but less suited, for designs governed by the ultimate limit states with ductile behaviour, and it is unsuitable for the ultimate limit states if brittle behaviour takes place.

### 3 CONTRACTUAL ASPECTS

When discussing the possibilities of the Observational Method in geotechnical engineering, it becomes obvious that contract requirements should facilitate or, to say the least, should not obstruct its use. In The Netherlands projects are awarded based on the so called UAV (Uniform Administrative Conditions) or the UAV-gc (Uniform Administrative Conditions for integrated contracts). In contracts where the UAV-applies, the client is responsible for the design and the contractor is responsible for the execution of the works (Traditional contract). Since it is virtually impossible to make a design with the Observational Method without expert knowledge of construction methods, there are limitations to the use of the OM in this kind of contracts. Once the contract is awarded, for instance when a contractor is selected based on general conditions and unit prices, it is possible to change the design using the expertise of the contractor.

If the UAV-gc applies the contractor is responsible for both the design and the executions of the works (Design and Construct contract). All though the possibilities for the use of the OM as a design method are significantly greater than compared to the UAV type of contract, there are still a number of challenges to overcome. One of the main challenges is that in order to get the contract awarded, the contractor first has to be selected. Since the only award criterion that is deemed truly objectively is price, a problem arises in selecting the best offer for the works. The cost price resulting from a design based on OM will vary around the cost price of the most probable way of execution of the works. By nature of the method, it is impossible to submit such a price in a bid. In the Netherlands it was concluded that in order to use the OM as a design method from the start, it is strongly advised and beneficial to execute the project in an alliance between client and contractor.

In this kind of contract client and contractor share a common objective, for example the execution of the project in a safe and cost-effective manner with a minimised risk for the surroundings. All the unknowns in a project that is designed using the OM can be a shared responsibility. Both client and contractor will be fully involved in all decision making and will have an equal part in any additional costs or benefits. Part of the Betuwelijn Cargo Rail Line (Huybrechts, 2000) has been successfully constructed in this way. The challenge of selecting the most qualified contractor remains. One of the suggestions to overcome this challenge is to have a “beauty contest” and a known budget price for the total works. In this way the client is able to select a contractor based on value (best value procurement). Contractors are asked to present themselves not only with reference to the projects they carried out in the past (track record), but also with respect to the proposed method of cooperation with the client. The staff that the contractor wants to deploy for the project will be judged not only on their technical know-how, but also on their “soft skills”, since cooperation is the key-word in an alliance type of contract.

Over the last years several projects in the Netherlands have been awarded in this manner. For the OM to be used within such contracts, all other requirements for the successful use of the OM should also be fulfilled. However, an alliance type of contract comes close to the ideal contract framework that was described as being “utopia” in CIRIA Report 185 (Nicholson et al., 1999).

### 4 PROJECT ASPECTS

Some project examples are given in this section with their relative appropriateness to the use of the OM. It must be mentioned that each project should be considered in their specific settings, both physically and organizationally. In the examples, only the most common aspects have been considered.

For deep excavations the use of the OM is usually limited to the focus on the settlements in the surrounding structures or soil. In some cases, struts can be optimized but it may not

always be possible to decide in time whether a strut layer actually can be omitted. If long cut and cover lengths are present, the subsequent sections may learn from earlier sections. Chapman describes several cases where the use of the OM was successful; whereas Karlsrud and Andresen (2008) state that the OM is not particularly suitable for deep excavations. It can be dangerous if sudden increases in water pressures may happen, accidents such as strut failure or unforeseen loads next to excavation happen. It is rather difficult to apply the OM to assure the vertical equilibrium of deep excavations, although this was actually done in Rokin station for the Amsterdam North South Line, as best way out, see Figure 1. Usually this aspect is considered as a potentially brittle behaviour, but in this specific case the behaviour was expected to be more ductile since the water carrying sand layer causing the possible uplift was very thin.

For deep foundations the method is usually difficult to apply because strength at failure often governs the design. There are however good examples that for the re-use of existing piles (Huybrechts, 2000) the OM shows some good possibilities. For TBM tunnelling the OM is often used to control the settlements, and for example not to design the tunnel lining, where standardization is always more efficient than optimization over shorter lengths. For NATM tunnelling the method is often mentioned and it should be possible if a safe base design is present. (Muir Wood, 1990) and (Kovari and Lunardi 2000) state however that the OM for NATM is actually not working in a correct way.

Embankments are usually well suited for the application of the OM. Examples are mainly related to settlement control and staged construction, but also include the control of stability (Lee, 2012). In a similar way especially suited for the OM seem projects where a surcharge is placed, a tank is filled or similar loading of soil with storage takes place. The flexible use of (pre)loading has proved very efficient in many cases.

Other types of projects suitable for the application of the OM are pipelines when deformation limits are very strict, because the allowable values are difficult to assess in design. Environmental projects (contaminated sites) have been presented by Morgenstern (1994) and drainage works by (Roberts and Preene, 1994).

Very simple structures (‘in the backyard’) are usually not suitable for the OM, because the costs of the additional monitoring are often larger than the benefits for the project.

In all types of projects where buildings are present at short distance, the method may be beneficial because they can be strictly monitored. On the other hand, much more flexibility in the system is present if no such buildings/structures are present. Usually in dealing with stringent deformation limits it is necessary to have a more robust design, which reduces the effectiveness of the use of OM.

### 5 CONCLUSIONS

Conclusions in this paper are given in the form of Go/No Go items for clients and project initiators, as well as designers in a very early stage of the project, to determine whether or not the OM could be a wise approach in their specific project, given the specific circumstances. These Go/No Go items are listed by importance, based on the opinion of the authors. Some issues form the Go/No Go list may be given facts for a project, some may be project choices that may benefit (or contradict) the use of the OM. Some items should be taken merely as reminders of how to organize the project most efficiently. These items are labelled in the third category ‘To overcome’.

Go:

- Multistage projects and/or projects with an incremental construction process.
- Presence of risks with low, but unacceptable a priori probability of exceedance and significant consequences.

- Integrated responsibility for both design and construction.
- High ground heterogeneity and/or uncertainty in failure mechanism.
- Displacements as leading design characteristic.
- Short project duration in relation with beneficial short term behaviour of soil.
- Flexible and risk based culture.
- Critical attitude of stakeholders related to the project.
- Best way out.

#### No go:

- Too little time between measurements and measures.
- Quickly changing loads.
- Failure mechanism/parameter is not measurable.
- Change of failure mechanism during construction.
- Measurements only useful after failure.
- Costs for changes during construction are higher than benefits minus costs for monitoring.

#### To be overcome:

- Communication between site and design office.
- Unwillingness of authorities.
- Time restrictions.
- Calculation methods do not always allow easy use of OM.

# Development of Method for Evaluating and Visualizing 3-dimensional Deformation of Earth Retaining Wall for Excavation

Développement des méthodes d'évaluation et de visualisation de la déformation tridimensionnelle des murs de soutènement dans les excavations

Matsumaru T., Kojima K.  
Railway Technical Research Institute

**ABSTRACT:** Monitoring of deformation of earth retaining wall for excavation is important in order to keep surrounding environment and structures safe during construction. However, there are some problems in monitoring of earth retaining walls. For example, it is difficult for the partial measurement by plum bobs to evaluate the overall behavior of the retaining walls, and the multipoint measurement using multi-element inclinometers tends to be expensive. In this paper, we developed a system to evaluate and visualize retaining wall as three-dimensional curved surface. The validity was confirmed by the simulation of the loading test on the model wall. In order to confirm the effectiveness of the proposed system to actual monitoring, we tried to apply the system to the on-site measurement. Furthermore, we proposed a method to conduct monitoring of retaining walls using this system and simple inclinometers.

**RÉSUMÉ :** Le contrôle de la déformation des murs de soutènement dans les excavations est important pour assurer la sécurité de l'environnement et des structures lors de la construction. Toutefois, le contrôle des murs de soutènement pose un certain nombre de problèmes. Il est par exemple difficile de procéder à des mesures partielles au fil à plomb pour évaluer le comportement général des murs de soutènement et les mesures multipoint à l'aide d'inclinomètres multiéléments sont plutôt onéreuses. Dans cet article, nous présentons un système d'évaluation et de visualisation des murs de soutènement sous forme d'une surface courbe tridimensionnelle. La validité du système a été confirmée par simulation d'un essai de charge sur la paroi du mur testé. Afin de vérifier l'efficacité du système proposé dans des conditions de contrôle réelles, nous avons tenté de l'appliquer lors de mesures sur le terrain. Nous proposons également une méthode de conduite du contrôle des murs de soutènement à l'aide de ce système et d'inclinomètres simples.

**KEYWORDS:** earth retaining wall, 3-dimensional deformation, cubic B-spline function, measurement, incline

## 1 INTRODUCTION

Monitoring of deformation of earth retaining wall for excavation is important in order to keep surrounding environment and structures safe during construction. However, there are some problems in monitoring of earth retaining walls. For example, it is difficult for the partial measurement by plum bobs to evaluate the overall behavior of the retaining walls, and the multipoint measurement using multi-element inclinometers tends to be expensive.

Considering these problems as backgrounds, we developed a system to evaluate and visualize retaining wall as three-dimensional curved surface. In this system, the cubic B-spline function is adopted as analytical technique, which is employed for describing shape of land as three-dimensional curved surface based on sets of data of the elevation altitude (Nonogaki et. al., 2008). We proposed a method to evaluate inclinometer data as surface without transforming incline into displacement. The validity and the adequacy was confirmed by loading test and field measurement. Furthermore, we searched the way two conduct measurement easily by using the proposed method.

## 2 EVALUATING AND VISUALIZING DEFORMATION OF RETAINING WALL IN 3-DIMENSIONAL SPACE

### 2.1 Cubic B-spline function

Figure 1 shows the 3-dimensional coordinate space for describing the deformation of the earth retaining wall. In this figure,  $x$ ,  $y$ , and  $z$  axis means the direction of the retaining wall, the depth, and the direction toward which the wall deforms. The earth retaining wall is expressed as smooth and continuous surface by the following equation.

$$f(x, y) = z \quad (1)$$

In the cubic B-spline function (Nonogaki et. al., 2008), the region for drawing the surface is divided in  $M_x$  and  $M_y$  equally-spaced areas in  $x$  and  $y$  axis. By setting the  $M_x+7$  and  $M_y+7$  equally-spaced nodes, the surface is expressed by the following equation:

$$f(x, y) = \sum_{i=1}^{M_x+3} \sum_{j=1}^{M_y+3} c_{ij} N_i(x) N_j(y) \quad (2)$$

where  $N_i(x)$  and  $N_j(y)$  is the cubic B-spline function, and  $c_{ij}$  is unknown coefficient.

In order to determine the surface, objective function  $Q$  was defined as following equation:

$$Q(f; \alpha) = J(f) + \alpha R(f) \quad (3)$$

where  $J(f)$  is the functional for evaluating the smoothness of the surface,  $R(f)$  is the function which expresses the sufficiency degree of data, and  $\alpha$  is the parameter balancing for these two functions. The surface is determined by substituting  $c_{ij}$  into equation (2) obtained from  $\partial Q(f; \alpha) / \partial c_{ij} = 0$ .  $J(f)$  is written by Shiono et al (2001).

The function which expresses the sufficiency,  $R(f)$ , is mentioned as below. The coordinate  $(x_p, y_p, z_p)$ , where a measurement equipment is placed, and the measured displacement  $u_p$  has following relationship.

$$f(x_p, y_p) = z_p + u_p \quad (4)$$

Therefore, using the error average  $\varepsilon_p$  of squares between the curved surface and the obtained displacement data,  $R(f)$  is evaluated as following equation.

$$R(f) = \sum \varepsilon_p^2 / n_p \quad (5)$$

$$\epsilon_p = \sum_{i=1}^{M_x+3} \sum_{j=1}^{M_y+3} c_{ij} N_i(x_p) N_j(y_p) - (z_p + u_p) \quad (6)$$

where  $n_h$  is the number which satisfies equation (4).

Figure 1. 3-dimensional coordinate space for drawing deformation of retaining wall

### 2.2 Use of measured inclination

In the monitoring of the retaining wall, we often measure not the displacement but the inclination because of its easiness. For this reason, it is important for developing the method to take incline data for evaluating the deformation. As follows, we show the proposed method for using the incline data.

The function  $R(f)$  is divided into two functions,  $R_h(f)$  and  $R_d(f)$ .  $R_h(f)$  expresses the sufficiency degree of displacements, and  $R_d(f)$  expresses that of inclines. Using these functions,  $R(f)$  is expressed as follow equation:

$$R(f) = R_h(f) + \gamma R_d(f) \quad (7)$$

where  $\gamma$  describes the weight of the sufficiency of inclines.  $R_h(f)$  is expressed by equation (5).

On the other hand,  $R_d(f)$  is defined as follows. At the position where an inclinometer located,  $(x_q, y_q, z_q)$ , the derivative of the function  $f$  is described by the following equation.

$$f_y(x_q, y_q) = -\tan \theta_q \quad (8)$$

Therefore, the functional  $R_d(f)$  is expressed as following equation:

$$R_d(f) = \sum_{i=1}^{n_d} \left\{ \sum_{i=1}^{M_x+3} \sum_{j=1}^{M_y+3} c_{ij} N_i(x) N_j(y) + \tan \theta_q \right\}^2 / n_d \quad (9)$$

where  $n_d$  is the number of the obtained incline data.

## 3 SIMULATION OF LOADING TEST OF MODEL WALL

### 3.1 Loading test of model wall

Figure 2 shows the photograph of loading test. The wall was 2m in height, 3m in width and 10mm in thickness. The loading was conducted for several cases, changing boundary conditions and displacement. During the loading, the displacement and the incline of the wall were measured using a lot of measurement equipments. In the following simulation, we used only the data obtained from the survey by total station (T.S.) and inclinometers.

Figure 2. Loading test of model wall.

### 3.2 Conditions of simulation

Figure 3 shows the arrangement of measurement equipments used in the simulations. (a) is the arrangement using all 128 points for the survey by T.S., (b) is using only 35 points, and (c) is using 25 inclinometers. Figure 9 shows the pattern of loading.

Figure 3. Arrangement of measuring points used in simulations

Figure 4 shows the arrangement of measurement equipments used in this simulation. In CASE1, 80 mm displacement was given at the top center of the wall. In CASE2, 30 mm displacement was given at the right middle part.

Figure 4. Loading cases used in simulation

### 3.3 Results of simulation

Figure 5 shows the simulated and visualized surface using 128 points for T.S. (arrangement (a) as shown in figure 3) in both loading cases. Figure 6 shows the distributions of displacement at the cross section shown in figure 4, in both loading cases. In figure 5, displacement obtained from the contact-type displacement gauges was also plotted. From these figures, it is seemed to be that the simulation could describe the deformed surface in 3-dimension. Furthermore, the simulated displacement for each case almost coincides with measured results using the cross-section displacement gauges, regardless of arrangements or kind of used measurement equipments.

Figure 5. Evaluated and visualized deformations of wall.

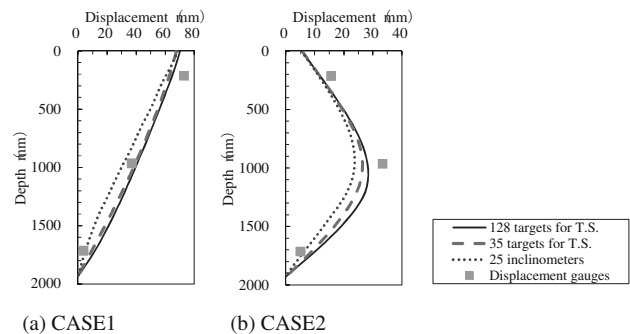

Figure 6. Distributions of displacement at cross section.

From these results, it was revealed that the developed method was suitable for the evaluation and visualization of the deformation of earth retaining wall.

#### 4 ADOPTATION OF PUROPOSED METHOD FOR FIELD MEASUREMENT

##### 4.1 Field condition of construction and measurement

Figure 7 shows the field conditions of construction and arrangement of measurement equipment. The excavating work was conducted 39 m times 16 m in area, and 9 m in depth. The surface layer of the ground was a very soft alluvial clay layer about 13m in thickness, with a small N-value of SPT, followed by a gravel layer. The type of the retaining walls was bracing method. The materials of the walls were steel sheet piles. The excavation consisted of three steps as shown in figure 7.

Monitoring the wall was conducted at the south section in order to keep safe the existing tunnel for cars. Monitoring was implemented by multi-element inclinometers. As shown in figure 7, there were four survey lines and six inclinometers were set on each line. For checking monitoring data, the survey of the displacement of the wall using the total station was also conducted at regular intervals around Line No.1 and Line No.2.

Evaluating and visualizing the deformation of the wall in 3-dimensional space was conducted in the region about 33.4m in width. Two arrangements of the measurement equipments were considered. CASE1 was the arrangement using only 24 multi-element inclinometers. CASE2 was using not only inclinometers but also the displacement obtained from the survey using T.S.

Figure 7. Conditions of field construction and measurement.

##### 4.2 3-dimensional evaluation and visualization of deformation of retaining wall

Figure 8 shows the deformed wall which was evaluated and visualized after conducted excavation at each step in CASE1. From the beginning to the end of the work, the deformation of the wall was represented satisfactorily as 3-dimensional surface. The deformation was increased as the progress of the excavating work. On the other hand, as the progress, the depth where the maximum displacement occurred at deeper depth and the deformation close to the ground level was decreased due to the influence of the reaction force by installing braces.

Figure 9 shows the distributions of deformation at the cross section No.1 and No.4 as shown in figure 7. In this figure, we also showed the displacement converted from the angle obtained from inclinometers and the distances between two inclinometers, and the displacements obtained from the survey by T.S. The distributions of displacement evaluated by proposed method coincides with the mode of directly measured deformation. The displacement obtained from the proposed method was more smoothed. Furthermore, the distributions of displacement were changed largely depending on use of results obtained from survey by T.S. In this simulation, this tendency was dramatic at section No.1, where lots of targets for survey of T.S. were located. The displacement evaluated using the targets

changed toward the displacement obtained from the survey at the top of the wall.

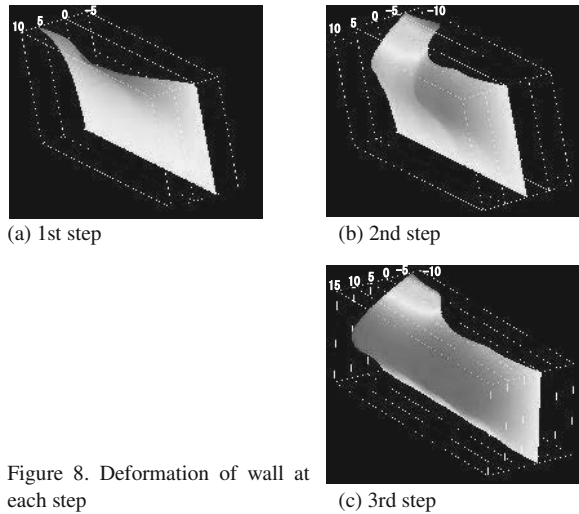

Figure 8. Deformation of wall at each step

Figure 9. Distributions of displacement at cross section.

From these results, the proposed method was proved to be beneficial for field measurement.

#### 5 ADOPTATION OF PROPOSED METHOD FOR FIELD MEASUREMENT

From the study mentioned in previous sections, the validity of the proposed method was confirmed. The advantage of this method is that the data obtained from inclinometers is useful without converting to displacement. So, we can conduct the measurement using convenient inclinometers without making survey line. Therefore, by combining the proposed method and simple inclinometers, we would be able to realize precise and not expensive measurement. However, there are some problems in this method.

##### 5.1 Study of using data only upper ground

For the measurement using convenient inclinometers, it seems to be difficult to set inclinometers under the ground. The inclinometers will be set as the progress of excavating work. So, in the case only using the inclinometers located above the

ground, we studied the difference from the deformation evaluated by using all inclinometers, based on the field data mentioned in the previous section.

The number of used inclinometers in this simulation is 4 at 1st step, 12 at 2nd step and 20 at 3rd step. In this simulation, the data obtained from the survey using T.S. was also considered from 1st step.

Figure 10 shows the distributions of the displacement of the wall. The displacement at Line No.1 was quite similar with the one using all inclinometers, CASE1 in previous chapter. On the other hand, the displacement at Line No.4 was quite different because the direct measurement of displacement by T.S. was not conducted around Line No.4. So, we also simulated the monitoring case using multi-element inclinometers were added at Line No.3. The displacement almost coincided with the results using all inclinometers.

In monitoring of field excavating work, direct measurement of displacement or installation of one line for multi-inclinometers would enable the measurement using convenient inclinometers.

Figure 10. Distributions of displacement at cross section.

## 5.2 Study of optimal arrangement of convenient inclinometers

Finding optimal arrangement for conventional inclinometers would be executed by evaluating of degree of accuracy and choosing the most suitable surface for all considerable arrangements. Therefore, we conducted the simulation the accuracy of evaluated surface by iterative calculation.

Monte Carlo approach was adopted for iterative calculation and the number of iteration was 1000. The step of excavating work selected for calculation was 3rd step. For the simulation, the surface was evaluated by 8 inclinometers selected from 20 ones above the ground at random.

Figure 11 showed the obtained histogram. The horizontal axis is the evaluated average difference (Matsumaru et. al., 2011) from the surface simulated by using all inclinometers. It was revealed that the accuracy of evaluated deformation of the wall changed largely depending on the arrangement of inclinometers. However, the minimum of the difference was smaller than 1 mm. This mentioned that the monitoring using small number of measurement equipments had the possibility to maintain the accuracy of measurement depending on the arrangement. By conducting iterative calculation about considerable arrangement, the optimal arrangement would be realize.

Figure 11. Histogram of average difference for considerable arrangements.

## 6 CONCLUSIONS

The purpose of this paper was system to evaluate and visualize deformation of retaining wall as three-dimensional curved surface. As the results, we achieved the following conclusions:

1. We developed a system adopting the cubic B-spline function as analytical technique and also proposed a method to evaluate inclinometer data as surface without transform inclines into displacements. The validity of the method was confirmed by the simulation of the loading tests of the model wall, because correct surfaces were droved using a small amount of data of displacement or using only inclines.
2. The adequacy of the proposed system was examined by applying this method to measurement of the field site of excavating work. From the beginning to the end of the work, the deformation of the wall was represented satisfactorily as three-dimensional surface. Furthermore, it was revealed that the evaluated deformation of the wall coincided with the surveyed displacement by the total station.
3. In order to realize easy monitoring of retaining walls, we checked the arrangement of inclinometers. By using the inclinometers installed above the excavation bottom, the deformation of the wall could be described almost in the same way as by all inclinometers. Furthermore, we checked the validity of the arrangement with smaller number of inclinometers by Monte Carlo approach. Though the evaluated deformation of the wall using smaller number of inclinometers was varied widely, the accuracy of the optimal arrangement was close to the one using all inclinometers.

## 7 ACKNOWLEDGEMENTS

The field measurement in this study was supported by Mr. Kiyoshi Kuwabara (East Japan Railway Co. Ltd) and Toshiyasu Hisashima (East Japan Railway Co. Ltd).

**ABSTRACT:** This article describes more than 30-year experience of scientific and technical support, design, construction and reconstruction of water supply and sewage facilities in St. Petersburg, Sochi, etc. It describes the specific defects of long-term operation of large-size pumping stations and deep-laid tunnels that cause risks and dangers of their use. It gives the results of geotechnical and design calculations, modeling of underground and tunnel constructions taking into account risk factors determined by defects that occur during construction and operation, and also taking into account external influences, including dynamic ones. The report gives a comparative analysis of calculated and industrial experiments, provides activity and implementation experience of geotechnical support of long-term operation of engineering infrastructure.

**RÉSUMÉ :** L'article décrit l'expérience de plus 30 ans d'assistance scientifique et technique, en conception, construction et restauration d'infrastructures de distribution d'eau et d'évacuation des eaux usées à Saint-Petersbourg, Sochi, etc. L'article détaille les défauts typiques des stations de pompage de grandes dimensions et des tunnels profonds, exploités sur le long terme et amenés à des niveaux de risque et de danger au cours de leur exploitation. On donne les résultats des calculs géotechniques et de conception, en simulant le fonctionnement des tunnels profonds, compte tenu des facteurs de risque induits par les défauts apparus aux étapes de la construction et de l'exploitation, ainsi que des influences extérieures, y compris les influences dynamiques. Le rapport présente l'analyse comparative des expériences théoriques et pratiques, et fournit les mesures à mettre en œuvre pour la sécurité géotechnique des ouvrages de génie civil exploités à long terme.

## 1. GENERAL INFORMATION ABOUT THE OBJECTS OF DEEP ENGINEERING INFRASTRUCTURE IN LARGE CITIES

With long-term operation and intensive development of engineering infrastructure of megalopolises increase the requirements to the ecology and efficient usage of land resources. During engineering development of underground spaces of such a megalopolis, design of integrated measures for protection of town-planning environment against negative anthropogenic impact is of special actuality. Thereupon there must be introduced special safety requirements for the sewage and water treatment facilities.

Sewage (transportation) of waste waters is done through the city sewerage system and tunnel collectors. In the general drainage system these facilities account for up to 60% in large cities and up to 70% in difficult hydrogeological conditions by construction volumes and costs.

Sewerage system objects data for the most typical Russian cities with the population over 1 million people is given in table 1.

Yekaterinburg	1220	230
Novosibirsk	1150	145
Samara	1200	215
Ufa	900	180

By now around 88% of all sewage collectors are made of ferroconcrete, around 7% - of metal (steel, cast iron), around 3% - of bricks, plastic, ceramics. Tunnel sewage collectors diameter is from 1.2 to 5.6 m, they are buried from 3 to 60 m underground. For example, in St. Petersburg all sewage network is divided into three basins that serve three main pumping plants up to 70 m deep and up to 66 m in diameter, with productivity of 1.5 mln m<sup>3</sup> of sewage per day. For such conditions the main constructive solution for the tunnels are the ferroconcrete tubings with inner ferroconcrete jackets.

Transportation volumes of waste waters in some sections of the tunnels reach 20 m<sup>3</sup> per sec, and in case of decrease of their operational reliability or failure will inevitably lead to a technospheric catastrophe.

"Lengiproinzhprouekt" institute together with the St. Petersburg State Transportation University has been providing scientific and engineering maintenance, design, construction and rehabilitation of St. Petersburg sewerage system objects for more than 30 years: more than 70 pumping plants, including those with depth of 45 m, 59 m and 71 m, and with diameters of 47 m, 59 m and 66 m; more than 15 km of tunnel sewage collectors with diameters of 1.85, 2.5 and 3.4 m and with depth of 16 m, 24 and 37 m.

Table 2 shows the most typical defects of long-term operated pumping plants and deep tunnels.

Table 1. Length of sewerage networks and tunnel collectors in large cities of Russian Federation.

City	Sewerage networks length, km	Tunnel collectors length, km
Moscow	8354	550
St. Petersburg	8245	290
Volgograd	1054	52

Analysis of the materials of the investigations shows that at the moment 60% of gravity sewage tunnels and 80% of pressure sewage tunnels require repairs and sanitation. Instrumental probing (with geological radar) shows that 70-75% of inner surface of pumping plants wells and sewage tunnels have continuity violation and cracks which require strengthening of construct and renewal of waterproof shell.

Table 2. The list of defects typical for the long-term operated (more than 30-45 years) deep pumping plants and tunnel collectors.

Location of the defect	Description and photo of the defect		
Sunk wells walls	Up to -25±30m marks. On some sections of sunk well walls there's leakage through knots. In the knots area there's leakage of concrete corrosion. Defects are of repetitive nature.	-30 to -40±45m marks. On the surface of the wall there're marks of intense leakage through the cracks. Defects are of mass nature. In the knots area there's leakage of concrete corrosion.	More than -45m marks. On the surface of the wall there're marks of intense leakage through the cracks. In the knots area there's leakage of concrete corrosion. Defects are of mass nature.
Sewage tunnels lining	Tubing lining shows leakage. Underground waters go to the collector through cracks and knots in solid ferroconcrete inside lining. There's leakage of concrete corrosion and salts.	There's a water-filled space in the form of a thin gap between the tubing lining and the jacket of collector. Defects are hidden, can be found geological radar probing of collector facilities.	Solid ferroconcrete inner lining (jacket) is destroyed, there's intense leakage in welded seams.

## 2. ANALYSIS OF FACTORS INFLUENCING THE SAFETY OF DEEP ENGINEERING STRUCTURES AND MEASURES FOR THEIR ELIMINATION

### 2.1 Analysis of monitoring data for the construction of sunk large pumping plants and of the inspection results after long term operation

The slotted soil column for construction of sunk wells for main pumping plants in the conditions of St. Petersburg is characterized as follows: top part is presented by quaternary beddings to the depth of 14.0-25.0 meters (middle-density water-saturated dust sand  $E=11$  MPa,  $C=0$  MPa,  $\phi=30^\circ$ ; laminar silt sandy loam  $E=4$  MPa,  $C=0.01$  MPa,  $\phi=15^\circ$ ; laminar silt loam, very soft  $E=9$  MPa,  $C=0.025$  MPa,  $\phi=16$ ; semisolid silt loam with gravel, pebbles  $E=14$  MPa,  $C=0.028$  MPa,  $\phi=28^\circ$ ), lower part is represented by top of positioned Proterozoic bluestone ( $E=19$  MPa,  $C=0.04\pm 0.06$  MPa,  $\phi=18-21^\circ$ ).

Figure 1 shows the monitoring results for the construction of a large sunk well using the method of PSTU (Perminov N.A., Lombas S.V., 2004).

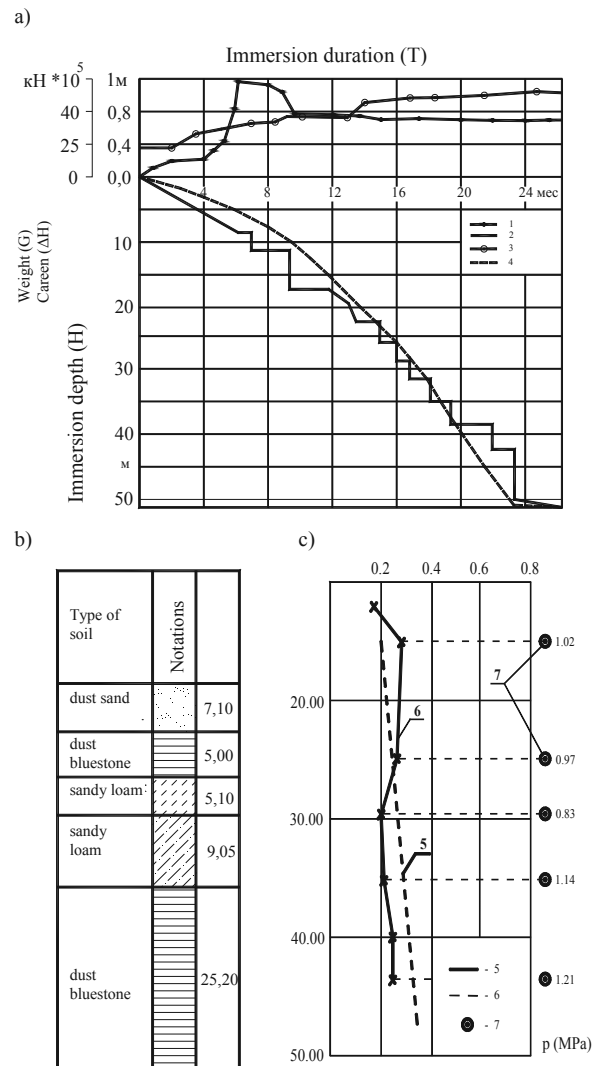

Figure 1. The monitoring results for the immersion of a large sunk well:

a) motiongram of immersion; b) engineering and geological conditions; c) monitoring data  
1 – diagram of vertical misalignment (careen); 2 – diagram of immersion; 3 – weigh of the well shell; 4 –ditch bottom; 5,6,7 – correspondingly, calculated, averaged and peak values of lateral soil pressure.

The stresses in the reinforcement and concrete were measured using primary device string type PSAS and PLDS. To determine the soil pressure membrane load cells with a range of 0 to 12MPa and measurement error of 5-7% were used. The measurement was done both in the discrete and continuous mode using the local electronic switches (LEC), and data storages (END).

Analysis of monitoring data of large sunk wells with diameters from 50 to 66m and a depth of immersion of 55 to 71m shows (see Figure 1) that in the process of immersion in the soils with different strengths and asymmetric structures deviation from the vertical axis (careen) is observed, with a shift of the center up to 1.5-1.8 m. In this case, according to an automated continuous monitoring, as a result of abrupt landings (breakdowns) stresses in the reinforcement, concrete and soil pressure may exceed the calculated and the average values (according to the discrete measurements) 12-15 times.

To estimate the stress-strain state of the well shell with a sharp landing (breakdown) numerical modeling was conducted. In the calculations the finite element method (FEM) and the software package Robot Professional 2010 were used. The calculation is carried out for spatial shell with

diameter of 66m and a height of 71m (with the number of three-dimensional finite elements equal 50828), falling under its own weight at an angle of  $15^\circ$  from a height of 140 cm on the compliant soil (average coefficient of elasticity for multilayer soil is taken  $K = 16500\text{kN/m}^3$ ). In the model because of the inclination angle the friction forces on the lateral side of the well were applied in the upper part of the shell on one side and in the bottom part on the opposite side.

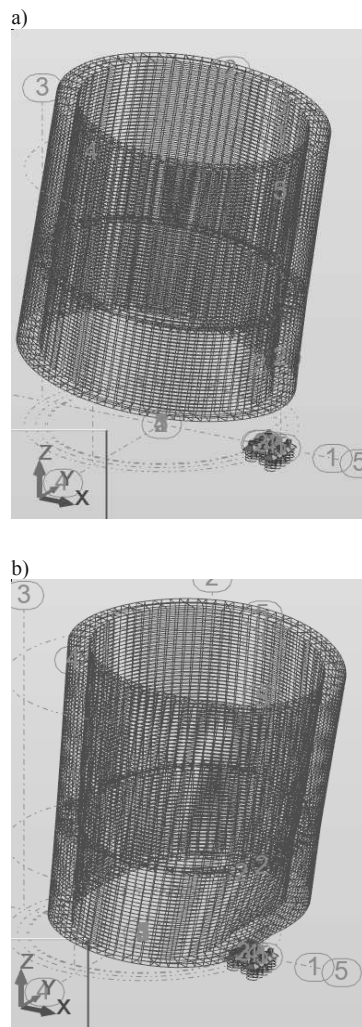

Figure 2. The results of numerical modeling of a sunk well with diameter of 66 m and a height of 71 m for the conditions of a abrupt landing (breakdown): a) the original position, and b) position after a fall from a height of 1.4 m at an angle of  $15^\circ$ .

The results of numerical modeling have shown (see Fig. 2) that in case of a dynamic blow (if the well is dropped from a height of 140 cm) equivalent von Mises stresses in the construct equal  $S_{din} = 256\text{MPa}$  at the top of the shell and  $S_{din} = 1538\text{MPa}$  in the area of the bottom rest, which respectively exceeds the limiting strength of concrete class B30 [Spred] to 14 or more times, and the changes in the geometry of the shell are observed.

Thus, already in the process of the well immersion the construction of the well is damaged and the concrete is disintegrated due to breakdowns. Later during operation micro cracks lead to leakage, seepage and corrosion of concrete. To further ensure the safety of operation of facilities of this type it is necessary to strengthen and waterproof the construct by high-pressure injection of polymer resins.

## 2.2 Geotechnical analysis of technical condition of the sewage tunnels under intensive anthropogenic impact and long term operation

Geotechnical analysis of the sewage tunnel was carried out for the most typical section located in a zone of intense dynamic impact of transport and the impact of new construction.

Figure 3 shows the diagram of the tunnel compressions for more than 35 years of service life.

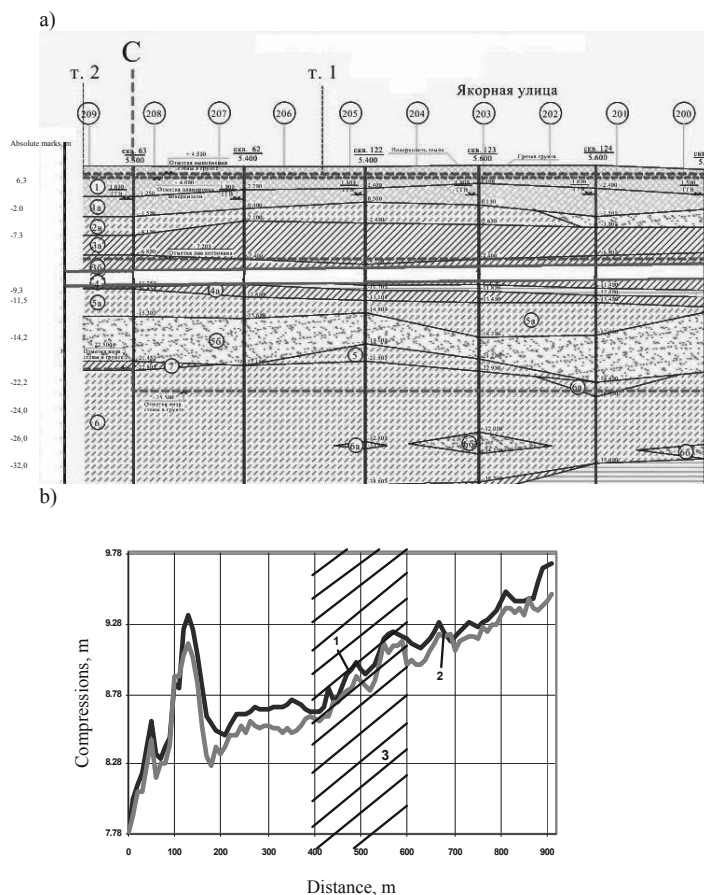

Figure 3. The diagram of comparison of the compressions on the arch axis of the collector: a) engineering and geological section, typical for laying-out sewage tunnels in St. Petersburg, b) the diagram of compressions: 1 - survey results of 2010, 2 - executive survey data of 1975, 3-area of the collector, protected from the influence of the construction by a screen of low modular material.

Uneven tunnel compressions, modified on the arch axis range from 5 to 276 mm. Comparative analysis of engineering and geological section on the tunnel route and its placement on the plan relative to the traffic junction showed that the greatest compressions up to 276 mm are located in the area of the tunnel under intense dynamic effects of the traffic, passing the layer of thixotropic quaternary deposits.

Evaluation of the dynamic impact of the transport was carried out by the study of the oscillatory process with a set of manifold gauges CM TSP installed in the arch and blocks of the recording equipment (Perminov N.A., 2011)

The frequency of the oscillations of the collector during various traffic loads from 15 to 35 Hz, and the vibration amplitude to 35-70 microns was recorded. According to the research (Goldshtein M.N., Lapidus L.S., Reznikov O.M., Storozhenko V.I., Sinaevsky N.I., 1973) for this type of ground deposits and the appropriate level of the dynamic effects the decrease of strength characteristics  $C$  and  $\phi$  is up to 35% and 17%, respectively. To ensure the operational

reliability of tunnels vibration protection measures, such as the use of spiral-wound technology for internal lining the tunnel are suggested.

For this section of the collector the numerical modeling was carried out to determine the maximum allowable axis displacement of tunnel lining. The criterion for the safety of the construct is the maximum allowable tensile stress of the concrete in the typical points of lining. Maximum allowable deformation and displacement values are presented in Figure 4.

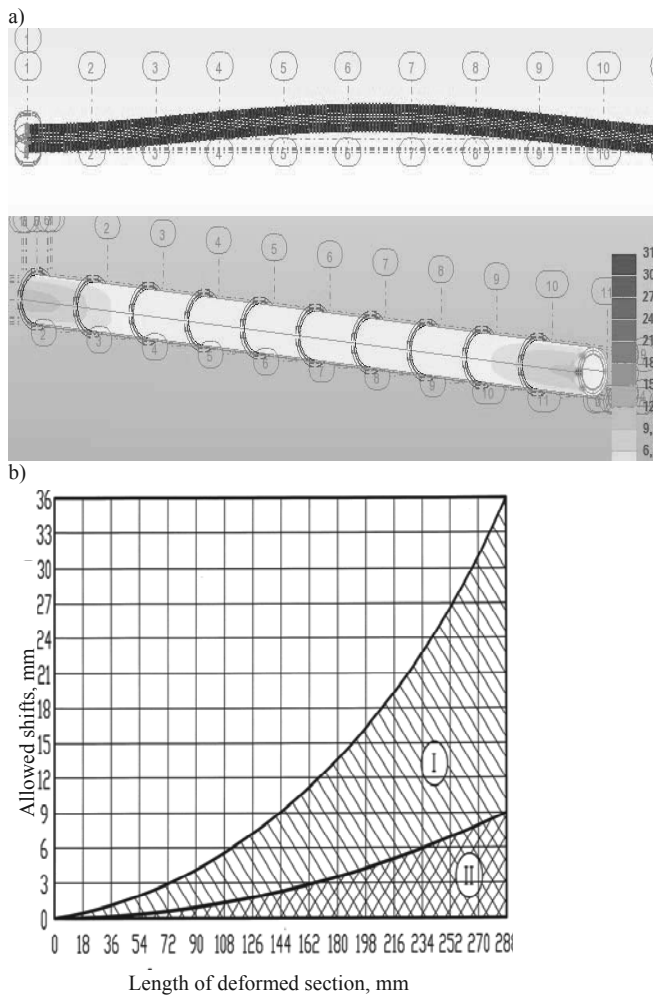

Figure 4. Calculated model of the tunnel (a), the diagram of maximum allowable tunnel lining deformation (b): 1 - Safe displacement values after the lining has been strengthened, 2 - reference value of allowed displacement

### 3. SUMMARY (CONCLUSION)

Data received from long-term field observations for continuous operated embedded constructions being a part of megapolis water discharge system as well as the results of calculation and modeling allowed to conduct geotechnical analysis of the residual bearing capacity and to develop measures to ensure the safe operation of facilities of such type under the conditions of intensive external influences.

As experience shows, the presence of geotechnical tracking of environmentally hazardous facilities of such type for the entire period of their life cycle, including design, construction and long-term operation (even under intensive man-induced impact) provides the safety of the stable functioning of the megapolis utility infrastructure.

**ABSTRACT:** The objective of this study is to demonstrate the numerical and the practical applicability of the particle filter (PF) to some geotechnical problems, i.e., the parameter identification of elasto-plastic geomaterials and the prediction of the deformation behavior of soil deposits and geotechnical structures, by applying the methodology to hypothetical experiments and an actual construction project. The results of the hypothetical experiments reveal that the parameters identified by the PF, based on the sequential importance sampling (SIS) algorithm, have converged into their true values, and that the approach presented herein can provide a highly accurate parameter identification strategy for elasto-plastic geomaterials. Moreover, the simulation results using the identified parameters are close to the actual observation data, and the ensemble-based approach produces more information about the parameters of interest than simple estimated values obtained from optimization methods. In other words, the identification comes in the form of a probability density function.

**RÉSUMÉ :** L'objet de cette étude est de démontrer l'applicabilité numérique et pratique du filtrage des particules (FP) pour certains problèmes géotechniques, à savoir, l'identification des paramètres de géomatériaux élastoplastiques et la prédiction du comportement en déformation de dépôts de sol et de structures géotechniques, en appliquant la méthodologie à des expériences hypothétiques et à des projets de construction existants. Les résultats des expériences à partir d'hypothèses montrent que les paramètres identifiés par le FP, basé sur l'algorithme d'échantillonnage d'importance séquentiel (SIS), ont convergé vers leurs valeurs réelles, et que l'approche présentée ici peut fournir une stratégie d'identification paramétrique très précise pour les géomatériaux élastoplastiques. En outre, les résultats de la simulation utilisant les paramètres identifiés sont proches des données d'observation réelles, et l'approche groupée produit plus d'informations sur les paramètres d'intérêt que de simples valeurs estimées obtenues à partir des méthodes d'optimisation. En d'autres termes, l'identification se présente sous la forme d'une fonction de densité de probabilité.

**KEYWORDS:** data assimilation, particle filter, parameter identification

## 1 INTRODUCTION

Inverse analyses have been successfully applied to linear elastic problems in which the deformation to be addressed is linear and depends only on the model parameters and the applied load; it does not depend on the loading history. However, the mechanical behavior of geomaterials is commonly described by an elasto-plastic model, and the deformation behavior displays strong nonlinearity and depends not only on the values of the parameters, but also to a great extent on the stress state and the history, whereby the identification of elasto-plastic parameters still remains a major challenge.

Data assimilation (DA) is available as a methodology to tackle the above difficulties (Nakamura *et al.* 2005). The estimation of the interest dynamic system via DA involves a combination of observation data and the underlying dynamical principles governing the system. The melding of data and dynamics is a powerful methodology, which makes efficient and realistic estimations possible. This approach has recently proven fruitful in earth science, e.g., geophysics, meteorology, and oceanography (e.g., Awaji *et al.* 2009).

Several kinds of powerful DA methods have been proposed. Among the existing strategies, this study focuses on the filtering techniques referred to as the particle filter (PF, Gordon *et al.* 1993), because it can be applied to nonlinear and non-Gaussian problems and can provide a simple conceptual formulation and ease of implementation.

Herein numerical and practical effectiveness of the DA strategies using the PF are examined for geotechnical problems through their applications to the numerical experiments and an actual construction project. For this purpose, first, we outline the concepts and methods of DA and refer to the PF. Second,

we deal with the parameter identification of elasto-plastic parameters for geomaterials applying the PF to initial and boundary value problems in geomechanics. Finally, we investigate the applicability of the PF to a practical settlement prediction of a well-documented construction project, Kobe Airport Island, comparing the obtained simulation with the observation data, and the practical effectiveness of the DA based on the PF is discussed.

## 2 DA: CONCEPTS AND METHODS

DA is a versatile methodology for estimating the state of a dynamic system of interest by merging sparse observation data into a numerical model for the system. The state of the system is usually estimated with deterministic simulation models, which are subject to the uncertainty that arises due to a lack of knowledge and a poor understanding of the physical phenomena. Meanwhile, observation data, which represent the true state, but are subject to stochastic uncertainty and randomness, may occasionally be available as a function of a subset of the system variables. Based upon a prognostic model and a limited number of observations, DA attempts to provide a more comprehensive system analysis which may lead to more accurate predictions. This approach has recently proven useful in earth science (Awaji *et al.* 2009).

Novel sequential data assimilation methods include the Ensemble Kalman Filter (EnKF, Evensen 1994) and the PF which are categorized into nonlinear Kalman filtering. Although the EnKF can be applied to nonlinear systems, it basically assumes a linear relationship between a state and the observation data in calculating a Kalman gain. Therefore, the

EnKF cannot produce satisfactory estimates if its linear approximation is invalid. This means that its application to geomaterials is difficult, because the materials display strong nonlinearity. On the other hand, as the PF does not require assumptions of linearity or Gaussianity, it is applicable to general problems. Therefore, the PF has higher potential for application to geotechnical engineering and can obtain meaningful outcomes. Brief description of the PF is summarized below.

The PF approximates probability density functions (PDFs) via a set of realizations called an ensemble that has weights, and each realization is referred to as a ‘particle’ or a ‘sample’. For example, a filtered distribution at time  $t-1$ ,  $p(x_{t-1}|y_{1:t-1})$ , where  $y_{1:t-1}$  denotes  $\{y_1, y_2, \dots, y_{t-1}\}$ , is approximated with ensemble  $\{x_{t-1}^{(1)}, x_{t-1}^{(2)}, \dots, x_{t-1}^{(N)}\}$  and weights  $\{w_{t-1}^{(1)}, w_{t-1}^{(2)}, \dots, w_{t-1}^{(N)}\}$  by the following equation:

$$p(x_{t-1}|y_{1:t-1}) \approx \frac{1}{N} \sum_{i=1}^N w_{t-1}^{(i)} \delta(x_{t-1} - x_{t-1}^{(i)}) \quad (1)$$

where  $N$  is the number of particles and  $\delta$  is the Dirac delta function.  $w_{t-1}^{(i)}$  is the weight attached to particles  $x_{t-1}^{(i)}$  and should suffice  $w_{t-1}^{(i)} \geq 1$  and  $\sum w_{t-1}^{(i)} = 1$ .

A general approach for filtering is known as sequential importance sampling (SIS) (Doucet *et al.* 2000). The SIS algorithm is based on using the importance sampling to estimate the expectations of functions of the state variables. The algorithm of SIS is summarized as follows:

1. **Initialization:**  
Generate an ensemble (set of particles)  $\{x_0^{(1)}, x_0^{(2)}, \dots, x_0^{(N)}\}$  from the initial distribution  $p(x_0)$ .
2. **Prediction:**  
Each particle  $x_{t-1}^{(i)}$  evolves according to the numerical dynamic model given by a numerical simulation method such as FEM.
3. **Filtering:**  
After obtaining measurement data  $y_t$ , calculate weight  $w_t^{(i)}$ , which expresses the ‘fitness’ of the prior particles to the observation data, and assign a weight,  $w_t^{(i)}$ , to each  $x_{t-1}^{(i)}$ .
4. **Weight update:**  
The set of weighted particles  $\{x_t^{(i)}\}$  results in an ensemble approximation of filtered distribution  $p(x_t|y_{1:t})$ .  
Set  $t = t + 1$  and go back to Step 2.

Figure 1 shows the algorithm of the PF based on the SIS.

Figure 1. Algorithm of the PF based on SIS.

### 3 PARAMETER IDENTIFICATION OF CAM-CLAY MODEL USING THE PF

This chapter focuses on the soil-water coupled behavior of a clay foundation under monotonic loading, where the numerical simulation for hypothetical soil deposit under embankment is implemented to study the efficiency of the PF as a parameter identification method.

The soil-water coupled finite element analysis using the Cam-clay model were used in this example. The finite element mesh and the loading history are shown in Figures 2 and 3, respectively. Table 1 lists the parameters of the clay foundation. The placement of the observation points is also shown in Figure 2; the vertical displacements and the horizontal displacements are located at S1-S3 and at L1-L3, respectively. Some of the parameters are chosen to be identified and their values are called ‘true values’ as listed in Table 2, and we carried out 100 Monte Carlo Simulations using the sets of particles which were generated with uniform random numbers in the range shown in Table 2.

Figure 4 shows the time evolution of the identified parameters ( $\lambda$ ,  $\kappa$ , and  $M$ ). Identified parameters are computed as the weighted mean value of the particles computed by

Figure 2. Finite element mesh.

Figure 3. Loading history.

Table 1. Cam-clay parameters of the model foundation.

$\lambda$	$\kappa$	$e_0$	M
0.190	0.065	0.992	1.154

Table 2. True values of the parameters to be identified and range of particle generation.

Parameter	True value	Range
$\lambda$	0.239	0.090 ~ 0.290
$\kappa$	0.091	0.015 ~ 0.115
M	1.084	0.854 ~ 1.454

$$\bar{\phi}_t = \sum_{i=1}^N w_t^{(i)} \phi_t^{(i)} \quad (2)$$

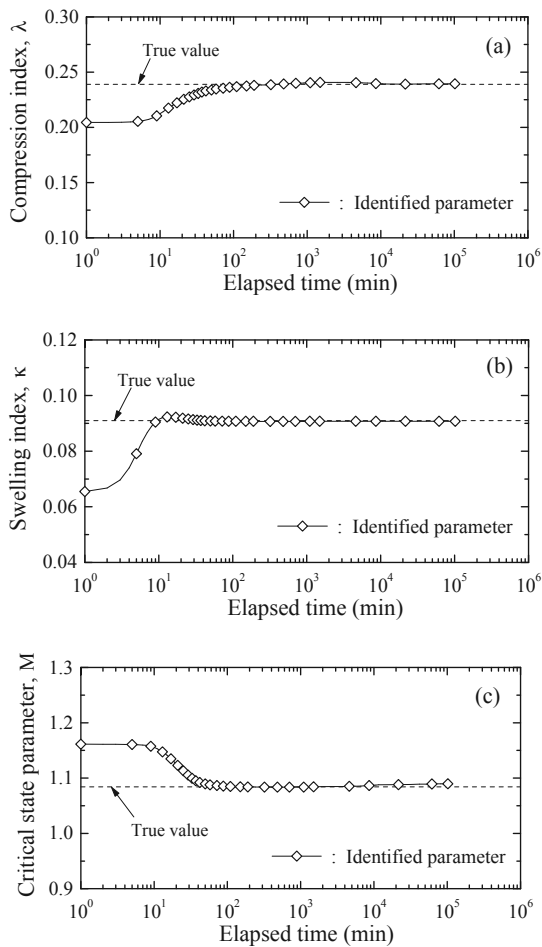

Figure 4. Time evolution of identified parameters.

where  $\bar{\phi}_t$  and  $\phi_t^{(i)}$  indicate the identified parameter at time step  $t$  and the parameter of particle number ( $i$ ) at time step  $t$ , respectively.

The parameter identification of unknown parameters approaches the true values, although the identification starts with an incorrect  $\bar{\phi}_0$  in all cases purposefully. These results verify the effectiveness of the PF for the parameter identification of the elasto-plastic model, which presents strong nonlinear behavior.

#### 4 APPLICATION OF THE PF TO SETTLEMENT BEHAVIOR OF KOBE AIRPORT ISLAND CONSTRUCTED ON RECLAIMED LAND

The objective of this chapter is to investigate the applicability of the PF to an actual settlement prediction of a well-documented geotechnical construction project, Kobe Airport Island. To accomplish this objective, firstly, the settlements of the island are evaluated using a soil-water coupled finite element analysis with the Cam-clay model. Then, the parameters are identified using the PF. Finally, comparing the recomputed simulation using identified parameters with the observation data, the practical effectiveness of the methodology based on the PF is discussed. Some outcomes obtained from this application example were reported in Murakami *et al.* (2012).

Kobe Airport was constructed on an artificially reclaimed island just off the coast of Kobe. Figure 5 shows the cross section of the construction site. Vertical sand drains were installed in the soft clay layer in order to accelerate the settlement and increase the strength (e.g. Yamamoto *et al.* 2010).

 Figure 5. Cross section of the construction site (Yamamoto *et al.* 2010).

 Figure 6. Finite element mesh (Murakami *et al.* 2012).

The soil-water coupled finite element analysis with the Cam-clay model was adopted for analyzing the deformation behavior of the seawall and the foundation subjected to the construction and reclamation work. Figure 6 shows the finite element mesh. In the model ground, the top surface, bottom surface and the sides of sand/gravel layers were assumed to have permeable boundary conditions, whereas the sides of clay layers were assumed to have impermeable boundary conditions. The sand layers and reclaimed ground were assumed to be linear elastic, and the clay foundations were represented by the Cam-clay model.

The *mass permeability* concept, which was proposed by Asaoka *et al.* (1995), was incorporated into this analysis. Mass permeability is the permeability representative of a clay foundation, which includes the effects of inhomogeneity, partial drainage, and load intensity. We also adopted the concept in the same sense. The analysis in this chapter focuses on the settlement behavior of only the improved alluvial clay foundation, because the soil layers which are just below the improved ground, called Ds1-Ds3, are thick, have high rigidity (the N-value obtained from SPT is more than 100), and do not significantly affect the settlement of the island.

Firstly, we considered the improved ground to be homogeneous by incorporating the mass permeability concept. Then, using the PF, some parameters of the treated ground, the so-called *mass parameter* were identified to simulate settlement of the ground under the airport island. Although the some parameters affect settlement of the ground, the compression index  $\lambda$  and the permeability  $k$  were treated as the only parameters to be identified, because these two parameters directly govern consolidation behavior of clay grounds. Finally, the simulations were implemented using the identified mass parameters and observation data were compared to evaluate the practical usability of the PF.

The representative parameters of the improved grounds, referred to as mass parameter ( $P_{\text{mass}}$ ) in this study, are determined here by using equation (3) for simplicity.

$$P_{\text{mass}} = \frac{P_1 h_1 + P_2 h_2 + \dots + P_n h_n}{h_1 + h_2 + \dots + h_n} \quad (i=1,2,\dots,n) \quad (3)$$

where  $P_i$ ,  $h_i$ , and  $n$  are the parameters, the thickness of each layer, and the number of soil layers, respectively.

We conducted Monte Carlo simulations with 200 particles over the feasible space listed as follows:

$$0.30 \leq \lambda \leq 0.60, \quad 1 \times 10^{-0} \leq k \leq 1 \times 10^{-3}. \quad (4)$$

Figure 7. Time evolution of identified parameters.

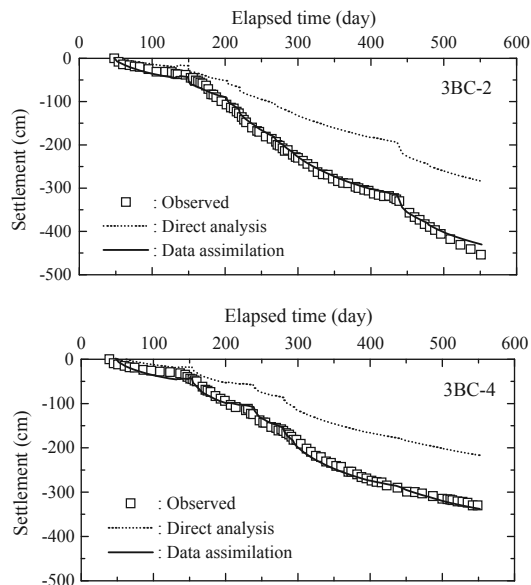

Figure 9. Simulation results using the identified parameters.

Each parameter was assumed to follow uniform randomly and was generated independently. All 200 simulations were conducted up to 676 days after the construction was started. Only the settlement values observed on the seabed were used for parameter identification.

Figure 7 shows the time evolution of the identified parameters. In the figure, the estimates for  $\lambda$  hardly change through the assimilation. In particular, after the 300<sup>th</sup> day, the path changes dramatically. On the other hand, in the result of  $k$ , the identified parameter shows almost constant value through the assimilation.

Figure 8 shows filtered PDFs of a settlement value at the 148 days after construction began. In this figure, the vertical axis represents the weight of the particle, while the horizontal axis represents settlement value. It can be seen from the Figure 8 that the distribution of the weight approximately follows the normal distribution which has sharp peak around -3.5m. From the result, we can see that the use of a large number of particles contributes to the accurate estimation of the arbitrary PDFs for settlements. This is the remarkable advantage of the PF.

The simulation results for the time-settlement relationship at observation points 3BC-2 and 3BC-4, which were placed on seabed, via the identified parameters are shown in Figure 9. The identified parameters mean the values at the end of the identification process, that is,  $t = 456$  days. In the figures, dotted line represents the result of direct analysis. Although the results of direct analysis underestimate the observation data, the simulations using the identified parameters yielded predictions with high accuracy.

Figure 8. Filtered PDF of a settlement value.

## 5 CONCLUSIONS

In this study, we have investigated the numerical and the practical effectiveness of the DA strategies using the PF for geotechnical problems through their applications to the hypothetical experiment and the actual construction project.

The parameters identified by the PF have converged into their true values, and the presented approach has shown effective parameter-identification method for elasto-plastic geomaterials. Moreover, the simulated time-settlement behavior using the identified mass parameters has provided a good agreement with the actual observation.

In conclusion, the DA using the PF has been proven a powerful strategy for identifying elasto-plastic parameters of geomaterials and more accurate predictions of the mechanical behavior of geotechnical structures.

**ABSTRACT:** A large scale model test was carried out in this study to investigate the relationship between the potential risk of slope failure and an increase of the shear strain in the shallow section. A model slope made of soft deposit of Kanto-loam with 30 degrees inclination and 3.5m height was prepared. Compact shear strain meters as well as inclinometers and extensometers were installed to measure the movements of slope prior to failure. Seven steps of cuttings were carried out from the toe to make the slope unstable. The model slope did not fail soon after completion of the final cutting, and it lasted 7 minutes before it finally failed. Clear increases in the shear strain  $\theta$  had been measured as the cuttings progress. The obtained data of  $\theta$  and the displacement showed good agreement in their reactions. Accordingly, it is proven that the potential risk of slope failure was detectable by monitoring of the shear strain in the shallow section for simplicity.

**RÉSUMÉ :** Un essai sur modèle à grande échelle a été réalisé dans cette étude pour étudier la relation entre le risque potentiel de rupture de pente et une augmentation de la déformation de cisaillement dans la partie peu profonde. Une pente modèle composée de dépôts mous de Kanto-limoneux a été préparée avec une pente de 30 degrés et une hauteur de 3,5 m. Des capteurs de déformations de cisaillement compacts ont été développés et installés avec des inclinomètres et des extensomètres pour mesurer les mouvements de pente avant la rupture. Sept phases d'excavation ont été réalisées au pied pour rendre la pente instable. Le modèle de la pente ne s'est pas écroulé tout de suite après la coupe finale, et il y a eu un intervalle de 7 minutes avant la rupture. Une nette augmentation de la déformation de cisaillement  $\theta$  a été mesurée lors des excavations. Les données de  $\theta$  obtenues et le déplacement montrent un bon accord dans leurs comportements. Ainsi, il a été montré que le risque potentiel de rupture d'une pente est détectable par le suivi de la déformation de cisaillement au pied du talus pour la simplicité.

**KEYWORDS:** slope failure, monitoring, shear strain in shallow section, large scale model test.

## 1 INTRODUCTION

Slope failures frequently cause occupational accidents at construction sites. It is also known that even a small collapse can cause serious injury to workers. Therefore, slope failures must be avoided for safety reasons, and temporary retaining walls are needed to support slopes at worksite. In addition, the practice of immediate escape is also important to save human lives, and warning must be given prior to failure. Consequently, monitoring of the slopes is needed to detect increase of the potential risk of failure.

This paper will first summarize hazards that exist in the slope works. Next it will explain a large scale model test carried out to simulate the slope failure. It will also introduce a compact shear strain meter developed to measure increase of shear strain in the shallow section of slopes. Finally, its applicability will be discussed in consideration of results from the test.

## 2 HAZARDS IN WORKS ON SLOPES

Excavations and cuttings are frequently performed in many aspects of slope works. Cuttings at the toe of slopes are common in the building of retaining walls. However, cuttings may cause the slope to be unstable even though its duration is only short term. Itoh et al. (2005) reported that the volume of collapsed soil blocks in almost 60 % of all accidents was less than 50m<sup>3</sup>. Accordingly, serious damage to the workers are caused by small amount of collapsed soil blocks. In addition, safety must be maintained at the recovering operation after disasters. Collapsed soil deposited is soft and loose after seismic failure, and shear strength of remaining soil slopes was also

reduced by seismic acceleration. Therefore, slopes will become unstable after earthquakes. Meanwhile, when quick operations are also required to save refugees, sufficient time for both installation of temporary structures to support the unstable slopes and survey of the ground conditions in detail will not be given.

Hazards exist to people who work on the slopes as well as under the slopes. Moreover, the time for escape may be not given to the adjacent workers. Consequently, warning prior to the failures is important to save workers as well as an installation of temporary supports.

## 3 A LARGE SCALE MODEL TEST

### 3.1 Preparation of model ground and method of model test

A model slope of 3.5m height, 4.0m width and 30 degrees inclination was made by filling soil material as shown in Figure 1. Any compaction was not provided to simulate loose deposit of collapsed soil after seismic disasters. Several sheets of tarpaulins are placed to lubricate the friction between the retaining wall and the soil so that the plane strain condition was undertaken.

Soil material used in the test was Kanto loam that has soil properties as shown in Table 1. Figure 2 shows the relationship between the cone penetration resistance  $q_c$  and the depth from the top of slope  $d$ . Values of  $q_c$  roughly show a linear increase to  $d$  because the self-weight was loaded for consolidation.

Figure 1. A profile view of model slope.

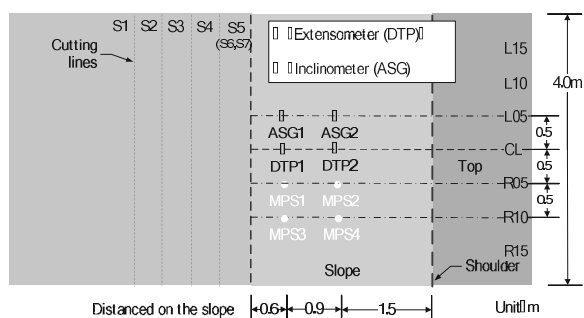

Figure 3. A plane view to show the installed position of sensors

Property	Value
Density of soil particles $\rho_s$ ( $g/cm^3$ )	2.759
Sand (0.075 ~ 2mm) %	6.2
Silt (0.005 ~ 0.075mm) %	45.3
Clay (Diameter < 0.005mm) %	48.5
Liquid limit $w_L$ (%)	158.3
Plastic limit $w_p$ (%)	97.7
Plasticity index $I_p$	60.6
Dry density $\rho_{dmax}$ ( $g/cm^3$ )	0.665
Optimum water content $w_{opt}$ (%)	102.0

Figure 2. Relationship between cone penetration resistance and depth from the top of slope.

Seven steps of cuttings were carried out by construction machinery in the toe of slope. 60 degrees angle in the cuttings was performed from S1 to S5 that was 0.5m long from front to back as shown in Figure 1. As for S6 and S7, the cutting angle was increased to 70 degrees and 75 degrees, respectively. Thirty minutes interval time between the steps was provided to observe the movement of the slopes.

### 3.2 Installation of sensors

Three kinds of sensors, extensometers (DTP), inclinometers (ASG), and compact shear strain meters (MPS), were installed to measure the movement of the slope during the test. Figure 3 shows the installed positions of the sensors. Two sets of DTP were installed to measure increment of the displacement  $d$  by giving 0.9m interval at the center column (CL). Sensor units of DTP were set on a beam bridging over the retaining walls while extended wires were connected to pegs on the slope.

Figure 5. Shape and structure of a developed compact shear strain meter (MPS).

Photo 1. Installation of MPS

Two sets of ASG were installed to measure an increment of the angle of inclination  $\alpha$  on the surface at the column of L05 at same height as DTP. Four sets of MPS to be explained in the following section were also installed to measure increment of the interpreted shear strain  $\theta$  at the columns of both R05 and R10 in the same manner as the installation in ASG.

## 4 MEASUREMENT OF SHEAR STRAIN IN THE SHALLOW SECTION

### 4.1 Development of compact shear strain meter

A compact shear strain meter called MPS was developed to measure the shear strain in the shallow section of slopes (Tamate, 2010). MPS made of compact size rod 0.6m in length, 10mm in diameter, and 3.6N in weight is shown in Figure 4. A screw point of 80mm in length attached in the lower end enables to penetrate the unit into the ground without pre-boring. A taper end of 100mm in length is used to provide a lateral compression to the surrounding soil so that MPS reacts to the slope movement by its bending deformation. A connector terminal for data transmission composed of 7 poles is mounted at the center of a hexangular plug for rotational installation by a hand drill.

A bending pipe of 420mm in length is positioned between the screw point and the taper end. Four strain gages are pasted on both front and back of the pipe so that the electrical output increases with the bending deformation. A heat shrinkable tube covers the pipe to protect the gages from surrounding soil at installations. Since duration for the installation was less than 10 seconds, easy and quick installation is available in practice as shown in Photo 1.

### 4.2 Basic idea for the monitoring

Figure 5 shows a schematic image of distribution of displacement and shear strain in the slope. An increment of the displacements occurs near the slip plane whereas the increment converges as the distance increases. Accordingly, major shear strain develops along the slip plane. However, this study aims to monitor the shear strain in the shallow section of slopes from the easily application viewpoint (Tamate et al. 2009). MPS was developed to measure the small shear strain in the shallow sections easily.

Figure 5. Schematic image of distribution of shear strain at slope failure.

a) Outline of method for calibration of MPS

 b) Electrical output  $r_s$  and interpreted shear strain  $\theta$     c) Load  $F$  and settlement  $s$   
 Figure 6. Stiffness and sensitivity of MPS

A calibration of MPS was carried out to investigate the relationship between the electrical output from MPS  $r_s$  ( $\mu\epsilon$ ) and the interpreted shear strain  $\theta$  (%).  $\theta$  was defined as the ratio of the settlement  $s$  to the effective length  $L$  of MPS as shown in Equation 1.

$$\theta(\%) = \frac{s}{L} \times 100 \quad (1)$$

A vertical load  $F$  was applied to the end of MPS that was supported by cantilever beam as shown in Figure 6. A clear linear relationship is obtained between  $r_s$  and  $\theta$  as well as between  $F$  and  $s$ . Since  $653 \mu\epsilon$  in  $r_s$  was output at 1% in  $\theta$ , a high resolution on the shear strain was confirmed.

## 5 EXPERIMENTAL ANALYSES ON MOVEMENT IN SLOPE

### 5.1 Comparison of reactions by sensors

Figure 7 shows the reactions from three kinds of the monitoring sensors. Horizontal axis means the actual time at the test. The first cutting (S1) begun at 13:00 and the final cutting (S7) was completed at 16:20. The slope collapsed twice at 16:27 and 16:36. This meant that 7 minutes remained prior to the first failure and 16 minutes existed up to the second failures after the completion of S7 as shown in Photo 2. An increase of values appeared in each curve as reactions to increase of potential risk of slope failure.

Figure 7. Comparison of reaction of sensors in the model test

Photo 2. Process of failures in the model slope

 Figure 8. The relationship between the interpreted shear strain  $\theta$  and the displacement  $d$  (in left) and the relationship between the angles of inclination  $a$  and  $d$  (in right).

First small increase can be seen at S3 in  $\theta$  and its value shows the step increase from S3 to S7. After S7, however, values of  $\theta$  kept on increasing from 16:20 to 16:27. Both MPS2 and MPS4 installed at the upper side of the slope show the same increase. Both two curves bent at 16:27 when the first failure occurred. Moreover, values of  $\theta$  were built up again at 16:36 of the second failure.

Figure 9. Increases of shear strain in the shallow section prior to the first failure and the second failure

Figure 10. Decrease of the inverse velocity of shear strain prior to the first failure (Overall view in left and expanded view in right)

In addition, a displacement  $d$  increased in DTP1 installed at the lower side of slope in advance, and its value showed the step increase from S5 and S6. Same phenomena in the increase can be seen in both sets of DTP and MPS. Meanwhile, curves on angle of inclination  $a$  did not show clear reactions corresponding to the series of cuttings. A value of ASG1 was kept stable while a value of ASG2 gradual increase from S3. There was no clear reaction on  $a$  excluding those at the moment of the second failure while the slope was getting unstable.

Figure 8 shows the relationship between  $\theta$  and  $d$  in addition to the relationship between  $a$  and  $d$ .  $\theta$  shows a clear increase prior to the first failure when  $d$  hovered between 4 and 7.  $\theta$  also reacted to the second failure so that  $\theta$  still increased where  $d > 7$ . Meanwhile, values of  $a$  increased very little from -0.4 to -0.8 deg to the  $d$  though -0.4 deg of the initial drift appeared.

### 5.2 Increment of the shear strain in the shallow section prior to failure

Figure 9 shows the relationship between  $\theta$  and an elapsed time  $t_e$  recorded by 4 sets of MPS. Both MPS1 and MPS2 were installed in the column of R05 whereas MPS3 and MPS4 were installed in the R10 as shown in Figure 3.  $t_e$  is a modified value that is calculated as zero at the beginning of the first failure. Accordingly, negative values mean the remaining time until the first failure. Recorded data by both lower MPS1 and MPS3 ended at 0 of  $t_e$  because these dropped together with collapsed soil at the first failure. Upper MPS 2 and MPS4 had recorded data until the second failure. Four curves commonly show a linear increase at around -5 of  $t_e$ , and this phenomena was similar to the 2<sup>nd</sup> creep that was well known as the plastic deformation prior to failures. In addition, the value of both MPS1 and MPS3 installed inside of the failure block accelerated these increases from -3 of  $t_e$ . Same acceleration on

the increase was seen in the values of both MPS2 and MPS4 before the second failure.

The left side figure on Figure 10 shows the entire relationship between the inverse velocity of the shear strain  $1/v_\theta$  and  $t_e$  by a logarithmic scale on a vertical axis.  $v_\theta$  is defined as a value of the increment of  $\theta$  per minute.  $1/v_\theta$  of both MPS1 and MPS3 were distributed at higher values from 1,000 and 30,000, when  $t_e$  was between -35 and -10. This means at least that little  $v_\theta$  appeared 10 minutes before the first failure. However,  $1/v_\theta$  shows the drastic decrease corresponding to the beginning of the final cutting of S7. However, the slope did not fail soon. A couple minutes of time lag existed prior to both failures, and this causes people's misunderstanding of the stability.

The right side figure shows an expanded view by a linear scale on a vertical axis.  $1/v_\theta$  indicated the values between 30 and 80 min/% while 4 minutes between -7 and -3 of  $t_e$ . Accordingly, the values of  $v_\theta$  were interpreted as between 0.01 and 0.03 %/min. Consequently, the shear strain increased at mostly constant rate in the same manner as the 2<sup>nd</sup> creep. Moreover,  $1/v_\theta$  in MPS1 and MPS3 linearly decreased from -2 and -4 of  $t_e$ , respectively. This proves that values of  $\theta$  were accelerating these increases just before failures, the same as the 3<sup>rd</sup> creep. Accordingly, a clear increase of shear strain in the shallow section of the slope was confirmed in the large scale model test. In addition, it was proven that this phenomenon reflects an increase of potential risk of slope failure. Therefore, a couple of minutes could be provided for escape by identifying either the 2<sup>nd</sup> creep or the 3<sup>rd</sup> creep.

## 6 CONCLUSIONS

A large scale model test was carried out in this study to investigate relationship between the potential risk of slope failure and an increase of the shear strain in the shallow section. Developed compact shear strain meters as well as conventional sensors of inclinometers and extensometers were used in the test to measure the movement of the slope prior to failure. Seven steps of cuttings were performed in the toe to make unstable. The model slope did not fail soon after a completion of the final cutting, and around 7 minutes of the time lag existed until the beginning of failure. Clear increases in the responses of shear strains  $\theta$  in the shallow section were measured with the progress of the cuttings. The obtained data of  $\theta$  and the displacement  $d$  showed good agreement in their reactions. Accordingly, it is proven that the potential risk of slope failure was detectable by monitoring of the shear strain in the shallow section for simplicity.

## 7 ACKNOWLEDGEMENTS

The authors would like to thank Prof. Toshiyuki Kadada, Mr. Nozomu Yamamoto of Tokyo City University, Dr. Kazuya Itoh and Dr. Naotaka Kikkawa of the National Institute of Occupational Safety and Health, Japan for their cooperation in the large scale model test and analyses.

# Soutènements de grande hauteur soutenus par butons ou multi-ancrages à Monaco : de la modélisation au comportement réel

Retaining wall with struts or multi-anchored for a deep excavation in Monaco: from modeling to real behaviour

Utter N., Dervillé B.  
Soletanche-Bachy, France

Beth M.  
Soldata, France

**RÉSUMÉ :** La construction de l'immeuble Teotista comporte la réalisation d'un parking enterré de 6 sous-sols, donc d'une excavation profonde présentant toutes les particularités des projets monégasques, à savoir un environnement exigü, des ouvrages mitoyens sensibles, et la nécessité d'entailler une forte pente d'éboulis. La hauteur terrassée se trouve ainsi variable de 20 m côté aval à 30 m côté amont, nécessitant la mise en œuvre d'une paroi à contreforts prolongée par des micropieux dans le marno-calcaire rencontré en profondeur, et d'un butonnage fortement dissymétrique sur 5 niveaux, engendrant concentration d'efforts et mise en butée du terrain aval.

La complexité de la structure et du phasage, ainsi que la sensibilité de l'environnement, ont nécessité la mise en œuvre de différents types de modélisations (méthode des coefficients de réaction et méthode des éléments finis), et motivé la mise en œuvre d'une instrumentation qui a permis de confronter à la réalité ces différentes modélisations dans toutes les phases de construction.

Il a ainsi été possible de mettre en évidence la validité des calculs traditionnels dans leur domaine d'application, mais aussi de progresser dans l'appréhension correcte des frontières entre modèles de comportement et méthodes de calcul associées.

**ABSTRACT:** This paper aims at presenting the works carried out for the construction of the so-called Teotista building including a six floors underground parking requiring a deep excavation with all the specifications of the projects implemented in Monaco, i.e. a confined environment, sensitive structures in the vicinity, and the necessity to scrape a deep slope of taluses. The height thus excavated is at a range of 20 m on the downstream side to 30 m on the upstream side. This implies the implementation of buttresses with micropiles drilled in marl and limestone soil and to deal with very dissymmetrical forces transferred by five levels of inclined and pre-stresses struts.

The complexity of the structure itself, the phasing stages and the sensitive environment as well have required the implementation of several modeling systems (finite elements analysis and coefficient of subgrade reaction method), accurate monitoring system which provided a kind of reality check to ensure the assumptions made by modelling at all the stages of the construction.

By doing so, we demonstrated the validity of the traditional editing calculation notes and help advance in the right apprehension of borders between soil behaviour and associated methods for calculations.

**MOTS-CLÉS :** soutènement, butons, précontrainte, contreforts, méthode observationnelle

**KEYWORDS:** retaining wall, struts, pre-stress, buttresses, observational method

## 1 UN PROJET A FORTES CONTRAINTES

### 1.1 Une emprise limitée

Situé en Principauté de Monaco, le projet de la Tour Teotista comporte l'édification d'un immeuble de 20 étages dans un environnement particulièrement exigü. La surface au sol n'est que de 30 x 30 m et prend la forme d'un talus d'environ 25° dont la cote varie de 132 NGM à l'amont et 118 NGM à l'Aval.

### 1.2 Un voisinage dense

Le projet est situé dans un contexte urbain dense et bordé :

- au Sud par le bâtiment Garden House, immeuble R+7 fondé à 107 NGM.

- au Nord par la Villa Béatrice, habitation R+9 fondée sur semelle à 118 NGM à proximité immédiate du projet.

- à l'Ouest par l'Avenue Hector Otto Supérieure et particulièrement à proximité du Patio Palace, immeuble R+14 de 5 niveaux de sous sols.

- à l'Est par l'Avenue Hector Otto Inférieure donnant sur les Villas du Parc, bâtiment de 10 étages fondé à 108 NGM.

### 1.3 Un contexte géologique difficile

Les sondages font apparaître une stratigraphie constituée de remblais surmontant une épaisse couche d'éboulis et de colluvions à matrice argileuse. Une frange d'altération d'épaisseur variable surmonte un substratum compact constitué de formations marneuses et marno-calcaires d'âge crétacé.

La résistance élevée des couches profondes ( $E_m = 250$  à  $500$  MPa) et la géométrie étriquée du chantier ont nettement orienté la technique de soutènement utilisée. Le projet a consisté en un soutènement mixte composé d'une paroi moulée prolongée par une fiche en micropieux à partir de 1 m sous le fond de fouille.

L'utilisation d'une hydrofraise était rendue impossible par l'emprise restreinte du chantier, et l'utilisation d'une benne preneuse n'aurait pas permis d'assurer entièrement l'excavation des couches compactes.

Figure 1. Coupe générale du projet

#### 1.4 Des tolérances de déplacements strictes associées à une forte contrainte architecturale

Le projet comporte 6 niveaux de sous-sols et la cote du fond de fouille est située à 103,3 NGM à l'Amont et 100,4 NGM à l'aval. Dans ce contexte urbanisé très dense et suite aux désordres observés lors de la construction du Patio Palace mitoyen, les critères de déplacements imposés par le contrat sont très sévères : les soutènements ont été dimensionnés pour que le déplacement en tête de paroi amont ne dépasse pas 2 cm, là où pour un soutènement de 30 m, il est généralement admis que les déplacements observés seront de l'ordre du 1/1000<sup>ème</sup> de la hauteur. Le tassement différentiel sous les immeubles avoisinants est limité à 0,8 pour mille.

En outre une contrainte architecturale forte qui impose dans la toute dernière phase des travaux, planchers de la tour construits, de détruire une partie des contreforts du soutènement amont afin d'obtenir une paroi en console sur 8 m de haut. La contrainte principale visait donc à réduire au maximum les déplacements de la paroi pendant les phases provisoires d'excavation pour garantir ce critère lors de la destruction des contreforts.

## 2 UN PHASAGE DE CONSTRUCTION COMPLEXE

Pour répondre à ces contraintes, il a fallu maîtriser l'espace réduit du chantier, gérer l'ensemble des techniques de travaux mis en jeu et combiner ainsi les multiples plateformes associées à chaque soutènement.

Figure 2. Vue générale du chantier en phase de forage

### 2.1 Soutènement Amont-Aval

La différence de hauteur entre le terrain naturel à l'amont et à l'aval induit une dissymétrie de poussée qu'il est nécessaire de maîtriser pour éviter tout basculement de l'ouvrage. La mise en

place de tirants longs ancrés dans le substratum étant interdite à l'amont, l'ensemble des efforts transite de l'amont vers l'aval par un système complexe de dalles, contreforts, butons et planchers.

Figure 3. Vue générale des soutènements et des plateformes associées

En phase travaux, la paroi moulée amont de 0,82 m d'épaisseur s'appuie sur 9 niveaux de bandes de planchers réalisées en descendant. D'environ 3 m de large, elles permettent de transférer et concentrer les efforts au niveau des 4 contreforts de 3,75 x 0,50 m espacés tous les 12 m.

Cinq lits de butons de gros diamètre,  $\phi 1200$  mm (see Figure 10) équilibrant jusqu'à 10 000 kN chacun, retransmettent ensuite les efforts des contreforts amont aux contreforts aval. Ces butons sont précontraints afin de garantir le minimum de déplacements.

Les contreforts aval de 4,75 x 0,50 m retransmettent ensuite les efforts à la paroi moulée aval de 0,62 m d'épaisseur par l'intermédiaire des bandes de planchers. Elles transfèrent l'intégralité des efforts des contreforts aux parois puis ensuite au terrain en butée.

En phase service, la paroi moulée amont s'appuie sur les planchers et le noyau dur de la tour dont l'inertie est primordiale pour la stabilité globale de l'ouvrage. Les micropieux d'ancrage des parois sont par ailleurs sollicités pour reprendre les éventuels efforts de traction, au séisme notamment.

### 2.2 Soutènement Villa Béatrice

Le long de la Villa Béatrice, le soutènement exécuté est une paroi moulée de 0,62 m d'épaisseur maintenue en phase provisoire par 6 lits de tirants précontraints et en phase définitive par les planchers de la tour Teotista. La réalisation des tirants précontraints longs engage les tréfonds de la Villa Béatrice sur 15 m de longueur.

Figure 4. Coupe sur Villa Béatrice

### 2.3 Soutènement Garden House

Les fondations du Garden House se situant à 105 NGM soit environ à 4,60 m seulement du fond de fouille, il a été possible de réaliser une micro berlinoise constituée de tubes 177,8 ép 25 mm disposés tous les 1.30 m.

Figure 5. Elévation le long du Garden House

La partie haute du voile ne reprend aucun effort. Deux butons de principe sont cependant disposés à titre conservatoire.

## 3 DIMENSIONNEMENT

### 3.1 Modélisation et méthodes de calcul.

Afin d'estimer au mieux les déplacements du futur ouvrage, les calculs ont été effectués pour chaque soutènement au moyen du programme PARIS basé sur la méthode du coefficient de réaction (Schmitt 2009). Ce logiciel a permis de modéliser et dimensionner l'ensemble des parois, des butons, planchers et noyau central de la Tour. Le programme PLAXIS a permis, quant à lui, d'évaluer les tassements et d'appréhender le comportement global du massif.

Dans les deux modélisations, chaque paramètre a été choisi avec soin pour refléter au mieux les sollicitations réelles sur l'ouvrage. Les coefficients de poussée ont été déterminés à l'aide des tables de Kerisel Absi avec prise en compte du pendage moyen des terrains. Les coefficients de réaction sont estimés à l'aide de la formule semi-empirique de Schmitt (CNJOG 2009). Les circulations d'eau occasionnelles pouvant exister à l'interface entre les couches d'altération et du marnocalcaire compact ont été considérées sur toute la hauteur du substratum pour prendre en compte un éventuel effet barrage. Les calculs PLAXIS ont été réalisés en considérant une loi de comportement de type Hardening Soil Model (HSM), modélisant un comportement élasto-plastique des sols avec écrouissage, avec un module  $E_{50ref}$  de l'ordre de  $3Em/\alpha$ .

### 3.2 Interaction avec le Gros Œuvre

L'inertie de la tour joue un rôle essentiel dans les déplacements atteints lors de la construction, le démontage des butons et la destruction des contreforts. Les caractéristiques des éléments verticaux de l'infrastructure ont été communiquées par l'entreprise de Gros Œuvre et intégrées sous forme d'une baïonnette centrale dans l'ensemble des modélisations PARIS et PLAXIS.

En phase séisme, le Bureau d'études Structures a modélisé, l'ensemble du bâtiment en 3D à l'aide des caractéristiques d'interfaces terrain/paroi du projet, y compris les parois moulées et micro-berlinoises périmétrales. Le dimensionnement des soutènements a été effectué à l'aide des sollicitations sismiques transmises par le BET Structures. Une vérification PLAXIS a permis par ailleurs de contrôler que la butée aval obtenue était compatible avec le terrain en place.

### 3.3 Le rôle des soutènements latéraux

Les soutènements latéraux au droit de la Villa Béatrice et du Garden House ont une double fonction. Ils permettent bien évidemment de soutenir les terres mais aussi de re-transférer les efforts provenant de l'amont vers l'aval. Tout comme les butons mis en place il a été vérifié que ces soutènements étaient capables de reprendre les efforts mis en jeu.

Au droit de la Villa Béatrice, le ferrailage prévu pour les panneaux de paroi moulée a notamment été vérifié en considérant un cas de figure pénalisant où aucun frottement ne serait considéré pour la transmission des efforts entre la paroi et le sol et entre les parois au niveau des joints de panneaux.

La paroi moulée a donc été modélisée en considérant les panneaux comme indépendants et réagissant tels des « dominos » appuyés les uns sur les autres. Chaque panneau de paroi, modélisé comme un élément de poutre vertical, a ensuite été vérifié en flexion déviée.

Figure 6. Modélisation PARIS – transmission des efforts Amont-Aval.

## 4 SUIVI DU COMPORTEMENT DE L'OUVRAGE

### 4.1 Dispositif de mesures

Le dispositif d'auscultation propre de la paroi comporte 7 inclinomètres et un ensemble de 20 cibles. L'instrumentation des avoisinants comprend 31 prismes, 8 capteurs de vibrations et 16 cibles réparties sur les différentes habitations jouxtant le chantier. Un ensemble de 16 extensomètres sur armatures ont été mis en place dans la paroi moulée amont. Les butons Amont-Aval sont équipés d'un système de précontrainte à perte compensée. La fréquence des mesures est continue pour l'ajustement de la précontrainte des butons et le suivi des capteurs de vibration. Le suivi topographique est hebdomadaire et bi-hebdomadaire pour les inclinomètres.

### 4.2 Suivi du soutènement Amont-Aval

La courbure des inclinomètres est globalement identique au calcul et les déplacements mis en jeu restent du même ordre de grandeur que ceux calculés. Le comportement réel de l'ouvrage est maîtrisé et aucune action corrective n'a été menée durant l'exécution des travaux.

Le déplacement maximal obtenu au fond de fouille est resté inférieur à 10 mm montrant qu'il est possible par l'application de précontrainte de garantir des déplacements exceptionnellement faibles pour une telle hauteur soutenue. Le graphique ci-dessous présente la comparaison entre déplacements mesurés et calculés. Les mesures à l'aval indiquent clairement que la transition entre l'inertie des contreforts et les micropieux se fait sur plusieurs mètres de hauteur. La modélisation du soutènement par l'association d'une part, d'un contrefort rigide, et d'autre part, de micropieux souples n'est donc pas tout à fait réaliste. Il conviendrait d'ajouter un élément intermédiaire d'inertie moyenne. Le comportement d'ensemble reste cohérent cependant.

Figure 7. Comparaison des déplacements calculés et mesurés

### 4.3 Soutènement Villa Béatrice

Les mesures inclinométriques montrent que, si les déformées sont du même ordre de grandeur que celles estimées, la courbure est en revanche notablement différente de celle estimée par la méthode au coefficient de réaction, faisant apparaître un « mouvement d'ensemble ». Pourtant, la vérification de la stabilité de chaque massif d'ancrage par la méthode de Kranz fait apparaître des coefficients de sécurité largement satisfaisants (supérieurs à 1,5), voir la Figure 9. L'origine de cette déformée se trouve dans la déformation d'ensemble du massif de sol sollicité par les différents niveaux d'ancrage. La déformation théorique de ce « gabion » d'environ 15 mètres de large par 25 mètres de haut due au cisaillement induit par la poussée des terres, calculée par intégration des formules de Bresse, est en effet tout à fait comparable à celle mesurée (Bustamante et Gouvenot 1978)

Figure 8. Comparaison des déplacements calculés et mesurés

Figure 9. Vérification Kranz – Stabilité du massif d'ancrage

### 4.4 Optimisation du dimensionnement.

Après destruction des contreforts amont, les déplacements en tête de paroi moulée ont été moins prononcés que prévu. Il a donc été possible d'optimiser des places de parking en procédant au découpage des contreforts sur une hauteur supplémentaire de 2 niveaux entre le RDC et le R+2.

Figure 10. Vue du chantier – Phase réalisation du radier

## 5 CONCLUSION

L'auscultation du soutènement et des mitoyens a permis de réaliser un projet complexe en toute sécurité et de livrer au Maître d'Ouvrage un bâtiment conforme à ses spécifications. Le suivi observationnel a montré la remarquable aptitude du programme PARIS multiparois à simuler le comportement fortement interactif des parois amont et aval, et ce sans aucun recalage des paramètres géotechniques utilisés pour le projet: il faut y voir à la fois une validation du modèle de calcul lui-même, et le fruit d'une expérience antérieure du comportement des terrains monégasques et des paramètres de calcul associés.

Le suivi géotechnique a par ailleurs permis d'optimiser le soutènement d'une part, et de mettre en évidence d'autre part, la particularité des écrans avec multi-ancrage, dont l'étude ne saurait se limiter à celle de la stabilité des massifs d'ancrage, mais doit intégrer l'effet de la déformation d'ensemble.

# New Sensing Technology and New Applications in Geotechnical Engineering

## Nouvelle technologie de détection et nouvelles applications à l'ingénierie géotechnique

Wang Y.H., Ooi G.L., Gao Y.

Department of Civil and Environmental Engineering, The Hong Kong University of Science and Technology, Hong Kong

**ABSTRACT:** Soils are inherently a particulate medium, and relevant physical principles behind the macro-scale engineering properties originate from particle interactions. However, it is difficult in general to conduct measurements which can monitor soil particle movement and even characterize micromechanics behind different soil behaviour. Advancement of sensing technologies in recent years offers us the opportunity to do so. Two examples are presented in this paper. The first is on using the tactile pressure sensor (film-like sensor) to monitor the evolution of contact normal forces among particles in aged sand. The measurement reveals that the contact forces are continuously redistributed during aging. This ultimately strengthens the soil structure and therefore increases the associated small-strain shear modulus. The second is on using the miniature MEMS accelerometer to characterize the soil movement in a laboratory flow landslide. The MEMS sensors demonstrate promising results in describing the rich features of local responses of soil movement in the shear zone, e.g. liquefaction, deceleration, contraction and dilation.

**RÉSUMÉ :** Les sols sont intrinsèquement un milieu particulaire et les principes physiques pertinents derrière les propriétés mécaniques à macro-échelle proviennent d'interactions entre particules. Cependant, il est difficile en général d'effectuer des mesures qui peuvent suivre le mouvement des particules du sol et même de caractériser la micromécanique derrière différents comportements du sol. L'avancée des technologies de détection ces dernières années nous offre la possibilité de le faire. Deux exemples sont présentés dans cet article. Le premier utilise le capteur de pression tactile pour suivre l'évolution des forces de contact normales entre des particules dans du sable âgé. La mesure révèle que les forces de contact sont continuellement redistribuées au cours du vieillissement. Cela renforce finalement la structure du sol et augmente donc le module de cisaillement associé à petites déformations. Le second utilise l'accéléromètre miniature MEMS pour caractériser en laboratoire le mouvement du sol dans un glissement de terrain. Les capteurs MEMS démontrent des résultats prometteurs pour la description des caractéristiques abondantes des réponses locales du mouvement du sol dans la zone de cisaillement, par exemple, la liquéfaction, la décélération, la contraction et la dilatation.

**KEYWORDS:** tactile pressure sensor; aging mechanism; MEMS • landslide initiation mechanism.

## 1 INTRODUCTION

Measurements of micromechanical interactions among soil particles are invaluable to constitute insights into the underlying physics of different soil behavior encountered in geotechnical engineering. However, it is difficult in general to conduct measurements which can monitor soil particle movements and even characterize micromechanics involved. In recent years, manufacturing industries witness breakthroughs in both miniaturization of sensors and improvement of sensing technologies. Therefore, we have an opportunity to carry out measurement at the particulate scale. In this paper we would like to introduce two applications in laboratory testing using such new technologies: (1) tactile pressure sensor to characterize the underlying mechanisms of aging in sand, and (2) 3D Micro-Electro-Mechanical-Systems (MEMS) accelerometers to capture soil movement in the initiation process of a laboratory flow landslide.

Aging can occur in all types of soils: for instance, increases in their shear strength and shear modulus are observed as time elapses. Such aging effects in sands have been reported not only from laboratory tests but also via field observations (e.g., see review in Schmertmann 1991, Mitchell and Soga 2005, Wang and Tsui 2009; Gao et al. 2013). Nevertheless, at present, the associated underlying mechanisms remain inconclusive. In the first study, the tactile pressure sensor installed in a tailor-made oedometer was used to characterize the evolution of contact normal force among particles in dry sand during aging. The bender element sets were also utilized in parallel to monitor the associated changes in the small-strain shear modulus,  $G_{max}$ . The

ultimate goal of this experiment is to provide evidence that could account for the underlying mechanisms of aging effects.

Initiation mechanisms of flow landslides are likewise still an unsettled open discussion. There had been published studies linking the initiation process of flow landslides to pore pressure rise and presence of fines in soil (Iverson et al. 2000, Wang and Sassa 2003); however, exactly how the shear zone develops, liquefies or decelerates due to dilation prior to complete fluidization is not measured. The miniature size of 3D MEMS accelerometers (in the range of *mm*) makes the measurements of localized soil responses inside slope possible since they can move like a soil particle without any pronouncing inertial effect. Reported MEMS sensor responses shed lights on a variety of soil movement involved in the initiation process of flow landslide, which will be discussed in detail in the second study.

## 2 USING TACTILE PRESSURE SENSOR FOR THE STUDY OF AGING MECHANISMS

### 2.1 The I-scan system

Tactile pressure sensors are ultra-thin and flexible and comprise numerous individual tiny sensing elements, called sensels. These features resolve the problems associated with the conventional load cells and enable us to accurately measure stress inside soils. Fig. 1 presents the pressure mapping system used in the first study, i.e., the I-Scan® system (Tekscan Inc., MA., USA). This system consists of software, scanning electronics (called a handle), and a tactile pressure sensor. There are 1936 sensels in the sensor adopted in this study (model 5076). The sensel is a force-sensitive resistor, whose impedance

changes in response to different loading. When a force is applied to the sensor, the analog-to-digital converter assigns a digital output (DO) value between 0 and 255 (i.e., 8-bit resolution) to each sensel, depending on the corresponding impedance value. This DO can then be correlated to the pressure or other engineering units through calibration.

Figure 1. The I-Scan system.

2.2 Experimental setup and plan

Fig. 2 presents the experimental setup. A tailor-made oedometer with inner dimensions of  $100 \times 100 \times 40$  mm was used. Two sets of bender elements were utilized to obtain the small-strain, shear moduli  $G_{hv}$  and  $G_{hh}$ , where the first and second subscripts specify the directions of wave propagation and polarization, respectively;  $h$  means the horizontal direction and  $v$  stands for the vertical direction. Each set of bender elements consisted of one source and one receiver. The distance  $d$  between the source and the receiver is fixed at 80 mm throughout the test. The corresponding shear wave velocity  $V_s$  and shear modulus can be derived by  $G = \rho(V_s)^2 = \rho(d/t)^2$  where  $\rho$  is the soil density. The tactile pressure sensor was put between the upper and bottom box to measure the stress distribution inside soils. The calibration of tactile sensors including the creep (or drift) effect followed the procedure suggested by Gao and Wang (2012). The testing material was dry Leighton Buzzard sand (fraction E).

Figure 2. Experimental setup.

During the aging process, the applied vertical stress onto the sand sample was kept constant at  $\sigma_v = 197.21$  kPa for three days. The associated shear modulus changes was continuously monitored using the bender element tests and the evolution of contact normal forces among particles was constantly characterized by the tactile pressure sensor and the I-scan system.

2.3 Experimental results and discussion

Fig. 3 presents the variations in  $G_{hv}$  and  $G_{hh}$  during the aging process. The variations are presented in terms of the modulus change, i.e.,  $(G_t - G_{in})/G_{in}$  where  $G_t$  and  $G_{in}$  are the moduli at any time  $t$  and at the initial stage of  $t = 10$  min, respectively. As expected, the stiffness continues to increase, suggesting the sample is strengthened during the process of aging. In addition, the increase is greater in  $G_{hv}$  than in  $G_{hh}$ .

Figure 3. The experimental results of shear modulus changes versus time during three days of aging at  $\sigma_v = 197.21$  kPa.

Fig. 4 shows the probability distributions of measured, normalized contact forces (in the vertical direction,  $F_z$ ) by the tactile pressure sensor before and after three days of aging under  $\sigma_v = 197.21$  kPa. It can be readily seen that the contact forces are redistributed after three days of aging.

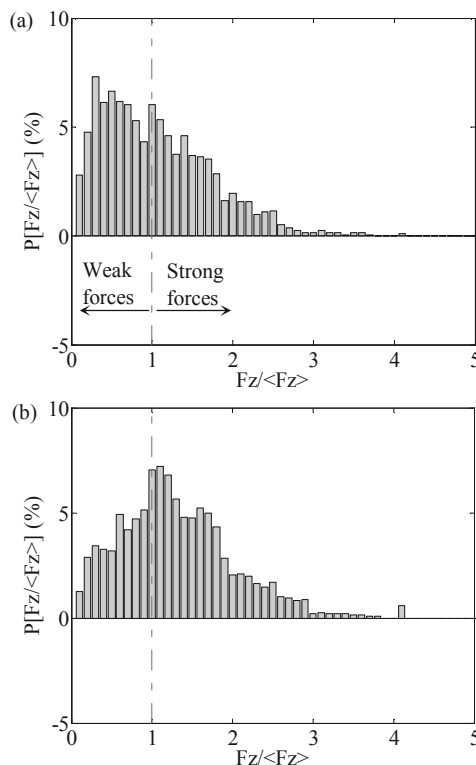

Figure 4 Experimental results of the probability distributions of normalized contact forces at  $\sigma_v = 197.21$  kPa (a) before and (b) after aging.

In order to further discuss such behavior, the contact forces are categorized into two groups, i.e., strong and weak forces. The categorization of strong and weak forces (i.e., the contact normal forces at strong and weak contacts or at strong and weak

networks) follows the suggestion of Radjai et al. (1996). When the normal contact force  $F_n$  is greater than its mean  $\langle F_n \rangle$  (i.e.,  $F_n / \langle F_n \rangle > 1$ ), it is regarded as a “strong” force; otherwise it is a “weak” force. Also found in Fig. 4 is that the probability distributions of weak forces decrease after aging. That is, the force redistribution leads to increasing contact normal forces in the weak force network such that some of the contact normal forces that originally belong to weak ones can be changed to the group of strong forces. In addition, the force distribution becomes more homogenized after aging because the associated coefficient of variation (CV) in  $F_z$  reduces from 0.726 to 0.705. Since the weak forces become fewer and the contact forces become more homogenized in the sample, the soil structure is strengthened and so is the associated  $G_{hv}$ . A comprehensive data set and more detailed explanations with the aid of DEM simulations can be found in Gao (2012) and Gao and Wang (2013).

### 3 USING THE 3D MEMS ACCELEROMETER FOR THE STUDY OF LANDSLIDE INITIATION PROCESS

Micro-Electro-Mechanical-Systems (MEMS) is a classification of devices, as well as the means of fabrication and manufacturing. In 1959, Richard Feynman took the helm of describing the “problem of manipulating and controlling things on a small scale” and thence pioneers like Analog Devices have since miniaturized conventional sensors from the size of a closed fist to that of a quarter of fingernail (Feynman 1959). The MEMS technology allows for batch-wise etching production, thereby minimizing manufacturing cost and at the same time promising standard accuracy and quality across sensors. Up until the recent 5 years only does stable 3-dimensional MEMS accelerometer become available in the market. The ADXL335 accelerometer model by Analog Devices is selected for the second study to characterize localized soil responses prior to and during landslide initiation.

The Analog Devices’ ADXL335 is a miniature accelerometer which measures  $4 \times 4 \times 1.45 \text{ mm}$  (Length  $\times$  Width  $\times$  Thickness) in size and comes at a low price, about couple US dollars per piece. It utilizes low power, typically functioning at  $3.0 \text{ V}$  and  $350 \mu\text{A}$ . The accelerometer is capable of 3-axis sensing and measures full-scale acceleration within  $\pm 3.6 \text{ g}$  with a frequency bandwidth ranging from  $0.5$  to  $1600 \text{ Hz}$  for the X and Y axes, and a range of  $0.5$  to  $550 \text{ Hz}$  for the Z axis. Fig. 5 illustrates the ADXL335 surface mounted on an in-house designed printed circuit board (PCB) since soldering by hand is impossible for the tiny pins; the PCB is  $11 \times 11 \times 2 \text{ mm}$  (Length  $\times$  Width  $\times$  Thickness) in size and the circuitry directs the corresponding pins to larger soldering points. The package was coated with several layers of air-dry polyurethane for waterproof. Also shown in Fig. 5 are the positive directions of X, Y and Z axes. The MEMS accelerometer is attractive not just because of its light-weight, miniature size, low-cost and standardized quality; it also boasts of the unique features of measuring the static acceleration of gravity in tilt-sensing applications, as well as dynamic acceleration resulting from motion, shock or vibration.

These unique features provide us with two kinds of information coming in one package. The DC bias offset in signal conditioned voltage output gives us the tilt angle in reference to the gravity. When the accelerometer is static, we can calculate the current angles of tilt in three dimensions about the accelerometer’s center of mass, known as roll, pitch and yaw; when it is in motion, we can calculate the direction of movement by finding the vector sum of the acceleration. In total 10 MEMS accelerometers were installed in both vertical and horizontal array so that dilative or contractive behavior between layers of soil could also be identified.

Figure 5. Analog Devices’ ADXL335 surface mounted on PCB.

#### 3.1 Calibration of 3D MEMS Accelerometer

All the MEMS accelerometers were connected to a logging computer through National Instruments’ NI-USB 6353 analog-to-digital converter with 16-bit resolution. Sampling frequency of every axis was set at  $10,000 \text{ Hz}$ . Due to batch-wise production, factory performance results of Analog Devices’ ADXL335 are compiled from 1000 pieces to determine the mean bias offset value (Analog Devices 2010); however, to further verify whether the sensors we purchased fall within the range as documented, simple calibration using an earthquake shaking table and a high-frequency vibration exciter was carried out. The mean zero bias offset value for X-axis was found to peak at  $1.51 \text{ V}$ , and for Y and Z axes the value was  $1.49 \text{ V}$ ; all sensors are functioning as detailed in the datasheet. The sensors were also left operating overnight to check for possible noise drift over time. Nothing anomalous happened and the sensors performed normally as documented in the manual. Subsequent conversions from voltage to acceleration which required parameters from the datasheet were cited directly thereafter.

#### 3.2 Laboratory Water Flume

Fig. 6 presents a side view of the well-instrumented laboratory water flume. The rectangular soil prism made of acrylic is of size  $100 \times 45.2 \times 20 \text{ cm}$  (Length  $\times$  Width  $\times$  Height). A saturation box was affixed at the back to provide standardized antecedent condition before each experiment. In addition to the MEMS accelerometer array (for the positions of accelerometer M1 to M10 see Fig. 6), basal porewater pressure transducers were also installed as indicated by the little squares; a video camera was shooting the process from the top. A layer of bottom porous stone was affixed to the flume rack to provide similar friction angle as the soil specimen at the bottom boundary.

Figure 6. Laboratory water flume setup.

### 3.3 Characterization of Shear Zone Behavior with MEMS

In this section, we will demonstrate qualitative results from one of the water flume tests set out to investigate how shear zone liquefaction evolves in loose slope without any fines present. MEMS accelerometer M8 situated right within the shear zone in the rear middle of the soil mass was selected to illustrate the landslide mechanism (see Fig. 6). The loose slope was saturated by slow and little groundwater inflow at start, and a fixed interval later a sudden rise of groundwater inflow twice the original volume was first invoked at the bottom of the slope toe (indicated by T1 in Fig. 6); minutes later the rear bottom (T2 in Fig. 6). Both groundwater supply events are also indicated by vertical black lines in Fig. 7.

There are in total 3 sliding events recorded and their occurrence instances are punctuated by the vertical red lines in Fig. 7. The groundwater supply T1 at the slope bottom induced an abrupt liquefaction; inside the shear zone, Y axis of M8 registered a huge contraction and the Z-axis tracked a rotation towards the back then a forward charging jerk. However, the movement of the soil mass ceased as sudden as the initiation; the basal porewater pressure transducer tells us that the porewater pressure built up just then was dissipated. Although by now the groundwater supply T2 at the rear bottom was invoked, the soil mass did not exhibit any noticeable activity, a stark contrast to the loose slope with fines experiment in which complete fluidization occurred by the moment when T2 was invoked. Subsequently what we observed was replenishment of porewater pressure right before sliding event L2 happened and stopped almost instantaneously again; however, this time Y axis of M8 recorded a dilation instead. The porewater pressure abated after L2 then was built up again and finally the whole soil mass fluidized, initiating event L3. The movement was slow; it took 23.9 seconds in total to slide out of the flume. The activity inside shear zone as captured by M8 was a slow dilating rotation, upward and forward as the soil slowly discharged out.

In short, the MEMS accelerometers demonstrated promising results in describing the rich features of sliding events, including local responses of soil movement in the shear zone, e.g. contractions, dilations and the rolling components.

## 4 CONCLUSION

Two new sensing technologies (sensors) were successfully utilized in this paper to reveal aging mechanisms and to monitor local soil movement in a flow landslide event. Using the tactile pressure sensor allows us to measure the contact forces among soil particles and therefore is able to obtain experimental evidence that can explain the underlying mechanisms of aging effects. During aging the contact forces continue to be redistributed. This ultimately leads to increasing contact normal forces in the weak force network such that some of the contact normal forces that originally belong to weak ones can be changed to the group of strong forces. In addition, the force distribution becomes more homogenized. As a result, the soil structure is strengthened and so is the associated small-strain shear modulus.

Because of its miniature size and high sensitivity, the MEMS sensor is allowed to be buried in a laboratory slope to characterize the features of soil movement inside the shear zone during a flow landslide event, such as liquefaction, deceleration, contraction and dilation. All of these observations complement theoretical work and provides us insights into the initiation mechanisms of a flow landslide.

## 5 ACKNOWLEDGEMENTS

This research was supported by the Hong Kong Research Grants Council (GRF 621109 and 620310).

Figure 7. Characterization of sliding features within shear zone in loose slope without fines captured by MEMS accelerometer M8, demonstrating a gradual failure mode.

# General Report of TC 207 Foundations and Retaining Structures

## Rapport général du TC 207 Fondations et ouvrages de soutènement

Bilfinger W.  
Vecttor Projetos, Brazil

**ABSTRACT:** Forty nine papers were included in the theme Soil Structure Interaction. These papers were divided into those related to foundations and retaining structures. The number of research papers and case histories are almost equal, showing equilibrium between academicians and practitioners. Different types of foundations are presented, as well as different types of retaining structures.

**RÉSUMÉ :** Quarante neuf articles ont été inclus dans le thème « Interaction Sol-Structure ». Ces documents ont été divisés entre ceux qui sont liés aux fondations et ceux liés aux ouvrages de soutènement. Le nombre d'articles de recherche et d'études de cas sont presque égaux, montrant l'équilibre entre les universitaires et les praticiens. Sont présentés différents types de fondations, ainsi que différents types d'ouvrages de soutènement.

**KEYWORDS:** soil-structure interaction, foundation, retaining structure, excavation.

### 1 INTRODUCTION

Foundations and retaining structures are traditional and widely used geotechnical structures in which soil-structure interaction plays a major role. For this reason, this technical session was organized by TC 207 – Soil Structure Interaction.

A total of 49 papers were included in this session, 12 focused on foundations and 37 about retaining structures. Contributions came from 28 countries, divided regionally as presented in Figure 1. Almost  $\frac{3}{4}$  of all technical papers come from Europe.

Figure 1. Origin of published papers: Europe – 39, Asia – 11, North America – 3 and 1 – South America.

23 papers present case histories and 26 research results, which show a desired equilibrium between academia and practice.

This report includes:

- A brief summary of the papers related to foundations;
- Some selected topics related to foundations;
- A brief summary of the papers related to retaining structures;
- Some selected topics related to retaining structures;
- Conclusions.

### 2 BRIEF REVIEW OF PAPERS RELATED TO FOUNDATIONS

12 papers focusing on foundations were selected for this session, 5 of them describing case histories and 7 presenting

research results. Variable topics were presented and discussed, including shallow and deep foundations, as well as soil structure interaction, specially the interaction between foundations and deep excavations.

*M. Bidasaria* presents a case history about the cofferdam for the Indira Sagar Project in India. This cofferdam was built as a gravity dam, using precast hollow concrete blocks on the upstream and downstream faces. Between the two faces, rubble was filled and later grouted by a cement-sand mixture, forming a so called stonecrete. The paper presents interesting constructive details about the construction of the cofferdam.

*E. M. Comodromos et al.* present numerical simulations to evaluate the influence of diaphragm wall construction on adjacent buildings. The 3D simulations are specific about the excavation phase, where soil is substituted by bentonite slurry, and the concrete tremied into the panel. Obtained results showed maximum settlements in the order of 5 mm, for a 6 story building founded on direct footings located closely to the wall.

*F. Cuira and B. Simon* present an analytical model to evaluate soil reinforced by vertical inclusions, considering the interaction between the reinforced and un-reinforced soil along their boundary. An analytical method is compared to 3D FE simulations and good results are obtained. Further research using centrifuges is recommended in the conclusions.

*W. Guo and J. Chu* present results of model tests of suction caissons, focusing on shallow water for near shore use. The obtained results were in good agreement with an analytical results.

*G. Hannink and O. Oung* present a case history with prediction and monitoring results of the induced movements of a 9 story high apartment building, due to excavation of a 20 m deep closely located (7m distance) excavation, retained by strutted diaphragm walls. Measured horizontal and vertical movements of the apartment building were in the order of 10 mm.

*Horn-Da Lin et al.* present numerical simulation results, where the influence of a deep excavation on nearby located buildings is evaluated. The excavation depth is around 20 m. As benchmark, results of a documented published case history are used, and good agreement was obtained. Horizontal wall

deflections were in the order of 110 mm and maximum settlements at the surface, around 80 mm.

R. Katzenbach and S. Leppla describe results of ground heave and settlement due to excavations, building construction and de-construction. The measured behavior is time dependent and occurs during years and the magnitude of the displacements is in the order of several cm. The soil responsible for this time dependent behavior is the overconsolidated Frankfurt clay. An empirical formulation that approximately describes the time dependent behavior is also proposed.

M. Korff and R. Mair present building settlement results due to deep excavations in Amsterdam. The difference between ground surface and building response as a function of foundation is highlighted and a methodology to evaluate buildings response is presented. Surface settlements in the order of 70 to 110 mm are presented, while the piled building settles only in the order of 20 to 40 mm.

T. Mizutani and Y. Kikuchi describe shaking table model tests to test seismic behavior of caisson type quay walls. The aim of the tests was to verify the possibility to increase water depth in front of the quay after soil treatment – “solidification” in the caisson foundation. It was found, that six different factors affect the caissons improved by the “solidification”. Further research will be performed to allow the development of a design methodology.

T. Pucker and J. Grabe present the structural optimization method applied to geotechnical engineering design. This use is new and, according to the authors, promising results were obtained, showing potential economy and/or improvement in performance.

V. Sesov et al. present a methodology developed for the evaluation of seismic response of historical monuments in Macedonia. 3 Case histories are presented, where this methodology was used.

A. Siemińska-Lewandowska et al. describe different uses of diaphragm walls: retaining structures and foundations. Vertical load test results are presented, with up to 7,5 mm settlement for 150% of the working load. Interesting retaining structures using T shaped diaphragm walls are also presented.

### 3 SELECTED TOPICS RELATED TO FOUNDATIONS

The papers presented related to foundations cover a wide range of issues and foundation types:

#### Direct foundations:

- Gravity “concrete” dam;
- shallow footings (influence by diaphragm wall construction; influence by nearby deep excavations);
- caissons – quay wall;
- suction caissons;

#### Soil treatment for vertical loads by rigid inclusions;

#### Deep foundations:

- Driven timber piles (influenced by nearby excavation);
- Precast concrete piles (influenced by nearby excavation);
- Barrettes and Diaphragm walls (as foundations and retaining structures);

#### Seismic design and retrofitting of different foundations;

#### Long term settlement and heave in highly overconsolidated clay;

#### Structural optimization technique – use of new technique to optimize foundations.

Two topics were selected, among this wide range presented, and are discussed in more detail.

Specifically seismic issues will not be discussed in detail in this session, as a specific session at this same conference deals with the theme.

### 3.1 Influence of Excavations on Foundations

The evaluations of E. M. Comodromos et al. showed that the construction of diaphragm walls alone lead to settlement of closely located direct foundations in the order of 5 mm. The approach presented considered complex 3D nonlinear modeling, where the excavated soil is replaced by bentonite slurry.

Additionally to this theoretical aspect, it could be added that, in the field, several times, especially in sandy soil below the groundwater level or soft clays, the operation and movements of the excavation equipment (clam shell, etc ) can generate temporary negative suction pressures, leading to “cave-ins” and additional settlements, that can be in the order of several cm.

M. Korff and R. Mair and G. Hannink and O. Oung, present monitoring results, as well as simulations of settlements induced by deep excavations.

The results presented show significant difference between measured settlements: Korff and Mair show settlements, in Amsterdam, at the ground surface of more than 100 mm and, at 10 m from a 31 m deep excavation, building settlements of almost 40 mm. G. Hannink and O. Oung, on the other hand, present settlement measurements, in Rotterdam, of less than 10 mm for a building located 7 m from a 20 m deep excavation. Both excavations are supported by braced diaphragm walls. Possible explanations for these differences are probably:

- Different soil profiles;
- Different excavation depths;
- Different diaphragm and bracing stiffnesses;

Appart from these rather obvious aspects, certainly:

- Different pile length: in the case of the excavation in Amsterdam, the piles are located well above the excavation bottom, but in the case of Rotterdam, pile toes are located almost at the same elevations;
- Location of the buildings in relation to the excavation. No specific information is available from Amsterdam, but in Rotterdam, the building is located close to the excavation, as can be seen in figure 2.

Figure 2. Position of building with relation to excavation (G. Hannink and O. Oung)

This last topic can be confirmed by the analysis of the results presented by Horn-Da Lin et al: the evaluations presented show, qualitatively, that close to the excavation borders, settlements are significantly lower than in the central part, as can be seen in figure 3. The arrows show an approximate position of the apartment building. It is clear that the settlements are significantly lower than in the central part.

Depending of the geometrical conditions, it becomes clear that 3D analyses may be necessary to adequately evaluate soil-structure interaction.

With relation to settlements induced by excavation, in the author’s opinion, the methodologies presented and discussed in Korff and Mair present tools to adequately predict building response to deep excavations, in the case of deep foundations.

Figure 3. Settlements due to excavation (*Horn-Da Lin et al.*).

### 3.2 Loading and Unloading due to high rise buildings and excavations

The paper presented by *R. Katzenbach and S. Leppla* presents results of ground heave and settlement measurements due to excavations, building construction and de-construction. This behavior, which could be expected not only in Frankfurt, but also in other geological environments, was adequately documented during a significant time period for some buildings.

The first important issue, often neglected due to lack of reliable information, is the fact that unloading generates significant upward movement, in the order of some or even several cm.

The second issue is the time dependent behavior: a significant part of total displacements are measured at the end of construction, but between 30 and 50% of the observed behavior, occur during months or years after completion of the construction works.

*Katzenbach and Leppla* propose an empirical equation to represent this time dependent behavior. Just as an exercise, Figure 4 presents monitoring results and the equation proposed by *Katzenbach and Leppla*, and, additionally, settlements estimated using conventional consolidation theory. A consolidation coefficient at the recompression stage of  $c_v = 9 \times 10^{-2}$  cm/s was backanalyzed from the measured settlements. This value can be considered representative of overconsolidated clays.

Figure 4. Settlement in % using conventional consolidation theory, the equation proposed by *Katzenbach & Leppla* and monitoring results.

From the discussion above, it becomes clear that, especially in urban environments, even for material considered relatively stiff, time dependent behavior cannot be neglected, depending of local geology.

## 4 BRIEF REVIEW OF PAPERS RELATED TO RETAINING STRUCTURES

37 papers focusing on retaining structures were selected for this session, 18 of them associated to case histories and 19 with research results. A broad range of topics related to retaining structures was presented.

*M. Abramento et al.* present a case history from Brazil, of a mixed retaining structure, reinforced earth at the top and anchored wall at the bottom, in a geotechnical environment of expansive soils. The case history includes laboratory tests of the expansive soils and anchor pull out tests, demonstrating that

injection pressures have significant impact on anchor resistance. Monitoring results of the retaining structure are also presented, showing significant horizontal displacement of the reinforced earth face, and negligible horizontal displacements of the anchored stretch.

*D. Alexiew and H. Hangen* discuss a case history from Bulgaria, where reinforced earth structures were used as retaining structures. Relatively steep, 1H:10V, and high, over 20 m, structures are presented; constructive details are included. Design considerations, including seismic actions, are also discussed.

*S. Bagheri* present the case history of the deep excavation, in marl and weather marl, associated to the construction of the “Tour Odeon” in Monaco. The excavation is more than 70 m deep and the excavation is supported by anchors.

*Ö. Bilgin and E. Mansour* discuss theoretical analysis of sheet piles in expansive soils. For a typical sheet pile wall, 10 m high and with an anchor level at 2,5 m, significant increases in anchor reactions and bending moments occur, as swelling pressure increases. Higher wall penetrations also become necessary. Swelling pressures were associated to the Plasticity Index and moisture content variations.

*C. M. Chow and Y.C. Tan.* present data related the performance of soil nails in weathered granite and fill. Several soil nail pull out tests were performed in excavations up to 20 m depth. Lateral friction measurement results varied between 50 and 140 KPa. A conservative correlation for lateral friction of 5 x SPT (in KPa) blowcount is also proposed.

*I.P. Damians et al.* discuss the influence of vertical facing stiffness on reinforced soil wall design. Numerical results showed that the loads at the base of the vertical facing and in the reinforcement are affected by the backfill and foundation material, and that the face stiffness also affects reinforcement tensile forces.

*T. Durgunoglu et al.* present a case history from Turkey, an over 20 m deep excavation close to the Bosphorus. Top down construction method was used, including excavation of rock sockets into rock with a uniaxial compressive strength varying between less than 10 MPa, up to almost 100 MPa.

*R.J. Finno et al.* discuss ground movements due to top-down construction in Chicago. For this type of construction, according to these authors, normalized horizontal movements of 0,15% to 0,2% are expected. Approximately 40% of these movements can be attributed to time dependent behavior of the concrete slabs. Significant movements can be associated to activities other than the excavation, like potholing.

*R. Frischknecht et al.* present an environmental impact evaluation, comparing a conventional concrete structure with a geosynthetic reinforced earth structure. The conclusion of the evaluation is that geosynthetic retaining structure shows a 63% to 87% lower environmental impact.

*P.P. Ganne and X. Raucroix* discuss the design of cantilever walls with a relief floor. For unsaturated, sandy, silty and alluvial clayey soils, an analytical design methodology is proposed, including pre-design recommendations.

*A. Gomes Correia et al.* present a case history of a 13 m high CSM anchored retaining wall built in Portugal. The CSM wall was built in fill, sands and weathered sandstone, reinforced by steel beams with a horizontal spacing of 1,1m. Maximum measured horizontal displacements were of 16 mm.

*A. Guilloux et al.* discuss the design, modeling and monitoring of the Tour Odeon, also presented by *Bagheri*. A 3D numerical model is presented as main design tool. The use of the observational model with a maximum horizontal displacement of 17 mm is described.

*E. Guler et al.* present the case history of a 23 m deep excavation in Istanbul. 2D and 3D numerical modeling was used to evaluate interaction between 2 tunnels, a circular shaft and a deep braced excavation. 2D and 3D models were compared and the 2D analysis showed results on the safe side. Monitoring results obtained during construction yielded reduced

horizontal displacements, in the order of 8 mm, compatible with the 3D FE analysis.

*I. Gutjahr et al.* discuss comparisons between subgrade reaction calculations, FE analysis using 2 different softwares and monitoring results of an anchored retaining structure of the Vieux Blanc-Mesnil Basin, in France.

*V.A.Ilyichev and Y.A. Gotman* present a method to optimize diaphragm wall displacements in deep excavations, by means of using soil cement mix in the active and passive parts of the soil massif. The dimensions and stiffness of the soil cement mix can be estimated using the proposed computational method. FE calculations were used to calibrate the proposed calculation method and good agreement was obtained.

*Y. S. Jang et al.* discuss two case histories from Korea of deep excavations supported by diaphragm walls. Excavations depths of 1 case is 20 m and of the other, 31 m. The retaining walls are concrete diaphragm walls, steel profiles and timber, and steel profiles and shotcrete. Horizontally, the walls are supported by anchors, in one case, and by steel struts, in the other case. Horizontal movements of 30 to almost 100 mm were measured. Forces in anchors and struts were also measured and compared to numerical simulations.

*S. Jessee and K. Rollins* present model tests to evaluate the passive pressure on skewed bridge abutments. The performed tests showed that a significant reduction was measured, as the skew angle increases. These results were compatible with numerical simulations and a simple correction factor is proposed.

*M. Long et al.* present a number of case histories of excavations in glacial tills of Ireland. 12 cases are presented, where horizontal displacements were measured. The displacements were, in most of the cases, less than 0,1% H. The conclusion of the authors are that design has been conservative and more realistic design methods and construction methods can lead to more economic design.

*D. Loukidis and R. Salgado* discuss the results of numerical simulations of earth pressure on walls supporting granular soils. The simulations, using Ottawa and Toyoura sands, with varying relative densities, showed that a minimum active pressure is obtained at 0,5% H displacement. But with higher displacements, in the order of 10% H, critical state inside the soil mass is mobilized. An equation is proposed to estimate the variation of the earth pressure coefficient as a function of the wall crest displacement.

*R. Lüftenegger et al.* present case histories of non conventional retaining structures. The structures were conceived based on the necessity to avoid the installation under neighboring buildings. 3D FE analyses were used to understand behavior. Good adherence between prediction and monitoring was not obtained, and for this reason the use of the observational method is recommended.

*T. Maeda et al.* discuss the use of inclined braceless retaining structures in sandy soil. Instead of using a vertical face, inclining it slightly, 10°, allowed the excavation of an almost 10 m deep excavation without any bracing or anchor. An analytical design method was developed and verified by centrifuge tests. Monitoring results from the site showed that the design method lead to results on the safe side.

*S. Nakajima et al.* present a methodology to inspect exiting retaining structures. The methodology includes percussion tests and vibration tests, where the natural frequency of the structures is measured to evaluate its condition.

*C.Y. Ou et al.* discuss the mechanism of settlement influence zone due to deep excavation in soft clay. The USC model is used for parametric analyses a method for predicting the settlements is proposed.

*J. Philipsen* discusses the case history of a braced excavation, built under difficult conditions, in Copenhagen. The excavation was built in quaternary clays and sands, overlaying limestone.

*A. Pinto et al.* present a case history of an anchored excavation in Lisbon. The excavation was 13 m deep and supported by vertical steel profiles associated to a CSM wall and anchors. The geotechnical profile includes superficial fill, medium sands and sandstones, and GWT 5 m below the surface. The excavation was monitored through inclinometers, with maximum horizontal displacements close to the surface of around 40 mm.

Another paper by *A. Pinto et al.* present the case history of excavations for the Leixões Terminal in Portugal. 2 different solutions are presented: CSM panels with steel profiles and CSM panels with micropiles. The excavation is around 6,5 m deep and the geotechnical profile includes hydraulic fill placed on weathered schist. CSM UCS minimum measured values were of 4 MPa.

*H. Popa et al.* discuss a case history from Bucharest. 16 m had to be excavated to accommodate a 4 to 6 m deep basement mat and 2 basements. The subsoil profile included interbedded layers of medium to compact sands and medium to stiff clays, with groundwater level 2 to 3 m above the excavation bottom. An anchored diaphragm wall was designed, built and monitored, with maximum horizontal displacements of less than 10 mm.

*C. di Prisco and F. Pisanò,* present a new anchor type. FE analyses are used to evaluate the pull out behavior of the anchor. Based on the FE analyses, an analytical method is also developed and presented.

*N. Sanvitale et al.* discuss the role of the facing on the behaviour of soil-nailed slopes under surcharge loading, using small physical models in sand. Flexional and axial stiffness influence the performance of the soil nailing system.

*T. Tanaka et al.* present results of physical and numerical models, where 3D seepage effects influence stability. Uniform sand are used for the evaluations and results show that the 3D conditions differs from those of typical 2D conditions. Correction factors from an axisymmetric simulation to no axisymmetric conditions are also presented.

*P. Turček et al.* discuss case histories of deep excavations in Bratislava. Local subsoil includes superficial quaternary sediments, mainly gravel and sand, overlaying neogene marine sediments, mainly stiff clays. Groundwater is normally at shallow depth and its control is one of the main challenges for successful construction.

*M J Turner and N A Smith* present a case history of the stabilization of a gravity quay wall in the UK. The 17 m high wall, originally built at the end of the 19<sup>th</sup> century, suffered stability problems since the mid 1980s, with horizontal displacements of around 400 mm. Evaluations showed that the difference between the high tidal variations, more than 6 m, and the groundwater level behind the wall, were leading to increasing horizontal displacements. Stabilization measures included groundwater lowering and installation of anchors.

*L. Vollmert et al.* discuss results of large scale in situ tests, as well as long term monitoring results of a reinforced earth structure. For the monitored cases, with full height panel walls as facing, the actual lateral stress measured is significantly lower than FE calculations or classic earth pressure theory, showing that current design methods are on the safe side and, possibly, a correction factor can be introduced to EBGeo design methodology.

*G. Vukotić et al.* present results of anchor bond measurements in different soils and anchor length. The influence of the fixed anchor lengths is evaluated, showing that longer anchors are less efficient than shorter anchors. A proposition or design methodology is presented, including possible use of single bore multiple anchors – “SBMA”.

*L. Warren et al.* discuss the use of drystone retaining walls, including model tests performed in the UK. Different types of walls, based on their construction methods, horizontal, vertical and random, are discussed. The type of wall is presented as a

sustainable type of structure, due to lack of mortar, use of local materials and providing habitat for animals and plants.

C. A. Wiggan *et al.* present a numerical evaluation of potential pore pressure reduction on retaining walls due to the flow between piles. Not considering a wall of secant of contiguous piles impermeable, lead pore pressure reductions that act on the wall. Results of parametric evaluations are presented, where the distance between the piles are varied, showing significant pore pressure reductions. This approach, however, leads to increased settlements at the surface.

C. Yoo and D.W. Jang discuss results of laboratory tests performed on reduced models, to evaluate the influence of rainfall on the performance of reinforced earth structures. Test results showed that wetting and drying cycles may have cause additional wall displacements, especially for structures with low safety factor.

### 5 SELECTED TOPICS RELATED TO RETAINING STRUCTURES

The technical papers related to retaining structures cover a wide range of topics, including:

- Reinforced soil – 5 papers;
- Diaphragm walls – 4 papers;
- Secant pile walls – 1 paper;
- Sheet pile walls – 3 papers;
- Soldier type walls – 3 papers;
- Mixed in place soil structures – 5 papers;
- Soil nailing and anchors – 3 papers;
- Gravity and cantilver walls – 3 papers;
- Others.

From this wide range, some topics were selected and are discussed in more detail:

- Horizontal displacements;
- Earth pressures;
- Soil nailing and anchor lateral friction;
- Soil-cement mixtures.

Unfortunately, not all papers present sufficient technical data, to allow analyses and comparisons.

#### 5.1 Horizontal displacements

The selected papers present, in some cases, monitoring results, specifically, horizontal displacements, which are summarized in Figure 5 and 6.

Figure 5. Horizontal displacements x excavation depths.

Very variable results can be seen; horizontal displacements / heights (H/D) from less than 1/2000 to more than 1/200 were presented.

No clear tendency can be identified in figure 5. Visually, one possible conclusion is that deeper excavations, apparently, present lower D/H values, meaning that this type of construction is, due to its complexity, designed and built with higher safety margins and possibly, more rigid. Figure 6 below presents the same data, showing normalized horizontal displacements and

excluding 1 extreme value: the 70 m high excavation (in rock) presented by S. Bagheri and A. Guilloux *et al.*

Figure 6. Normalized horizontal displacements with respect to excavation heights (depths)

In comparison to other retaining structures, relatively high horizontal displacements (85 mm =>1,7%) were measured for a reinforced earth structure (M. Abramento *et al.*). However, this magnitude of displacement, according to common practice, can be considered normal for reinforced soil structures (Sayão *et al.*, 2004).

Figure 7 shows the same results, plotted together with the data presented by Long (2001).

Figure 7. Normalized horizontal displacements x excavation heights, including data presented by Long (2001).

It can be seen that the published horizontal displacements are compatible with several other measurements as compiled and published in 2001.

Other published databases are also compatible with the presented data:

- Leung and Ng (2007): 0,13 %H to 0,23 % H, depending on soil stiffness;
- Wang *et al.* (2010): 0,27%H to 1,5%H, depending of retaining structure type and soil stiffness.

Common conclusion of Long (2001), Leung and Ng (2007) and Wang *et al.* (2010) are that horizontal displacements are affected mainly by safety margins, system stiffness, soil type and construction method.

Finally, the conclusions presented by R.J. Finno *et al.* are interesting: for the cases where small displacements are measured, a significant part of these displacements may be caused by time dependant behavior of concrete floor slabs.

#### 5.2 Earth Pressures

Four papers deal specifically with earth pressures: Ö. Bilgin and E. Mansour, S. Jessee and K. Rollins, D. Loukidis and R. Salgado, T. Maeda *et al.*

*Ö. Bilgin and E. Mansour* discuss theoretical analysis of sheet piles in expansive soils. The presented analyses are based on a correlation between the plasticity index (PI) and swelling potential. The analyses presented assume that swelling pressure will act in the zone where moisture varies, relatively close to the surface. Figure 8 presents results of the authors analyses, correlating anchor loads of sheet pile wall to the PI

Figure 8. Effect of expansive soils on anchor force, according to *Ö. Bilgin and E. Mansour*

*S. Jessee and K. Rollins* present model tests to evaluate passive earth pressure on a “skewed” surface. Figure 9 presents a proposed reduction factor for the passive force, as a function of the skew angle.

Figure 9. Test results presented by *S. Jessee and K. Rollins*.

The performed tests showed that a significant reduction was obtained as the skew angle increases. These results were compatible with numerical simulations and a simple correction factor is proposed. Peak passive pressure was developed at 2,5% to 3,5% of abutment height. Significant reductions in passive pressure were measured beyond peak (4% to 6%), with a residual stress around 40%.

Results are interesting, but direct use of results for design shall be evaluated with care.

*D. Loukidis and R. Salgado* present the results of sophisticated numerical simulations of variation of earth pressure on walls supporting granular soils. Figure 10 present one of the presented outputs and some interesting qualitative conclusions can be drawn:

For horizontal displacements of around 0,5%, minimum lateral earth pressure develops. Considering  $K_0$  around 0,5,  $K_a$  results around 0,125. As horizontal displacement increases,  $K_a$  results in the order of 0,2. The authors state that the minimum earth pressure coefficient should not be used, at least for ultimate limit state design. However, when analyzing figure 7, where a significant number of case histories showed horizontal displacements of less than 0,4 %, possibly some optimization in terms of design earth pressures can be possible.

Figure 10. Results presented by *D. Loukidis and R. Salgado*: Variation of normalized lateral earth pressure coefficient with wall crest displacement from analyses with medium dense Toyoura sand ( $D_R=60\%$ )

*T. Maeda et al.* discuss the use of inclined braceless retaining structures in sandy soil. The presented evaluations showed that significant reduction in earth pressures acting on a cantilever wall can be obtained by inclining the wall facing. Figure 11 present horizontal displacements measured on model tests. It can be seen that, even for a reduced inclination of 10°, horizontal displacements reduced around 30%.

Figure 11. Relationship between excavation depth and horizontal displacement of retaining walls, considering horizontal and inclined structures, presented by *T. Maeda et al.*

Figure 12 presents earth pressures for the inclined and the vertical structure. It can be seen that, especially for deeper excavations, a significant reduction in earth pressures occurs.

Figure 12. Earth pressures for vertical and inclined structure, presented by *T. Maeda et al.*

In the author’s opinion, the simple approach of inclining slightly a cantilever structure can bring significant saving, should be further investigated and can be used in practice.

### 5.3 Soil nailing and anchor lateral resistance

*C. M. Chow and Y.C. Tan.* present data related to the performance of soil nails in weathered granite and fill. Several soil nail pull out tests were performed in excavations of up to 20 m depth. Figure 13 presents typical pull out results, showing that maximum load is obtained between 4 and 6 mm of displacement. After a peak value, only slight increases can be seen.

Figure 13. Pull out test results, presented by *C. M. Chow and Y.C. Tan*.

Lateral friction measurement results varied between 50 and 140 KPa. A conservative correlation for lateral friction of 5 x SPT (in KPa) blowcount is also proposed.

These results are comparable with data presented in Ortigão and Sayão (2004): for sands, approximate ratio between SPT blowcount and lateral friction is around 5, and for clays, around 3,4.

*M. Abramento et al.* presented results of pull out tests of anchors for different grouting conditions and resulting lateral friction between 80 KPa and 140 KPa. The soil where the anchors were built has an approximate SPT blowcount between 20 and 30.

Finally, just for comparison, Décourt (1982) presented a correlation between SPT blowcount and lateral friction for piles:

$$\text{Lateral friction} = 10 \times (\text{SPT} / 3 + 1).$$

Figure 14 presents graphically the lateral frictions and corresponding SPT blowcount values.

Figure 14. Lateral friction results, presented by *C. M. Chow and Y.C. Tan*, including values published by Ortigão and Sayão (2004) and Décourt (1982).

*A. Gomes Correia et al.* present results of anchor tests in medium dense sands, resulting in a lateral friction of 275 KPa. Similar results and even higher lateral frictions are presented by *G. Vukotic et al.* for tests in different soils. Unfortunately, there is no specific information available about the SPT blowcount, but probably results will be well above the graphs presented in Figure 14. Possibly, this difference occurs due the use of pressure grouting.

Even considering the limitations of the SPT blowcount as geotechnical design parameter, the correlations between the SPT and lateral friction proposed by *C. M. Chow and Y.C. Tan* seem compatible with previously published results for soil nails. Grout injection influence, in the author's opinion, shall be further investigated. Special anchor devices, like the one presented by *C. di Prisco and F. Pisanò* work completely different from cylindrical nails / anchors and further research is necessary to allow reliable comparisons.

#### 5.4 Soil mixing compressive strength

*A. Gomes Correia et al.* present a case history where CSM material, with a cement consumption of  $600 \text{ kg/m}^3$ , was tested and a minimum uniaxial compressive strength of 4 MPa was obtained. Minimum  $E_{50}$  values were 1 GPa. Unfortunately, few results with information about this important design parameter were presented. As complementary information, Figure 15 presents data published by Bilfinger et al, with results from uniaxial compressive strength tests results in soil treated with jet grouting technology.

Figure 15. Uniaxial compressive strength, Bilfinger et al. (2012).

It can be seen that soil type has major influence on uniaxial compressive strength, specially the organic matter content.

## 6 CONCLUSIONS

The technical papers included in this session cover a wide range of topics. In items 3 and 5 some of these topics were discussed in more detail.

Some conclusions may be drawn with relation to three areas:

**Design:** No detailed design procedures were presented, but some interesting conclusions can be drawn from the published papers:

- Numerical modeling is a common tool to model soil and structure interaction;
- Limit equilibrium analysis and beam-spring models continue to be used in design practice;
- The observational method, meaning, the use of monitoring to control and, possibly, adjust the design, is a widespread design “philosophy”.

**Construction:** Different construction techniques and structures are discussed and presented:

- Foundations: direct footings, caissons and suction caissons, barretes and diaphragm walls, soil treatment by rigid inclusions;
- Retaining structures: diaphragm walls, secant pile walls, sheet pile walls, soldier type walls, mixed in place structures, anchored and nailed structures, reinforced soil, cantilever and gravity walls.

Most of these construction techniques and structures are already well known and the focus and innovation presented in the papers are performance, size, depth and proximity to other structures. Two exceptions are: soil treatment techniques, used in different conditions and suction caissons.

**Research:** Different research themes were presented, but one of the important investigated issues is earth pressures for different conditions. Another topic researched are mathematical models associated to techniques to optimize design procedures, and not to represent soil constitutive models.

**ABSTRACT:** Due to traffic volume increase a large stretch of a major highway linking São Paulo and Campinas City, Brazil, has recently been widened. In order to achieve the construction of additional lanes, a construction of a mixed-type retaining wall became necessary. This mixed-retaining structure consisted of a 5m high anchored wall at the bottom and a 5m high steel-reinforced retaining wall at the top, totalling a 10m high retaining wall. The bottom wall was built in a cut slope in a stiff, highly expansive, clayey soil. The steel-reinforced retaining wall was built over the lower anchored wall with both faces aligned. Anchor loads at the bottom wall were applied in stages in order to account for the increasing loads during the construction of the top wall. In order to correctly design the bottom anchored wall several undisturbed soil samples were obtained from the stiff clay. Laboratory tests included complete characterization, shear strength and expansion pressure determination. The retaining system was monitored during all construction stages. This paper presents details on the laboratory tests results, design of the retaining walls, construction steps and monitoring.

**RÉSUMÉ :** En raison du volume de trafic une portion d'une route importante reliant São Paulo et Campinas, au Brésil, a récemment été élargie. Afin de réaliser la construction de voies supplémentaires, une construction d'un mur de type mixte devenait nécessaire. Cette structure mixte consistait en un mur ancré de 5m de haut en partie basse et un mur en sol renforcé en partie haute, pour une hauteur totale de 10m de soutènement. La paroi en partie basse a été construite dans une pente en déblai dans un sol argileux raide et très expansif. Le mur en sol renforcé a été construit sur la paroi inférieure ancrée avec les deux parements alignés. Les charges d'ancrage de la paroi en partie basse ont été appliquées par paliers afin de tenir compte des charges croissantes au cours de la construction de la paroi supérieure. Afin de concevoir correctement le mur ancré plusieurs échantillons de sol intacts ont été prélevés sur l'argile raide. Les tests de laboratoire incluent la caractérisation complète, la résistance au cisaillement et à la détermination des pressions de gonflement. Le système de soutènement a été suivi pendant toutes les étapes de la construction. Cet article présente des détails des résultats des tests de laboratoire, la conception des murs de soutènement, la construction et le suivi des mesures.

**KEYWORDS:** Reinforced wall, anchored wall, expansive soil, monitoring

## 1 INTRODUCTION

Due to traffic volume increase a section of approximately 3km of a major highway linking São Paulo and Campinas city, Brazil, had to be widened. In order to achieve the construction of additional lanes, and due to geometric constraints, a mixed-type retaining wall became necessary. This mixed-retaining structure is shown in Figure 1 and consists in a 5m high anchored wall at the bottom and a 5m high steel-reinforced retaining wall at the top, totalling a 10m high retaining wall.

This paper presents details on the laboratory tests results, design of the retaining walls, construction steps and monitoring, as well as a comparison of measured and predicted displacements and loads at the top and bottom retaining walls.

## 2 SITE INVESTIGATION AND LABORATORY TESTS

SPT borings show that the local soil consists of a superficial colluvial soil characterized as a soft porous silty clay 2 to 3m thick and with blowcounts varying from 2 to 3, followed by a medium, stiff and hard clay with blowcounts larger than 15 and reaching up to 40. A picture of this last layer is shown in Figure

Figure 1. Typical cross-section of mixed reinforced fill-anchored wall.

2. Figures 3 and 4 show typical SPT borings results for two of the wall sections. This stiff clay layer receives the load from the

reinforced fill and had to be cut and anchored in order to widen the roadway.

Therefore, this layer was fully investigated with:

- Several SPT borings.
- Laboratory tests: direct shear and expansion tests on undisturbed samples and characterization.
- Pullout tests on anchors.

Moreover, compaction and direct shear tests were carried out on fill materials.

Figure 2. Stiff to hard silty clay layer to be cut and retained with anchored wall and surcharged with reinforced soil fill.

### 3 TEST RESULTS – STIFF TO HARD CLAY

Table 1 presents results from direct shear tests. It is worth noting the large drop in shear strength for large displacements (residual conditions). Peak strength typically occurs for very small displacements, in the range of 1mm.

Table 1. Direct shear test results.

Sample	Specimen	$\sigma$ (kPa)	$\tau_{max}$ (kPa)	$\tau_{res}$ (kPa)
Natural	CP-1	51	232	32
	CP-2	154	305	22
	CP-3	306	419	92
Saturated	CP-1	51	228	77
	CP-2	151	264	72
	CP-3	304	304	34

Table 2 presents results from expansion tests carried out on the horizontal and vertical directions. The expansion pressure is very high in the vertical direction, whereas the expansion pressure in the horizontal direction is around 6% of the vertical pressure, showing the marked influence of clay structure on its behavior (Figure 2).

Table 2. Expansion pressure for vertical and horizontal directions.

Direction	Expansion Pressure (kPa)
Vertical	440
Horizontal	30

Table 3 presents results from pullout tests on anchors 10cm in diameter and 6m long as a function of injection pressure. Anchors 202, 207 and 212 had, respectively, one, three and two functioning pressure valves. Therefore, adhesion values varied significantly from 25 to 45kN/m, demonstrating marked influence of injection pressure on adhesion.

Table 3. Pullout tests on anchors.

Segment	Adhesion (kN/m)	Injection Pressure (kgf/cm <sup>2</sup> )
202	25	$\phi/\phi/20$ (1 valve)
207	45	50/20/30 (3 valves)
212	30	$\phi/30/20$ (2 valves)

### 4 DESIGN PARAMETERS

The following design conditions and strength parameters were considered for design:

- End-of-Construction (EOC): peak shear strength parameters and natural water content, with and without expansion pressure.
- Long-Term and Peak Condition (LTP): saturated peak shear strength parameters, with and without expansion pressure.
- Long-Term and Residual Condition (LTR): saturated residual shear strength parameters, with expansion pressure.

A possible decrease in adhesion due to soil saturation was also considered in adhesion. Increase in anchor loads due to expansion pressure was taken into account for anchor design.

With basis on the laboratory and field tests, and following the procedures outlined in ABNT NBR 11.682 – Slope Stability, the parameters presented in Table 5 were used in wall design.

Table 5 – Design parameters.

Parameter	Condition/			
	EOC	LTP	LTR	MSE*
Soil unit weight (kN/m <sup>3</sup> )	20	20	20	20
Cohesion intercept (kPa)	60	40	0	30
Friction angle (°)	30	18	18	25
Anchor adhesion (kPa)	Average	100	90	125
	Maximum	140	125	
Same with expansion (kPa)	Average	70	65	-
	Maximum	100	90	
Puncture anchor head (kN)		430		

\*MSE :Soil Parameters for Mechanically Stabilized Earth Wall

## 5 DESIGN AND CONSTRUCTION OF ANCHORED WALL

A limit equilibrium program was used to design the anchored wall, considering the reinforced wall on the top and a traffic surcharge of 25kPa. Potential failure surfaces were always very close to the anchored wall face. As a result, the free section of the anchors were short, in the order of 3.0m. This is the minimum length accepted by ABNT NBR 5629 – Anchored Walls. Anchor length was varied in order to achieve minimum Safety Factor of 1.8 for EOC, 1.5 for LTP, and 1.2 for LTR conditions, resulting the following anchor distribution:

- Cable anchors, 5x12,7mm 190RB, yield stress= 1708MPa
- Working load = 430kN
- Testing load = 760kN
- Minimum spacing = 1,6m
- Maximum spacing = 2,0m
- Inclination with horizontal = 20 degrees
- Free length = 3,0m
- Anchored length = varying from 6.0 to 9.0m
- Anchor diameter = 100mm

Water table close to the base of the anchored wall was found in several SPT bores. Therefore, horizontal drains 15m long were installed every 2.4m along the wall base. The stiff clay layer was carefully excavated to install the anchors and build the reinforced concrete face 30cm thick. For each anchor level the anchors were loaded to 50% of the working load. Construction of the reinforced fill started after the completion of the anchored wall. When the reinforced fill height reached around 70% of the final fill height the anchors were re-loaded with 100% of the final working load.

## 6 WALL MONITORING

In order to monitor wall behavior a monitoring system was installed along the wall. It consisted of:

- 3 inclinometers 15m deep installed
- 3 load cells installed at selected anchor heads
- 20 displacement pins

Inclinometers were installed in boreholes along the front face of the anchored wall, and extended upwards during placement of the reinforced fill.

Several readings were obtained during construction of the lower anchored section and continued during construction of the upper reinforced fill section.

## 7 MONITORING RESULTS

Figures 3 and 4 show inclinometers results for 2 of the instrumented sections: Section I-200 and Section I-205. The results show that:

- The displacements increase continuously with construction of the lower anchored wall and the upper reinforced soil wall.
- Displacements of the lower anchored wall were generally small, in the range of 5 to 10mm.
- Small face displacements were expected for the stiff clay layer. However, for these displacements level it is possible that residual conditions may be attained by the clay layer during wall construction.
- For the upper reinforced fill, however, face displacements were relatively high. Measured displacements varied from around 10mm at the bottom up to 70 to 80mm for the upper part of the fill.

Figure 3. Inclinometer results in Section I-200.

Figure 4. Inclinometer results in Section I-205.

## 8 CONSTRUCTION CONDITIONS

Figures 5 and 6 show construction conditions, especially the upper part of the reinforced soil fill with the reinforcing steel strips and the face of the anchored wall face at the bottom.

Figure 5. General view of the top part of the reinforced soil fill.

Figure 6. General view of the highest section of wall.

## 9 CONCLUSIONS

The following conclusions can be summarized:

- The stiff clay layer has relatively high strength parameters for peak conditions.
- Residual conditions are achieved for relatively low displacements, around 1mm.
- Due to structural conditions the stiff clay has relatively high vertical expansion pressures, around 440kPa, whereas horizontal pressures are relatively low, around 30kPa.
- Displacements of the lower anchored wall were generally small, in the range of 5 to 10mm.
- These small face displacements were expected for the stiff clay layer. However, for these displacements level it is possible that residual conditions may be attained by the clay layer during wall construction.
- For the upper reinforced fill, however, face displacements were relatively high. Measured displacements varied from around 10mm at the bottom up to 70 to 80mm for the upper part of the fill.

## 10 ACKNOWLEDGEMENTS

The authors are grateful to Ms. Karina Tomoko Hentona for helping in preparing the figures.

# Design and construction of high bermless geogrid walls in a problematic mountainous seismic region in Bulgaria

Conception et construction de murs renforcés par des géogrilles de grande hauteur et sans risberme dans une région montagneuse sismique problématique en Bulgarie

Alexiew D., Hangen H.  
HUESKER Synthetic GmbH, Gescher, Germany

Geogrids made of geosynthetics can replace conventional building materials like concrete. In this article, goal and scope, basic data and the results of a comparative life cycle assessment of concrete reinforced retaining walls (CRRW) and geosynthetics reinforced retaining walls (GRRW) are described. One running meter of a three meters high retaining wall forms the basis for comparison. The two walls have the same technical performance and an equal life time of 100 years. The GRRW has a lower demand of steel and concrete compared to the CRRW. The product system includes the supply of the raw materials, the manufacture of the geotextiles and the concrete, the construction of the wall, its use and its end of life. The life cycle assessment reveals that the GRRW causes lower environmental impacts. The cumulative greenhouse gas emissions of 300 m CRRW are 400 t and 70 t in case of GRRW. The use of an environmentally friendlier lorry in a sensitivity analysis and monte carlo simulation confirm the lower environmental impacts caused by the construction of a GRRW compared to a CRRW. More than 70 % of the environmental impacts of the geogrids production are caused by the raw material provision (plastic granulate) and the electricity demand in manufacturing.

**RÉSUMÉ :** Les Géogrilles peuvent remplacer les matériaux conventionnels comme le béton. Cet article contient une description de l'objectif et du champ d'étude, l'inventaire et les résultats d'une analyse comparative du cycle de vie d'un épaulement géotextile et d'un soutènement conventionnel. La comparaison est faite sur un mètre courant d'un épaulement de trois mètres de hauteur. Les deux alternatives ont les mêmes propriétés techniques et la même durée de vie de 100 ans. Les systèmes contiennent la provision des matériaux, la fabrication des géotextiles et du béton, la construction, l'utilisation et l'évacuation de l'épaulement. L'analyse de cycle de vie démontre qu'un mètre courant d'un épaulement géotextile cause moins d'impacts environnementaux qu'un mètre courant d'un épaulement de béton. 300 mètres d'un épaulement de béton entraînent 400 t CO<sub>2</sub>-eq, celui de géotextile 70 t CO<sub>2</sub>-eq des émissions des gaz à effet de serre. L'utilisation de camions avec des émissions réduites ne change pas les résultats. Une simulation « monte carlo » confirme la stabilité des résultats. La provision des matériaux et l'électricité utilisé dans la fabrication de la couche de filtre géotextile sont des facteurs primordiaux (plus de 70 %) en ce qui concerne les impacts environnementaux du géogrille utilisé dans l'épaulement géotextile.

**KEYWORDS:** geogrid-reinforced walls, facing, seismicity, slope instability, steep slopes  
**MOTS-CLÉS:** épaulement, géotextile, géogrillé, béton, analyse de cycle de vie, ACV

## 1. INTRODUCTION

In the Rhodope Mountains in the south of Bulgaria the route of the important Road III-868 from Devin to Mihalkovo being part of the National Road Network had to be completely changed due to the erection of a new dam on the River Vacha. The old road along the river had to be moved from the river valley to the hills by up to some hundred meters. The new route has a length of 11 km (Figure 1). Figure 2 provides an overview of the mountainous terrain, of the position of the old road in the valley and of the new road uphill. The mountainous terrain is characterized by sophisticated topography (very steep irregular slopes, Figure 2), varying geological and hydro logical conditions, instability tendencies in some places and non-availability of easy access for construction. Additionally, the region has a significant seismic activity.

Figure 1. Old route of Road III-868 in the valley and new one uphill through the mountains.

Figure 2. Overview of the mountainous terrain and exemplary positions of the old and new road.

The solution had to meet a wide range of criteria and goals: low costs, quick and easy construction, soil-mass balance (say minimum export / import of soil, say maximum re-use of excavated local soils), minimal environmental impact, as light as possible additional construction materials to ensure easy transportation and low energy consumption ("carbon finger print"), minimum use of heavy equipment, narrow base for retaining walls for an easy into-slope-adaptation, seismic resistance, and last but not least a tight time schedule of less than three years for the 11 km of new road incl. of a tunnel.

The final optimized solution meeting the criteria mentioned above in a balanced way included twenty walls from geogrid-reinforced soil (GRS) with a total length of 2 km, heights of up to 20+ m and a face inclination of 10v:1h (say nearly vertical) without any berms, what is quite unique (see below).

The GRS-walls were chosen (besides other advantages, e.g. more than 30% costs savings versus “common” concrete solutions) due to their excellent adaptation to the environment and their high ductility resulting in high robustness against seismic impact and slope movements. Flexible geogrids were used as reinforcement.

A special type of thin stone-filled wall facing was adapted to fit the landscape, to use local rocky material and to speed up construction. The facing is very flexible and thus of higher resistance against earthquakes and possible slope movements.

## 2. GENERAL CONCEPTS AND PHILOSOPHY

The project was developed by the General Consultant “Energoprojekt - Hydropower” (Sweco Group) Bulgaria and by the Road Designer “Burda Engineering” Bulgaria with consultancy from the company of the authors. Some specific points have to be mentioned:

A. Because of the very steep natural slopes (sometimes steeper than 1v:1h) the optimal positioning and foundation of all walls asked for almost vertical front inclinations of 10v:1h to achieve a better adaptation to the slope geometry. The base width of the cross-sections had to be minimized thus minimizing excavation (Figure 3c) and expansion down the slope as well (Figure 3a).

B. To optimize the soil mass balance but also based on common practice and conservatism three types of cross-sections were foreseen: without berms (typically up to 6-8 m), with one berm (typically up to 14 m) and with two berms (up to 22 m) (Figure 3).

C. The final stability analyses and design of the GRS-walls were to be completed after beginning of construction (due to site logistics few of the structures could be started at the same time, in reality a progressive construction was carried out along sections of the route). The specifications put to tender were founded on the basic concept and on the typical cross-sections in Figure 3 a, b, c (these were

Figure 3. Basic concepts for typical cross-sections: front (facing) inclination always 10v:1h, but different number of berms; from top to bottom: a, b, c.

indicative only, being based on preliminary stability analyses); it was assumed that these will be not the final solutions. The reason for this philosophy was the uncertainty in the real geotechnical and topographical conditions along the 11 km of road, because due to the extremely difficult access the survey and site investigation had been relatively modest.

D. The facing was an important issue. After checking different options the so called “Muralex® Stone” facing system was chosen. Its

concept is based on the idea of a “hanging facade” added and connected in a later construction stage to the “real” bearing geogrid structure (Figure 4).

The system leads to important advantages:

- the geogrids are hidden and protected against UV, impact, fire and vandalism;
- possible wall deformations during construction occur before facing installation - the facing starts its design life deformation-free;
- ductile behavior of the facing under seismic impact and generally under wall deformations of any type in the post-construction stage, because it is quite flexible, say there is no rigid connection to the “real” GRS (Figure 4);
- no special facing foundation is needed;
- a wide range of rocky material available from the excavations on site can be used etc.

Figure 4. A typical version of the facing system Muralex®.

## 3. GEOLOGICAL AND HYDROLOGICAL CONDITIONS

The geology along the new route varies significantly (Figure 5). The GRS-walls and their foundations can contact at the back resp. be embedded in (Figure 3) any local soil from silty or sandy clays with stone inclusions (slope talus) to more or less monolithic rock. This enormous inhomogeneity resulted in a low level of predictability not only regarding the local slope soils, but also regarding the parameters of the fill soil; the latter consists (although after pre-selection) from excavated local materials from different cuts along the new route.

The geotechnical survey before beginning of construction was not very detailed. It was decided together with the General Investor “National Electricity Company”, Bulgaria, the General Contractor “Alpine Bau”, Austria, the Consultants (see above) and the Bulgarian Subcontractors for the road construction to assume in all final stability analyses relatively conservative average local soils and fill parameters. Many of the walls cross small valleys; in such cases standard culverts were planned being integrated into the GRS-walls. No water veins were known before beginning of execution. Nevertheless for all walls drainage blankets were implemented at the wall base.

## 4. SOME STABILITY ANALYSIS ISSUES

For all stability analyses the well known method of circles according to Bishop was used together with additional analyses of polygonal failure planes using the so called Sliding Blocks Method. All analyses were performed in the Engineering Department of the company of the authors. The concept of global factor of safety (FOS) acc. to the German Codes (e.g. DIN 4084) was applied throughout the project from the same beginning (preliminary designs in 2004) until the last adaptations and changes under running execution in 2009, although in the meantime the Codes had changed to partial factors of safety.

Figure 5. Examples of the enormous inhomogeneity of the local soils and rocks.

“Internal”, “external” and “compound” stability modes were separately checked to keep conformity with the preliminary designs in 2004, although this differentiation is questionable; for more details see Alexiew (2004 & 2005).

Note that in the meantime in the new issue of the German recommendations EBGeo (2010) the distinction internal-external-compound was eliminated, as well as e.g. the formal distinction between “slopes” and “walls”.

Geogrids from the “FORTRAC® T”-family were chosen as reinforcement due to their high specific short- and long-term strength, low short- and long-term strain, low creep, high coefficient of bond to a wide range of soils and flexibility resulting into an easy installation. The range of geogrids for this project was from FORTRAC® T 55 to FORTRAC® T 200.

The required factors of safety (FOS) were chosen according to the Bulgarian Standards with  $FOS > 1.3$  for normal (static) conditions. In Figure 6 a typical Bishop circle analysis is shown (for the internal stability only, say the failure surface crosses exclusively the reinforced zone).

Figure 6. Typical example of stability analysis according to Bishop (only “internal” shown).

A specific issue was the seismic analysis; the region is of significant seismic activity with a magnitude of VII acc. to Richter.

The Bulgarian concepts for seismic design from 1980 being still valid with small modifications during the period of analysis were adopted throughout the project (CDBSSR 1987, CDRW 1986, SGDSR 1987).

Figure 7 shows an overview of the seismic activity in Bulgaria together with the position of the Devin-Mihalkovo project and the zone with VII acc. to Richter with a coefficient of horizontal acceleration  $k_h = 0.15$ . A vertical acceleration is not being taken into account.

For the acting seismic forces  $F_{seismic}$  the Equation 1 can be used (CDBSSR 1987, CDRW 1986, SGDSR 1987):

Figure 7. Seismic activities in Bulgaria, the project position is marked.

$$F_{seismic} = 1.30 \cdot R_{response} \cdot k_h \cdot (\text{permanent loads} + 0.50 \cdot \text{traffic loads}) \quad (1)$$

where  $R_{response}$  = coefficient of response of the structure to seismic impact;  $k_h$  = coefficient of horizontal acceleration; 1.30 and 0.50 = partial safety factors on the side of action for seismic design cases.

$R_{response}$  has higher values e.g. up to 0.40 for rigid (brittle, e.g. masonry, concrete) structures and lower values e.g. 0.25 for ductile structures like earth dams and embankments. It seems logic and conclusive that earth systems reinforced by flexible geogrids should be at least so ductile and able to dissipate seismic energy remaining intact as non-reinforced earth dams.

This concept and the corresponding calculation results seem to be coherent with the experience, conclusions and recommendations in e.g. Tatsuoka et al (1998) and other publications confirming the very advantageous behavior of GRS-walls under seismic impact.

Note that for seismic analyses the Bulgarian codes (CDBSSR 1987, CDRW 1986, SGDSR 1987) ask for a  $FOS > 1.1$ , for more details and previous “seismic” projects see e.g. Jossifowa & Alexiew (2002).

One specific issue more in the Bulgarian codes is the reduction of the angle of internal friction acc. to Equations 2 & 3 depending on the intensity of earthquake:

$$\varphi_{characteristic, seismic} = \varphi_{characteristic, static} - \Delta\varphi \quad (2)$$

where

$$\Delta\varphi = \Delta\varphi(\text{magnitude acc. to Richter}) \quad (3)$$

For the project under discussion with a magnitude of VII acc. to Richter  $\Delta\varphi = 3.5^\circ$ .

Because the software used (GGU Stability by Civil Serve) does not include a calculation conform to Equation 1 and considers only directly  $k_h$ , the latter had to be modified “by hand” before the input.

## 5. EXECUTION, PROBLEMS, SOLUTIONS, EXPERIENCE

Execution started in summer 2007. First problems arose soon: the topography deviated sometimes significantly from the expected one, the real terrain was sometimes higher or lower than it should be, the real slope inclination often steeper. Step by step many of the cross-sections had to be re-designed. At the end of the day all GRS-walls, even the highest with over 20 m height, became “bermless”, what is quite unique.

The “bermless” solution offers significant advantages: the base width of the cross-sections becomes minimal (Figure 3). This helped to avoid deep cuts into the hillside and/or an expansion of the trapezoid beyond the steep slope line (to the left in Figure 3). Additionally, in some cases the geology deviated significantly from the assumptions; this resulted in re-design as well.

Often surprising water veins in the natural slopes had to be drained promptly. For this purpose thick wicks from rolled non-woven geotextiles were installed ending on the front side of wall as a quick ad hoc solution.

In Figure 8 typical construction stages and details are depicted. Figure 9 shows one of the completed walls just before handing the route over for operation.

Figure 8. Left: construction stages (formwork, geogrids, anchor bars, facing), right: top view of the stone-filled facing used.

Figure 9. Top view of a completed GRS-wall.

## 6. FINAL REMARKS

The new Road III-868 from Devin to Mihalkovo in the Rhodope Mountains in southern Bulgaria was a challenge in terms of optimal concept, design, execution, re-design during execution, time schedule and costs. It crosses a terrain with sophisticated topography and geology in a seismic region. Its length amounts to 11 km comprising one tunnel and twenty geogrid-reinforced almost vertical soil walls of totally 2 km length and up to 20+ m height.

A specific type of facing was adopted to fulfil a wide range of requirements.

Almost all GRS-walls had to be re-designed and adopted under running route execution, resulting throughout in non-common high bermless solutions.

Nevertheless, it was possible to meet all project goals regarding time schedule and costs (among others; see the description of criteria, goals and optimized solution in Chapter 1). The success is based on the one hand on the advantages and flexibility of geosynthetic solutions in geotechnical engineering in terms of easy and quick construction process and adaptation and on the other hand on the excellent co-operation of all participants: Investor, Owner, Consultants, Contractors and Geosynthetic Company.

The road is since summer 2010 under traffic, the GRS-walls demonstrate until now an excellent behavior both in terms of stability and low deformability.

This transportation project is may be the most distinctive in the Balkan region during the last years.

## 7. ACKNOWLEDGEMENTS

The authors would like to express their gratitude to all colleagues with the Investor, Consultants and Contractors for the excellent and competent collaboration during all project stages and even (and particularly) in some difficult phases.

# La fouille de la tour Odéon à Monaco : les quatre éléments remarquables de sa conception

The Deep Excavation of the Odéon Tower in Monaco: The four outstanding elements in its design

Baghery S.

Tractebel Engineering (France)/Coyne et Bellier, Gennevilliers (92), France

**RÉSUMÉ :** La construction de la tour Odéon à Monaco nécessite la réalisation d'une fouille profonde au sein d'un versant très pentu, dans des terrains de caractéristiques médiocres. Le soutènement en a été rendu possible par quatre options remarquables prises par le concepteur, à savoir (1) une construction « top-down » à l'aide d'appuis pré-fondés, (2) la constitution d'une voûte élastique dans le sol côté montagne, ceci par modulation de l'effort de pré-charge par tirants d'ancrage, (3) le fretage du sol au pied des parois à l'aide de clous verticaux en fibre de verre et (4) la prise en compte des effets du déchargement du sol sur les appuis pré-fondés.

**ABSTRACT:** The construction of the 180-meters-tall Odéon skyscraper building in Monaco calls for a 72-meters-deep excavation to be dug in a steep hillside. The design of the retaining system for this excavation was made possible by Tractebel Engineering (France)/Coyne et Bellier making four unique design choices, namely (1) a "top-down" construction method, (2) the mobilization of an elastic arch in the foundation soil on the upstream side of the works, (3) reinforcing by fibre glass nails the soil below the deepest elements of the foundation, and (4) taking into account the effects, on the supports, of the sequence of construction.

**KEYWORDS:** Retaining walls, top-and-down construction, vault effect, soil reinforcement, heaving

**MOTS-CLÉS:** Soutènement, Construction en taupe, Top-Down, Effet de voûte, renforcement de sol, gonflement de sol.

## 1 INTRODUCTION

Avec une hauteur totale de 180 mètres, la tour Odéon, actuellement construite à Monaco sous la maîtrise d'ouvrage de la SCI-Odéon, restera pour un certain temps la plus haute tour de la Principauté. Alexandre Giraldi en est l'architecte. Elle est construite par l'entreprise Vinci, avec la contribution de Soletanche-Bachy pour les travaux de la fouille.

La réalisation de cet ouvrage nécessite l'excavation d'une fouille atteignant 72 mètres dans la partie la plus profonde (Figure 1). Alors que de nombreuses constructions sensibles situées au voisinage doivent être maintenues intactes, les travaux d'excavation exigent la conception de solutions originales, à la hauteur de ce projet audacieux.

tour, en tant qu'éléments de contreventement et raidisseurs parasismiques. Tractebel Engineering (France)/Coyne et Bellier a assuré la conception de ces deux parties du projet.

Lorsque les profondeurs d'une excavation dépassent les valeurs critiques eu égard aux caractéristiques du sol, le concepteur est confronté à un déficit intrinsèque de butée dans le sol. Il doit alors adopter des mesures innovantes. C'est grâce à de telles mesures que la réalisation d'une fouille avec une profondeur rarement atteinte dans des terrains de telles caractéristiques a été possible. Des études et investigations très poussées ont été nécessaires en amont des phases de contractualisation. Elles ont notamment comporté des modélisations tridimensionnelles des travaux, du massif et des constructions environnantes.

Figure 1: Le site, la tour et sa fouille

La conception du soutènement a été étroitement associée à la méthode et au phasage de construction de la tour, à la géométrie de la fouille et à la topographie du site. Les ouvrages de soutènement remplissent eux-mêmes un rôle structurel pour la

Figure 2: Versant en terrasse, le dénivelé, nivellement

## 2 LE SITE

Il s'agit d'un site très exigu, sur un versant en terrasses. Le dénivelé du terrain naturel entre l'amont et l'aval de la tour est de l'ordre de 40 mètres (Figure 2).

Les profils géotechniques indiquent une couche supérieure de remblai et d'éboulis sur une épaisseur qui atteint 25 mètres en amont, tandis qu'en aval, cette épaisseur varie fortement du fait des constructions récentes. Sous cette couche superficielle, on rencontre une couche marno-calcaire avec des poches plus

ou moins altérées vers les profondeurs 35-50 NGM. La couche marno-calcaire repose sur un substratum calcaire profond. Le toit du calcaire dessine une surface chaotique et variable. Il se situe en général sous la cote 30 NGM (Figure 3).

Le pendage général de la couche marno-calcaire (non représenté ci-dessous) est dirigé de l'amont vers l'aval. Il est donc favorable, lors de l'ouverture de la fouille, à la stabilité au glissement du massif soutenu côté montagne.

Une grande partie des niveaux piézométriques varie entre 10 et 20 mètres sous le niveau du terrain naturel, avec des fluctuations importantes qui atteignent fréquemment 4 à 5 mètres. Il s'agit d'une nappe superficielle qui coule à la surface de la couche marno-calcaire. A cause de sa faible perméabilité, cette dernière sépare la nappe superficielle d'une nappe plus profonde qui baigne dans le calcaire avec un niveau piézométrique situé environ 40 mètres plus bas que celui de la nappe superficielle.

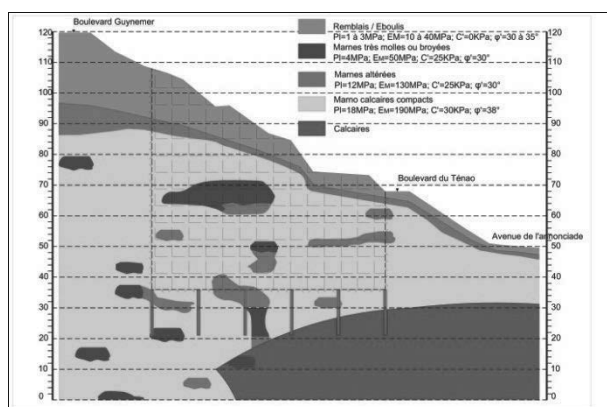

Figure 3: Coupe géologique, caractéristiques géotechniques

La bordure de la fouille est occupée par des bâtiments publics ou privés à des distances plus ou moins proches de la fouille. Compte tenu de la profondeur des excavations, un certain nombre d'entre eux se situe dans les zones d'influence des déplacements engendrés par les travaux d'excavation. Ce voisinage impose des contraintes d'exécution, notamment en termes du respect de déplacements admissibles.

### 3 OUVRAGES DE SOUTÈNEMENT: LES QUATRE ÉLÉMENTS REMARQUABLES

Les dix niveaux d'infrastructure comportent des planchers « butonnants » confinés entre les parois de la fouille. Ces planchers n'ont pas de joints et peuvent donc transmettre entre parois opposées les efforts de poussée ou de butée. La superstructure se développe au-dessus du boulevard du Ténac sur environ cinquante niveaux supplémentaires.

Si la stabilisation des parois de soutènement sous le boulevard du Ténac peut être assurée au moyen d'un système de planchers butonnants, ce n'est pas le cas pour les parois situées au-dessus de ce boulevard, à cause de l'absence de terrain offrant butée en vis-à-vis. C'est pourquoi les parois poussant au vide ont été stabilisées à l'aide de tirants d'ancrage.

Par ailleurs, l'exiguïté et les contraintes d'accès au site ont donné lieu à une solution de soutènement étagé des parois. En effet, la configuration des lieux avant les premiers travaux n'était pas défavorable à l'utilisation d'engins lourds. Ainsi, la réalisation des premiers écrans de soutènement à l'aide d'engins de taille réduite permet la réalisation de plateformes pouvant recevoir des engins plus encombrants. C'est pourquoi les premiers écrans de soutènement sont de type « mini-berlinoise », passant ensuite à des écrans de type berlinoise, avant de voir apparaître des écrans en paroi-moulée.

#### 3.1 Une construction "Top-Down"

Deux objectifs principaux nous ont conduit à adopter cette méthode de construction : a) Avantages offerts par des planchers butonnants (Figure 4) comme solution plus sûre d'équilibre des poussées en profondeur et dispositifs plus rigide pour limiter les déplacements des parois, et, b) Gain de temps dans la réalisation de la tour. En ce qui concerne ce dernier point, il a été considéré que dans le délai nécessaire à l'extraction des quelques 65 000 m<sup>3</sup> de terre des niveaux de sous-sol et à la réalisation en « taupe » des 10 niveaux de plancher correspondants, on pourrait construire simultanément les 50 niveaux de superstructure. Pour atteindre cet objectif, il a fallu réaliser des appuis profonds de la tour avant le démarrage de sa construction. Il s'agit des barrettes de fondation d'épaisseur 1m, forées aux environs de la cote 70 NGM, après les travaux d'excavation et de soutènement de la partie tirantée des parois. Il est à noter que la contrainte de compression moyenne développée dans ces barrettes par la tour en phase d'exploitation s'approchera de la valeur de 10 MPa. Ce niveau de sollicitation aurait pu rendre la solution non-faisable sans l'évolution des textes réglementaires, évolution apparue avec la mise en vigueur de la norme NF94-282 en février 2010, au moment de l'élaboration de la conception.

Figure 4 : Parois périphériques, barrettes et planchers butonnants

Au fur et à mesure de la construction des structures, les barrettes profondées reçoivent des charges gravitaires alors que les planchers de sous-sol, portés par les barrettes assurent le rôle simultané de diaphragmes dans la transmission des efforts horizontaux.

#### 3.2 Une voûte en sol

La topographie et la géométrie de l'excavation ont été mises au service de la conception du soutènement de la paroi la plus profonde de la fouille, dans la zone où les poussées sont les plus importantes du fait de la profondeur et de la pente du versant. Mais la portée de la paroi dans cette même zone est plus courte, ce qui nous a encouragé à en profiter pour inscrire dans le terrain le funiculaire des poussées, évitant notamment de solliciter la paroi profonde et limitant ainsi les déplacements. On aurait pu penser, a priori, que ce funiculaire existait en soi par le fait de la géométrie ("effet de voûte"). Mais cette affirmation ne tient pas compte du trop grand déviateur des contraintes (tangentielle et radiale), qui amène le sol de la "voûte" à se déformer à l'état plastique. Pour profiter de l'effet bénéfique de la voûte il a fallu ramener le sol qui la constitue à l'état élastique.

Si la limite élastique dans le sol à l'arrière de la paroi n'est pas dépassée à l'état initial, ce n'est pas forcément le cas avec l'excavation des sols devant la paroi, qui augmente progressivement la contrainte tangentielle dans le sol arrière. Dans le cas où la contrainte radiale reste trop faible, le déviateur s'agrandit et "pousse" le sol dans la plasticité qui engendre à son tour des déplacements importants (Figure 5).

Figure 5 : État de contraintes de la voûte en sol

La solution réside donc dans l'augmentation de la précontrainte radiale à l'aide des tirants d'ancrage qui sont disposés dans la même direction en amont de la fouille.

Figure 6: Voûte élastique dans le sol amont (gauche), cheminement des contraintes de la voûte vers les côtés latéraux de la fouille (droite)

La figure 6 (à gauche) montre une voûte en sol créée à l'arrière de la paroi amont, voûte qui redirige les poussées vers les côtés latéraux de la fouille (à droite), soulageant ainsi la paroi la plus profonde exposée à soutenir les charges les plus importantes.

 Figure 7: Etat d'avancement du chantier à  $\approx 40\%$  des excavations

En revanche, on peut y remarquer les zones plastiques formées dans la zone des bulbes d'ancrage et à l'arrière des parois plus ou moins rectilignes. Elle illustre également le cheminement des contraintes dans le sol et l'efficacité de la voûte élastique inscrite dans le sol. La figure 7 montre l'état d'avancement du chantier (à environ 40%) de soutènement et des excavations.

### 3.3 Frettage du sol

Lorsqu'une fouille dépasse 40 ou 50 mètres de profondeur dans des sols de cohésion faible à moyenne, deux solutions se présentent. La première consiste à mobiliser une masse très importante de sol en butée, ce qui nécessite une fiche de paroi très rigide et surtout très profonde. La seconde fait appel à une amélioration de la cohésion apparente du sol (Figure 8). Nous avons opté pour cette deuxième solution en frettant le sol au

pied des parois de grande profondeur à l'aide de clous verticaux en fibre de verre.

Notons que les barrettes de fondation réalisées par anticipation (appuis préfondés) contribuent, pour leur part, au frettage du sol. Néanmoins, il faudra tenir compte des sollicitations qu'elles encaissent par ailleurs. On vérifiera donc que l'accumulation des contraintes suivant les différents modes de fonctionnement (fondation, frette, inclusion soumise aux effets dus à l'expansion du sol –voir §3.4-) ne dépasse pas la résistance admissible de ces éléments.

L'évaluation de la cohésion apparente apportée par des frettes se fait en comparant la résistance (au glissement par exemple) du sol non-fretté, mais augmenté en cohésion, avec sa configuration frettée munie de la cohésion d'origine. Une analyse itérative des deux schémas aboutira à la valeur de la cohésion apparente qu'il faudra attribuer au sol d'origine pour être équivalent, en termes du critère de résistance choisie, avec le sol fretté.

✦ Dans ce terrain, l'équilibre des poussées exige, soit 28 mètres de fiche rigide avec la cohésion de base ( $3 \text{ t/m}^2$ ), soit une cohésion améliorée de  $18 \text{ t/m}^2$  avec 15 mètres de fiche.

Figure 8: Profondeur d'équilibre poussées-butées en fonction de la profondeur de la fiche ou de la valeur de la cohésion

### 3.4 Effets du déchargement du sol sur les préfondés

Comme il a été rappelé plus haut (§3.1), des barrettes de fondation ont été conçues pour être réalisées à un stade où il reste encore à excaver 35 mètres de terrain. Comme fondations, elles supportent les charges de la tour au fur et à mesure de sa construction. De ce fait, elles sont soumises à des contraintes de cisaillement puisqu'elles s'enfoncent dans le sol encaissant. Dans ce schéma, la contrainte de cisaillement développée le long du fût d'une barrette est dans la même direction que le mouvement du sol par rapport au fût, du bas vers le haut. Autrement dit, l'action du sol sur le fût est une contrainte tangentielle (frottement) dans le sens ascendant. Nous lui attribuons le signe « + ». Ces contraintes de cisaillement varient d'une valeur minimale à la base du fût vers une valeur maximale à sa tête (figure 9-a). Si la limite de plasticité devait être atteinte, elle le serait d'abord dans la partie supérieure où la courbe des valeurs serait plafonnée à la valeur plastique.

Par ailleurs, sous l'action des charges gravitaires, la valeur de l'effort de compression dans le fût diminue en profondeur, puisqu'une partie de cet effort est absorbée par le sol avec la mobilisation du cisaillement autour du fût (figure 9-b).

Avec l'excavation en présence des appuis préfondés, le sol encaissant autour de ces appuis (barrettes) se décharge et subit de ce fait une extension (gonflement), à l'opposé du phénomène de tassement, développant ainsi autour du fût des barrettes une deuxième catégorie de contraintes de cisaillement. Dans ce type de schéma (gonflement ou tassement du sol encaissant), et dans l'hypothèse d'un sol homogène doté d'un comportement linéaire, le bilan du cisaillement développé autour du fût est nul si l'effet sur le terme de pointe est négligé. La courbe de cisaillement à l'interface sol-fût, sous l'effet du gonflement du sol, possède un point d'inflexion (figure 10-a). Les contraintes de cisaillement changent de signe de part et d'autre de ce point. Dans le cas de gonflement du sol, les contraintes de cisaillement

sur la partie située au-dessus du point d'inflexion sont du même signe que les cisaillements provoqués par les charges gravitaires. Dans cette partie, les cisaillements dus à ces deux phénomènes se cumulent (figure 11-a). Nous sommes donc, en cas de gonflement du sol encaissant, face à des contraintes majorées de cisaillement dans la partie supérieure du fût. Sur la partie située sous le point d'inflexion, le signe de la contrainte de cisaillement à l'interface sol-fût provoquée par le gonflement du sol est à l'opposé du signe des cisaillements dus aux charges gravitaires. Sur cette partie, les deux catégories de cisaillements se retranchent et les contraintes de cisaillement résultantes sont minorées.

L'effort axial dû au seul phénomène de gonflement du sol est une traction (figure 10-b) et sa courbe de variation le long du fût est une courbe pseudo-parabolique. Sa valeur maximale se situe au droit du point d'inflexion de la courbe de cisaillement provoqué par le gonflement. En l'absence d'effet sur le terme de pointe, c'est une force interne et elle se retranche de l'effort de compression engendré par les charges gravitaires (figure 11-b). C'est précisément cette valeur résultante qu'il convient de contrôler à chaque phase en mettant en parallèle la vitesse de la construction des structures (« Top » - compression des barrettes) avec la vitesse des excavations (« Down » - traction des barrettes). Le risque est bien l'apparition d'une traction excessive à une phase donnée des travaux, traction qui serait incompatible avec la résistance admissible de la section des barrettes. Ce risque est d'autant plus grand que l'effort de compression axial dû aux charges gravitaires n'est pas grand, le module du sol au déchargement est faible, la raideur axiale des appuis profonds est forte et la raideur au cisaillement du sol est élevée.

On peut conclure, ici, que le gonflement du sol réduit l'effort de compression dû aux charges gravitaires dans le fût. Sous certaines conditions il peut même l'annuler et pousser la section résistante dans le domaine de la traction.

Figures 9(a,b): Cisaillement et effort axial dans les appuis profonds dus aux charges gravitaires (sans terme de pointe)

Figures 10(a,b): Cisaillement et effort axial dans appuis profonds dus au gonflement du sol encaissant (sans terme de pointe)

Il est à noter qu'en présence d'un terme de pointe à la base des appuis profonds, les contraintes de cisaillement et les efforts axiaux dus aux charges gravitaires ne se cumulent pas toujours linéairement. En effet, lorsqu'il devient prépondérant, le phénomène de gonflement peut totalement annuler le terme de pointe (effort de compression) dû aux charges gravitaires et créer ainsi une tendance au décollement de la pointe (figure 12). Dans ce cas, une analyse non-linéaire à chacune des phases de chargement où ce phénomène apparaît devient nécessaire.

Figures 11(a,b): Cisaillement et effort axial dans appuis profonds dus aux charges gravitaires + gonflement du sol encaissant (sans terme de pointe)

Figures 12: Cisaillement et effort axial dans appuis profonds dus aux charges gravitaires + gonflement du sol encaissant (avec terme de pointe) – Risque de décollement en pointe

Ce type d'analyse a été conduit sur l'ensemble des profonds (barrettes) de la tour Odéon. L'appréciation de l'amplitude du gonflement du sol dû aux excavations (déchargement) est un préalable à ce type d'analyse. Cela a été possible grâce aux études tridimensionnelles tenant compte du comportement non-linéaire du sol, englobant une large partie du massif et simulant les différentes phases de la construction. Toutes ces études complexes ont été conduites au stade de la conception, avant la contractualisation du marché d'entreprise.

#### 4 CONCLUSIONS

La construction de la tour Odéon nécessite la réalisation d'une fouille de 72 mètres de profondeur au sein d'un versant très pentu, dans des terrains de caractéristiques médiocres et sur un site urbain majeur. Les travaux et leurs séquences de réalisation devaient être conçus de telle sorte que les mouvements de nombreuses constructions sensibles situées en bordure immédiate de la fouille restent dans des limites restreintes. Quatre éléments remarquables et innovants de la conception ont été développés dans cet article :

- a) : une construction « top-down » à l'aide d'appuis pré-fondés,
- b) : la constitution d'une voûte élastique dans le sol côté montage,
- c) : le fretage du sol en pied des parois les plus hautes,
- d) : la prise en compte des effets du déchargement du sol sur les appuis pré-fondés.

Le premier élément (a) permet de réduire d'un an le délai global de la construction, qui est de quatre ans. Le deuxième élément (b) transforme le sol en une structure en voûte pour réorienter les poussées qu'il génère. Les deux derniers éléments (c et d) rendent possible le choix technique indiqué en (a).

**ABSTRACT:** This paper presents a 3D finite element study on a model to simulate an horizontal load test on a retaining pile wall. The piles wall was constructed at the site of Port Ghalib marina on the Red-Sea coast of Egypt which is considered as an active seismic area. The subsoil layers consist of 2 m to 3 m gravelly sand followed by a deep clayey silt layer. The ground water was observed at a depth of about 1.10 m below ground surface. The purpose of the test is to evaluate the pile displacement characteristics under exposed loads. Numerically a 10 m – length pile was modelled to simulate the actual case. Effect of surcharge, earth pressure and earthquake loads were taken into consideration. The numerical analysis was performed and the results have been found to be in good agreement with the measured field test results. In addition the finite element method make an ability to predict the deflection along the pile length.

**RÉSUMÉ :** Cet article présente un modèle 3D éléments de dimension par élément finie pour' simuler un chargement horizontal d'un mur de quai du port de plaisance de Port Ghalib sur les côtes égyptienne de la mer Rouge qui est une zone sismique. La stratigraphie est constitué d'une couche de 2 à 3 m de sable graveleux, en surface, suivie d'une couche de limon argileux, en profondeur. La nappe phréatique est située à 1,1 m de la surface. L'objectif de l'analyse est de caractériser le déplacement latéral du mur en fonction du chargement. Le modèle numérique a été construit pour simuler le cas réel. Les effets de la surcharge, pression des terres et effets des seismes, ont été pris en compte dans le modèle. L'analyse numérique et les résultats sont en accord avec les résultats des expérimentaux de terrain. En outre, la méthode des éléments finis donne une prédiction de la déviation le long du mur.

### 1. SUBSOIL PROFILE CONDITIONS AND PILE GEOMETRY

Soil investigation showed that the soil profile at the site is as follows:

Top layer (yellowish brown, gravel and sand) from ground surface with depth ranging from 2 to 3 m, followed by a layer of grey clayey silt, some fine sand, traces of broken shells, extended to the end of executed boreholes (at depth of about 20 m).

The Standard penetration test (SPT) shows the N values as follows:

- From depth of 2 m to 7 m level N has values between 2 and 13
- From depth of 7 m to 11 m level N = 3
- From depth 11m to the end of boring N has values between 7 and 11

Ground water was observed e at 1.10 m below ground surface. The pile wall consists of contiguous bored piles of 1.0m diameter and 10m length.

### 2. FINITE ELEMENT MODELLING

The finite element mesh considered in three dimensional nonlinear finite element analysis as discussed in Abouzaid et. Al. (2010) is shown in Figure (1-a). Based on symmetry, only one pile of the model is meshed. 20 nodes brick element Solid 95 were used to simulate both soil, and pile with cap. It should be noted that these quadratic elements exhibit high accuracy even for high aspect ratios and can model accurately bending of solid piles. During mesh design stage, a study was performed to

decide on appropriate (balanced) mesh size. The study showed that a much larger mesh, with more elements (of lower aspect ratios) would account for a fairly small change in results, so the current mesh is sufficient for analysis.

The concrete pile section, with a diameter of 1.0 m and pile cap beam have been meshed by Twenty node brick elements as shown in figure (1a-1b) with the elastic property of concrete. The soil domain has been simulated by strip of 1 m width with symmetry conditions on both sides. The depth of soil considered below the pile tip 10 times the pile diameter. The domain of soil considered has been found very much suitable for the analysis of the laterally loaded pile as when loaded till failure the soil elements at and near boundary do not experience any deflection. Also the soil elements at and near to the bottom boundary do not experience any deflection. The soil has been modeled as elastoplastic medium following Drucker-Prager (1952) .

Soil domain has vertically been divided to 20 layers, each of thickness 1/20 of the pile embedded length to allow the soil variation with depth. The elastic modulus is taken proportional to strength parameter (c).

The boundary conditions considered are shown in Figure (6-8a), the translations UX have been constrained in outer YZ plans, and only UZ and UY have been permitted whereas UY have been constrained in outer XZ plans, and only UZ, and UX have been permitted, also the translation UZ have been constrained over the area the soil block bottom and the translations UX, and UY have been permitted, this have been done to overcome the singularity of matrices and to help to get convergence. All nodes

of the symmetry plane have been constrained in direction perpendicular to the plane of symmetry.

The interface between the pile and soil have been represented by a couple of 8 node contact element named CONTACT 170 and 8 node target elements named TARGET 174, that was described in the chapter 3. The purpose of this couple is to mimic the installation effects on piles (drilled or driven). It also serves a purpose of a simplified interface which allows for tension cut-off (gaping) and controlled, coupled horizontal and vertical stiffness. The contact between pile and soil was supposed to be rough and were simulated by Drucker–Prager model with a friction angle of value corresponding to each layer.

Figure (1-a): 3D Finite Element Model for Contiguous Piles Wall.

Figure (1-b): Pile Cap Mesh.

### 3. LOADING CONDITIONS

Loading for this case is presented in Table (1). The pile cap has been proposed to laterally load  $P$  at the pile head in the negative direction of  $y$  axis, in addition to surcharge load, with excavation at various stages. Ten load cases were performed to simulate the lateral load test loads and study the pile behaviour under different load cases and compare with measured results

Table (1) Applied Load in Each loading Case for Contiguous Piles Wall.

Load case No.	Applied load ( $P$ ) (kN)
1	Before Applying surcharge load of 20 kN/m
2	Applying surcharge load of 20 kN/m
3	After excavation to -2.5 m from ground level
4	After excavation to -5 m from ground level
5	24 hrs after excavation to -5 m from ground level
6	Applying 21 ton horizontal load
7	After releasing 21 ton horizontal load

8	Just after Applying 300 kN horizontal load
9	24 hrs after Applying 300 kN horizontal load
10	After releasing 300 kN horizontal load

## 4. RESULTS AND DISCUSSION

### 4.1 Pile-Soil Deformation

Figures (2-a, b, c, d, and e) show the contour of pile and soil movement in direction  $Y$  axis, the deflection along the pile for the load cases no 2, 3, 4, 6, and 8.

In figure (2-a), after applying a vertical surcharge It is interesting to note that the plastic zone propagates deeply with a high densification in top layers till reaches the minimum values at the end of the model and extended below, this means that the settlement under the surcharge induced a lateral movement to the pile towards the settled side (right side), but the pile was rigid enough to retain the other side without movement especially the movements was very low so it does not extend far from the pile. Moreover, the instrumented side (right side) features much larger plastic zone while the plastic zone for the extension side (left side) is confined to the interface layer.

Figure (2-a) Contour of Deflections along the Pile under Surcharge Load .

In figure (2-b), after excavation to -2.5 m from ground level, It is noted that the excavation process resulted in a lateral movement of pile towards the excavation, and a small wedge of soil in front of the pile (left side) exhibits a small movement mobilizing a passive resistance in the front of the pile, but the right side is still affected by the surcharge load settlement which moves the soil very slightly in opposite direction

In figure (2-c), after excavation to -5.0 m from ground level, It is noted that the increase of excavation process resulted in increasing the lateral movement of pile towards the excavation, increasing the wedge of soil in front of the pile (left side) exhibits a bigger movement mobilizing a passive resistance in the front of the pile than the previous case, but the right side is still affected by the surcharge load settlement which moves the soil very slightly in opposite direction but less than the previous case.

In figure (2-d), Applying 21 ton horizontal load, It is noted that applying lateral load in increasing the lateral movement of pile towards the excavation, resulted increasing the wedge of soil in front of the pile (left side) exhibits a bigger movement mobilizing a passive resistance in the front of the pile the movement propagates deeper than the previous case and, but the right side is still affected by the surcharge load settlement which moves the soil very slightly in opposite direction but less than the previous case .

pressure was also performed to check results and it was found that soil pressure were within 97% accuracy.

$$PX = \frac{d(ROTX)}{dz} \tag{4}$$

4.2 Pile Head Displacement.

Figure (4) shows a comparison for the measured pile head displacement and that estimated from the present study. It is noted that a very well agreement between the two curves is existing where the R- squared value is 94%. The pile was just instrumented on the top, thus diagram column represent one case of loading.

Figure (4) Predicted, and Measured Pile Head Deflection .

4.3 Pile Straining Characteristics

Figures (5- a) to (5- c ), show the lateral deflection (UYn), bending moment (MYn), and soil reaction (pressure) (PYn) respectively along Pile Shaft due to the decided loading conditions illustrated in table (1). It is interesting to note that the change in location of maximum bending moment, peak zones of soil reactions, and points of hinges induced in different case of loading, where the point of maximum moment changed from -3 m to -5 m in case of excavation to -2.5m and -4 m , respectively. The beak of soil resistance is observed at -3.0 m in case of excavation to -2.5m and at -5.2 m in case of excavation to -5m. Also, the point of reversing soil reaction was observed at -7.75m.

Figure(5-a): Lateral Deflection along Pile Shaft .

Figure (5-b): Bending Moment along Pile Shaft

Figure (5-c): Soil Reaction along Pile Shaft.

5. CONCLUSIONS

The main findings can be summarized as follows:

- 3D finite element model gives the possibility of reaching high levels of loading until failure which is not available in full scale load tests.
- 3D finite elements can compensate for performing full scale lateral load tests with a good degree of trust to get reliable behavior of pile under loads saving time, effort , and cost.
- It is noted that good agreement between the measured and estimated from results of the finite element model. It is very important to obtain soil properties from high quality field or laboratory tests, as these will have direct effect on the analysis results.
- Pile and soil geometries must also be determined to a high degree of accuracy as these will also affect analysis outcome. Remembering the adage in computer modelling.

# Design and construction of a coffer dam on Narmada River for Indira Sagar project in central India: a case study of innovative foundation

## Conception innovante et construction d'un batardeau provisoire pour le barrage sur la rivière Narmada dans le cadre du projet Sagara en Inde centrale

Bidasaria M.  
*Ferro Concrete Const. (India)*

**ABSTRACT:** Indira Sagar Project in M.P., a multipurpose project, a 92 m high dam on Narmada river was required to be constructed but during off monsoon period flow of 300 cumecs of river Narmada was to be diverted so that dam can be constructed. For this, it was necessary to construct a 24 m high coffer dam to divert the off monsoon flow through a diversion tunnel from left abutment. This coffer dam was to be founded on a complex geological strata. To construct this 24 m high coffer dam, a new concept of innovative design used for first time in any country to construct a coffer dam, using 5 tons pre-cast blocks as shuttering on both faces of a coffer dam and filling the enclosure with boulders and stonecrete them under water. The work of 24 m high coffer dam has been done underground and under water for 12 m height using stonecrete and balance 12 m by conventional stone masonry.

**RÉSUMÉ :** Pour la construction du projet de barrage principal de 92m de hauteur sur la rivière Narmada des ouvrages provisoires de détournement de la rivière étaient nécessaires dans un contexte géologique difficile. L'article présente la conception innovante de batardeaux utilisant des blocs creux préfabriqués en béton avec bétonnage sous eau après mise en place d'encrochements.

### 1 INTRODUCTION

Indira Sagar Project is situated near Punasa about 60 Km. from Khandwa Town in Madhya Pradesh. To construct this dam, it was essential to divert Narmada river during off monsoon period from the original flow route, so that dam can be constructed without any hindrances. For this, conceptually it was necessary to have two important Component i.e. one u/s and d/s coffer dam to stop and divert Narmada river flowing from the original flow route, where proposed main dam was to be constructed and another a diversion tunnel through which Narmada post monsoon flow of 300 cumecs can be diverted during working period. That is how the construction of u/s and d/s coffer dam was necessitated. A sketch showing the various component like, u/s and d/s coffer dam diversion tunnel, proposed main dam etc. is shown in sketch – 1.

### 2. FOUNDATION AND GEOTECHNICAL PROBLEMS AND GEOLOGY

The Geological survey of India had carried out elaborate geological studies at the Indira Sagar Project dam site. It has been indicated that the dam site is located in the upper vindhyan inter bedded sequence of tough quartz arenites (quartzite), sand stones with minor silt stones. The bed in

general has an ENE-WSW strike and dip by 15-25 towards NNW with exceptional steep dips of 40-45 due to local warping. Bedding shears of 10-25 cm thickness confined to the silt stone beds are common features. The dam area in the river bed is occupied by a number of ENE-WSW trending vertical fault/shear zone, indicating horst/graben structure showing relative vertical displacement of blocks. It is WSW continuation of the Sone-Narmada fault. Mapping of the area has identified about five shear zones ranging steep dipping to vertical. These zones are braided with clayey gouge shear seams of 0.10-0.75 m thickness enveloping competent fractured lenses of quartzites and sand stone of 0.50 m to 2.5 m width sketch-2 shows geological L-section along main dam axis.

The fault zone includes the shearing (Sz-5), by virtue of its disposition and continuity, extends beyond the coffer dam located about 80 m upstream of the exposed section and opens in to the water pool, created by the upstream coffer dam inspite of being directly connected to this water pool, created by the upstream coffer dam. In spite of being directly connected to this water pool with a head difference of about 18-20 m the exposed section is completely dry and points to the near impervious nature of the fault zone material. Permeability test carried out in the new test holes in the fault zone confirm this observation (< 1 lugeon).

Except in the highly crushed zone/intrusion dyke, the fault zone material looks well compacted and was expected to have a high in situ density in the range of 2.2-2.3. The shear strength parameters were high and grain porosity may not exceed 20 %. The material did not show any significant deterioration notwithstanding the fact that there has been water to a depth of 1-2 m standing on it for a considerable time.

Even though the strata for foundation of coffer dam looked positive, for further dam design and stability of coffer dam foundation, detailed geotechnical investigation were necessary to eliminate geological surprises. Due to lukewarm report about highly Crushed zone/Intrusion dyke the foundations of coffer dam needed additional treatment to make it water tight. Further site investigation were carried out as given in the table below.

It may be observed that during pre-construction stages, to determine the detailed design parameters, following method of site investigations were performed :-

1	Geological mapping.	Over 0.75 Sq.Km on 1:1000 scale.
2	Core drilling	Double tube barrel – over 3000 m Triple tube barrel – over 500 m
3	Trenches	Three parallel trenches of +30 m. Six cross trenches of + 15 m
4	Shafts	Six shafts of 9.5 to 18m depth, 3.5 m dia.
5	Drifts	Four drifts of +16 – 23 m.
6	Bore hole camera studies	In 2 drill holes to study cavitations in silt stone/bedding shear zones.

This Data indicated that the sheared /crusted rock mass shall get consolidated if consolidation grouting is carried out and after completion of coffer dam, curtain grouting is also recommended, 1 m from the u/s face of coffer dam. Both these treatments were absolutely necessary in view of typical geotechnical problem faced. These treatments were carried out.

3. COFFER DAM - UPSTREAM AND DOWNSTREAM

The u/s coffer dam was necessitated to stop and divert the post monsoon river flow, to facilitate construction of main dam. This post monsoon flow ranging from 300 cumecs to 100 cumecs was required to be diverted from a diversion tunnel which was under construction through the left abutment.

As the construction of diversion tunnel was getting delayed considerably, provision of six sluices in the body of u/s coffer dam was envisaged to pass the post monsoon flow.

3.1 Concept.

The work consists of design and construction of upstream and downstream coffer dam of Indira Sagar Project. This was the new concept of design used for first time in any country to construct a coffer dam using 5 tons pre-cast blocks as shuttering on both faces u/s and d/s side of a dam, and filling the enclosure with boulders and stonecrete them under water. All work of coffer dam has been done underground and under water upto RL 193.5 m.

The maximum height of u/s coffer dam was 24 meter, 12 m under water and 12 m above water. The lowest foundation level in river bed was ± 180.60 m. For under water portion 5 ton hollow pre-cast c.c. blocks were casted and placed on the u/s and d/s face of dam, as a shuttering in a cell of 15 m length with the help of divers. Before placing the blocks, river bed was leveled by using blasting under water and with special technique, PC blocks were placed. Boulders were filled in the enclosure of a 15 m long cell and grout pipe with safety reinforcement were placed. The cell of 15 m was thoroughly caulked from outside, so that river flow does not have any effect in the cell. A colloidal grout, made out of sand, cement water and super plasticiser was pumped through the grout pipe at bottom and level of grout slowly built up from down upward. Thus colloidal grout (colcrete) replacing the water in the voids of the boulder and converting the boulder mass into concrete. This under water work was carried out upto 193.50 m level. About six pre-fabricated construction sluices of 2 m x 3 m were placed to take care of post monsoon discharges upto 300 cumecs as the diversion tunnel was under construction and was not ready.

Stone masonry was constructed above water level over the underwater works from RL 193.5 m and raised upto RL 204.50 m.

3.2 Design.

Height of u/s coffer dam was 24 m with the lowest foundation level kept at 180.6 and top of coffer dam as RL 204.5m. It has been designed on the principle of gravity dam, duly checked, for stability in various condition like Reservoir empty and Reservoir full etc. with following parameters :-

3.2.1 Cofferdam:

- a) Above water level, Random rubble masonry with a compressive strength of 10.5 N/mm<sup>2</sup> (cement mortar 1:4 approximate) with selected stone placed in u/s and d/s face.
- b) Under water stonecrete masonry in 1:2 and 1:3 concrete with P.C.C. Blocks on u/s & d/s faces.
- c) PCC blocks in M-15 grade Concrete.
- d) Coping : Concrete of M20 grade (c.c. 1:1.5:3) with 20 mm graded metal.

It may be observed that for underwater work, PCC blocks were kept on u/s and d/s section of the coffer dam and they were considered as a homogenous part of the full section. Dam cross section and L-section can be seen vide sketch – 3 and 4.

#### 4 CONSTRUCTION SEQUENCE OF COFFER DAM U/S.

Following is the Construction sequence.

##### 4.1 Casting yard for Pre-cast hollow blocks.

A casting yard having all facilities to cast hollow blocks under controlled conditions was made on left bank. The pre-cast/hollow blocks of size of 1.5 m x 1.5 m x 1.5 were casted in this yard. Suitable storage for form work and construction materials like stone grit, sand, water curing tank etc. were arranged on this platform to keep adequate stocks at site. The yard was equipped with form vibrators etc. and the traveling gantry with 10 T capacity. One electric hoist was fitted at this platform. The blocks were handled and loaded in flat bottom trucks by said gantry to carry it upto working platform on left flank from where, finally they were taken for construction using crawler mounted cranes at site.

##### 4.2 Precast Hollow Blocks :-

It was proposed to use hollow-precast blocks in the u/s and d/s of the dam profile under water. This enclosure were termed as stonecrete cell. At a time, 15 m length of coffer dam was undertaken in hand. Selected rubbles were filled within this enclosure along with colgrout pipes to carry out under water work. These colgrout pipe of 80 mm  $\phi$  were kept in a grid of 3 m and individual pipes were surrounded with a circular coil made of 6 mm, Tor to protect them during boulder filling. These blocks in addition to forming the enclosure have helped to stop flow of water within the enclosure as well as in voids of the rubbles.

The shape of the blocks on upstream and down streams faces of the coffer dam were nearly confirming to the designed profile.

To provide necessary interlocking amongst the blocks, male and female grooves were provided in each block. The blocks of special dimensions for maintaining uniform level of courses were casted as per requirement. The necessary shear keys and lifting hooks were provided in each block. The blocks were casted in the rigid steel forms so as to ensure uniform dimensions and minimum tolerances. The blocks were cast in advance and stacked in the casting yard.

##### 4.3 Preparation of Foundation.-

The left and right flanks which were much above water level of river were excavated to reach sound rock level to accommodate the length of coffer dam. Right flank in particular, was braided with clayey gougey shear seam of varying thickness from 2m to 6m. On the left flank excavation bedding shears of 16 to 25 cm thickness confined to the silt stones were commonly seen. Few photographs of the excavation and shear seam are exhibited below.

Foundation preparation in the river portion comprised of removal of silt, debris, loose rock and leveling of bed rock by underwater blasting wherever necessary. This was done using expert divers.

In order that the precast blocks from the pattern masonry walls required to be raised in uniform courses, the precise soundings were taken and loose materials were removed from its underneath. The area was leveled using special sizes of the blocks, or executing under water concreting for leveling course. It was observed that foundation rock was undulated at places. Hence levels were taken at a grid of 2 m and drawn on graph sheet. The gap between the leveled foundation and underneath of the blocks were caulked to achieve reasonable water tight joint.

##### 4.4 Launching of Blocks.

After the river bed is cleared of loose materials and leveled to receive the first course of the blocks as described under preparation of foundation para (III) above, the pre-cast hollow blocks were lifted from the working platform and carried by crane and lowered in position in the cell. Before lowering the PCC blocks, a steel frame made of 100 mm M.S. angle, is first lowered in place on 40 mm bed of stone chips and this frame is leveled horizontally on this bed. Expert divers had positioned the blocks at proper places either on the u/s or d/s of the enclosure as required, but within these steel frames which were leveled horizontally on the bed of 40 mm stone chips.

Each operation of block launching consisted of placement of blocks in the bottom course, to be followed by blocks in upper course. Till they were placed upto the level of 193.50 M. The launching of blocks is shown in photograph above.

Normally the blocks will be placed in required courses on up-stream and downstream sides of the u/s and d/s coffer dams. As the blocks are required to be in course it will be imperative to break the joints between the courses. Proper care was taken to break these joints in subsequent courses. As a matter of abundant precaution, the space in between the rows of blocks, will be filled with selected rubble near the blocks and around the pipes placed for colgrouting, so that the same does not get disturbed while filling up of rubble/stones in the cell

##### 4.5 Packing of Rubbles.

After the blocks are carefully launched and erected on either side in courses and the space in between interspersed with colcrete pipes, as stated above, rubble will be placed to fill-up the entire space between the rows of blocks in a 15 m cell. This rubble filling shall be done layer by layer in a systematic way using the large buckets with drop bottoms, handled by cranes.

##### 4.6 Stonecreting Operations.

The stonecrete process consists of making a grout of cement, sand and water in which cement has been so completely hydrated by high speed mechanical mixing, that the grout attains a colloidal form. This grout is stable and particularly fluent. It contains no chemical admixtures which might ultimately be harmful. When colloidal grout is poured in rubble aggregate the voids in the rubble filling are completely filled by penetration and the whole mass sets as a dense, solid concrete which is termed as "STONECRETE".

##### 4.7 Preparation of Colloidal Grout.

The Colloidal grout was prepared in double drum colcrete mixer consisting of sand, cement and water in desired proportions to obtain colloidal grout. In colloidal mixer, the

wetting of solid ingredients results from the shearing action which takes place in the specially designed impellers and matching casings of the colloidal mixers. The colloidal grout of specific gravity upto 1.8 to 2 is obtained using these high velocity mixers. Colloidal grout has enough fluidity to flow like grout and does not get separated when it comes in contact with water. It displaces water from the voids of stone/rubbles due to high specific gravity.

The double drum stonecrete mixer produces colloidal grout at the rate of 5 to 10 M<sup>3</sup>/hr. of 1:2 mix or 6 to 12 M<sup>3</sup>/hr. of 1:3 mix. When colloidal grout is stored without agitation in tanks after mixing, a little settlement is to be expected because sand invariably contains some oversize particles. When it is pumped direct by the mixer to the work in normal practice, the oversize particles do not have time to settle out.

#### 4.8 Placement of Colloidal Grout.

Colloidal grout does not mix with water unless agitated with it.

The colloidal grout so prepared is pumped, through 80 mm  $\Phi$  pipes placed in the rubbles using special roto or colmono pumps. The grout will be pumped at the bottom of pre-packed stones under pressure and will be allowed to rise uniformly in the cell displacing all the water from the voids due to its gravity. Once the grout travels upto the top of the course, the colgrouting is stopped when it emerges out of boulders at a level of 193.50 m of working platform level. After which the crawler mounted cranes will be advanced to tackle the next cell of the coffer dam till entire length 220 m length of u/s coffer dam is completed from one end. Construction sluices were left in the u/s coffer dam for diverting the water in final stages of closure of the coffer dam.

#### 4.9 Construction Sluices.

Pre fabricated M.S. sluice barrel were lowered in the central portion of u/s coffer dam keeping invert level at RL 186. In all, six sluices of 2 m x 3 m were installed. Rigid steel boxes were provided in the blocks for forming the approach tunnel for sluices. The construction sluices were installed under water with the help of the expert divers and is shown in photograph below.

4.10 Masonry Works above water level.

Construction of masonry in the flank blocks and above water level on stonecrete platform, upto top of coffer dam was done using conventional method of construction. The coffer dam above RL 193.5 was constructed in masonry upto RL 204.5 M and is shown in photograph. This was taken up immediately after the construction upto RL 193.5 under water using stonecrete. A coping 150 mm thick was laid at RL 204.5 m on the masonry using M-20 grade concrete.

## 5. DRILLING AND GROUTING.

### 5.1 Consolidation Grouting.

Looking to the geology, it was recommended to adopt a grid of drill holes at 3 m c/c on both side, besides about 82 Nos. of special grout holes were identified keeping in mind the location of various fault zones.

Depth of consolidation grout holes was 6 m in foundation rock.

## 6. CURTAIN GROUTING.

It was recommended to provide a single row of grout curtain, 1 m from the u/s face of the coffer dam, spacing of holes were kept as 3 m c/c. Depth of grout curtain holes in foundation rock was kept as 15 m.

This grout curtain was provided in stages of 5 m of drilling and grouting in descending order method.

It was observed that in consolidation grouting, intake of cement was 45 kg/meter and in curtain grouting it was 26 kg./meter.

## 7. D/S. COFFER DAM:

The construction of d/s coffer dam was done using the same methodology as explain under para 3 sub para I to IX. The top of d/s coffer dam was kept as 203.50 m i.e. 1 m below the u/s coffer dam. The main purpose of this coffer dam was, not to allow the river water which was diverted through the diversion tunnel (back water) in the d/s of the river.

### Closure of Sluices 6 Nos. in coffer dam:

It was essential to ensure following works completed before closure of sluices were taken in hand :-

## 8 CONCLUSION

Coffer Dam u/s and d/s, for the Indira Sagar Project had been successfully constructed and performed well, as a result the work of 92 m high I.S.P. main dam could be expeditiously carried out on mighty Narmada River.

The unique and innovative design, using 5 Tons Pre-cast hollow blocks with underwater stonecrete technique for the first time in the country, has successfully been used in Indira Sagar Project.

# Anchored sheet pile wall design in expansive soils

## Conception d'un mur de palplanches ancré dans les sols expansifs

Bilgin Ö., Mansour E.  
University of Dayton, Dayton, Ohio, U.S.A.

**ABSTRACT:** Expansive soils cause damage to civil engineering structures in various parts of the world, because they swell when absorb water and shrink when dry out. Due to swelling pressures, retaining walls can be subjected to additional lateral pressures causing increased wall deformations and bending moments. Anchor forces can also increase, if the walls are anchored. When expansive soils are present behind retaining walls, swell pressures should also be considered during design in addition to the traditional lateral earth pressures. This study proposes a method to predict potential swell pressures acting on retaining walls for use in design of these walls. A parametric study using the limit equilibrium approach was performed to investigate the effect of swell pressures on the design of anchored sheet pile walls in expansive soils. The results of the study show that the presence of expansive soils can significantly affect earth retaining structures and swell pressures should be considered in the design of retaining walls when the expansive soils are present at the site.

**RÉSUMÉ :** Les sols expansifs causent des dommages à des structures de génie civil dans diverses parties du monde, ils gonflent quand ils absorbent de l'eau et se contractent quand ils se dessèchent. En raison des pressions de gonflement, les murs de soutènement peuvent être soumis à des pressions latérales supplémentaires augmentant les déformations et les moments fléchissant. Les forces d'ancrage peuvent également augmenter, si les murs sont ancrés. Lorsque les sols expansifs sont présents derrière les murs de soutènement, les pressions de gonflement devraient également être envisagées, en plus des pressions latérales des terres traditionnelles. Dans cette étude, une méthode a été proposée pour prédire d'éventuelles pressions de gonflement agissant sur les murs de soutènement, à utiliser dans la conception de murs de soutènement. Une étude paramétrique en utilisant l'approche d'équilibre limite a été réalisée pour étudier l'effet des pressions de gonflement sur la conception de rideaux de palplanches ancrées dans les sols expansifs. Les résultats de l'étude montrent que la présence de sols expansifs, peut influencer considérablement la conception de structures de soutènement et doit être pris en compte dans la conception des murs lorsque les sols expansifs sont présents sur le site.

**KEYWORDS:** Retaining wall, anchored sheet pile wall, expansive soil, swell pressure, wall design.

## 1 INTRODUCTION AND OVERVIEW

The sidewalls of structures and retaining walls may experience additional lateral pressures when they are located within expansive soils. When the expansive soils absorb water the moisture content increases and the soil tends to expand. If the free swelling or expansion of the clay is restricted, then swell pressures develop and this cause an increase in the lateral pressures acting on the structures. The design of retaining walls usually specifies cohesionless soils as a backfill material behind the wall mainly to avoid hydrostatic pressures by providing easy drainage. These cohesionless materials also help to prevent swell pressures that may develop if cohesive soils are used.

Due to economical reasons, local soils which may be expansive are sometimes used as a backfill material (Thomas et al. 2009). However, use of these soils as backfill may result in wall failures (Marsh and Walsh 1996) not only because of the hydrostatic pressures but also due to the additional lateral earth pressures caused by the swelling of expansive soils.

The selection of soils behind the wall is not even optional for in-situ retaining walls, such as cantilever and anchored sheet pile walls, slurry walls, secant and tangent pile walls. These walls are installed in existing soils and front of the wall is usually excavated. When these walls are installed at locations where expansive soils are present, the walls would experience not only the traditional lateral earth pressures but also the swell pressures when soil's moisture content increases.

The objective of this study is to investigate the behavior of anchored sheet pile walls when they are installed in expansive soils and exposed to additional stresses due to the swelling of

these soils.

### 1.1 Expansive soils

The best way to deal with the shrinkage and swelling of expansive soils is to maintain constant soil moisture. If the soil moisture content does not change, there can be no shrinkage or swelling. However, it is usually not possible to maintain constant soil moisture. Moisture content fluctuates due to several factors, such as precipitation and evaporation. The seasonal variation of soil moisture is much higher at shallower depths and it decreases as the depth below the ground surface increases (Figure 1).

Figure 1. Moisture content fluctuations with depth.

Table 1. Classification of swell potential (after USACE 1983).

Classification of swell potential	Plasticity index, PI (%)
Low	< 25
Marginal	25 – 35
High	> 35

The depth where the seasonal soil moisture variations occur below the ground surface is called the active zone as shown in Figure 1. The depth of active zone is influenced by soil permeability, precipitation and evaporation amounts, seasonal temperature fluctuations, and presence of tree roots. Active zone depths in several U.S. cities were reported by O'Neill and Poormoayed (1980) as: 1.5 to 3.0 m in Houston, Texas; 2.1 to 4.2 m in Dallas, Texas; 3.0 to 4.6 m in Denver, Colorado; and 3.0 to 9.0 m in San Antonio, Texas.

The degree of swell potential of expansive soils can be classified by the soil's liquid limit,  $LL$ , or plasticity index,  $PI$ . As the liquid limit or plasticity index increases, the swell potential of the soil increases. The classification used by the U.S. Army Corps of Engineers (USACE) (1983) based on the plasticity index is given in Table 1.

### 1.2 Conventional sheet pile wall design

The design of sheet pile walls is based on active and passive earth pressures which are concerned with the failure condition using the Mohr-Coulomb failure criterion. For a typical wall section, the lateral earth pressures and the resulting forces acting on the wall are shown in Figure 2, where  $P'_A$  and  $P'_P$  are resultant effective active and passive earth forces, respectively;  $d_A$  and  $d_P$  are moment arms with respect to the anchor elevation; and  $FS$  is factor of safety. The factor of safety is applied to the passive loads during wall design (NAVFAC 1986; USACE 1994). The safety factors are used to take into account the uncertainties in soil conditions, method of stability analysis, loading conditions, as well as to restraint soil movements at an acceptable level (Potts and Fourie 1984).

Figure 2. Typical sheet pile wall section and forces acting on the wall.

Wall penetration depth required below the bottom of the excavation is determined by considering the moment equilibrium about the anchor elevation. Because the water level is assumed to be at the same elevation behind and in front of the wall during this study, hydrostatic forces cancel each other. Once the wall penetration depth is determined, the anchor force,  $A_p$ , is calculated from horizontal force equilibrium. Based on the active and passive pressure distributions and the calculated anchor force, maximum wall bending moment is determined. The design moment is calculated by applying the moment reduction factor (Rowe 1952) to the calculated maximum bending moment. The steel sheet pile section is then selected based on the design moment, and the wall design is completed by selection and design of an anchorage system. This conventional design approach does not take into account any

swell pressures that may affect walls when they are installed at locations where expansive soils are present.

## 2 METHOD OF APPROACH

The effect of swelling pressures on anchored sheet pile wall behavior has been investigated through a range of expansive soil activity. The swell pressures were calculated for a range of plasticity index values covering soils from low to high swell potential based on a study performed by Erzin and Erol (2007). Using these swell pressure potentials and moisture change profile in the ground within the active zone, the swell pressure distribution was developed. The swell pressure distribution developed was then applied on the anchored sheet pile wall as potential swell pressure, additional to the lateral earth pressures presented in Figure 2.

A parametric study for a range of plasticity index values, i.e. expansive soil activity and swell potentials, have been performed using the free earth support design method to investigate the effect of swell pressures on anchored sheet pile walls. Design of the wall was first performed for non-expansive soils, i.e. using only the traditional lateral earth pressure distributions, as a baseline case. Then the swell pressures, based on the varying plasticity index values, have been applied and the wall was re-analyzed.

## 3 SWELL PRESSURES

There are many factors that govern expansive behavior of soils. The primary factors are availability of moisture, amount and type of clay particles, and initial condition of soil in terms of dry density and moisture content (Day 1994). Several earlier studies (e.g., Snethen 1980, Erzin and Erol 2007) indicate that soil suction is the most relevant soil parameter for the characterization of swell behavior of expansive soils.

Multiple regression analyses carried out by Erzin and Erol (2007) revealed that the soil suction relates to the plasticity index and water content as

$$\log s = 2.02 + 0.00603 PI - 0.0769 w \quad (1)$$

where  $s$ =soil suction (in bar),  $PI$ =plasticity index (in percent), and  $w$ =water content (in percent). The study performed by Erzin and Erol (2007) also showed that the swell pressure, for pressures between 0 and 100 kPa, can be given as

$$\sigma_s = -3.72 + 0.0111 PI + 2.077 \rho_{dry} + 0.244 \log s \quad (2)$$

where  $\sigma_s$ =swell pressure ( $\text{kg}/\text{cm}^2$ ),  $PI$ =plasticity index (in percent),  $\rho_{dry}$ =dry density ( $\text{g}/\text{cm}^3$ ), and  $s$ =soil suction (in bar).

For this study, the plasticity index was used as the only variable to determine swell pressures. The plasticity index values considered ranged from 10% to 50%, which covers low to highly expansive soils as presented in Table 1. A constant value of 15% for the moisture content and a constant value of  $1.65 \text{ g}/\text{cm}^3$  for the dry density were used. These selected values represent average values of the ranges considered by Erzin and Erol (2007) in their study. The swell pressures calculated using Eq. 2 for the range of plasticity index values studied, with the moisture content of 15% and dry density of  $1.65 \text{ g}/\text{cm}^3$ , are shown in Figure 3.

### 3.1 Distribution of lateral swell pressures behind the wall

As shown in Figure 1, seasonal variation of soil moisture content is the highest at the ground surface and it diminishes as the depth from the ground surface increases. The change in the moisture content with increasing depth is not linear. However, the variation is assumed to be linear in this study. This

assumption is conservative, since the predicted swell pressures will be larger than the actual ones. The simplified linear model is shown in Figure 4.

Figure 3. Swell pressure versus plasticity index.

Figure 4. Change in moisture content with depth.

Because the change in moisture content causes the swelling of expansive soils, swell pressure will be maximum at the ground surface and will decrease as the depth increases. These maximum pressures, i.e. potential swell pressures, can be determined using Eq. 2. However, swell pressures close to the ground surface will not reach their potential due to shallow depths where soil confinement pressures are relatively lower. Soils closer to the ground surface will be able to expand, and full swell pressures determined by Eq. 2 will not be able to develop. When swelling occurs, passive lateral earth pressure conditions develop near the ground surface. Therefore, the passive earth pressures can be used as an upper limit for swell pressures near the ground surface. A schematic of the additional lateral pressure developed behind the wall due to the swelling of expansive soil is shown in Figure 5, where the potential swell pressure,  $\sigma_s$ , is determined by Eq. 2. When the swell pressures exceed the passive earth pressures near the ground surface (i.e., within the critical depth,  $z_c$ , shown in Figure 5), the additional lateral pressures due to the swelling of soil are capped by the passive earth pressures.

#### 4 ANALYSIS AND RESULTS

The analyses were performed for a fixed wall height of 10 m with anchor level located at 2.5 m below the top of the wall. The anchor level was selected based on a study performed by Bilgin and Erten (2009) which showed that the best anchor location to have minimum wall deformations was  $0.25 \times H$  below from the top of wall, where  $H$  is the wall height. The active zone depth used in the study was 5.0 m, selected based on the values given by O'Neill and Poormoayed (1980) as mentioned previously. The groundwater table is also assumed to be 5.0 m

below the top of wall and at the same elevation on both sides of the wall. A schematic of the pressure diagrams used to perform parametric study are shown in Figure 6.

The analysis results are shown in Figure 7 through Figure 9, as a percent increase in the wall penetration depth, maximum wall bending moment, and anchor force versus soil plasticity index. The percent increase is given with respect to the baseline case in which the anchored sheet pile wall was installed in non-expansive soil. The results show that as the plasticity index increases the wall penetration depth, maximum wall bending moment, and anchor force can increase significantly.

##### 4.1 Wall penetration depth

The effect of expansive soils and potential swell pressure, calculated based on the soil plasticity index, on anchored sheet pile wall penetration depth is presented in Figure 7. As shown in Figure 7, an increase in the plasticity index, i.e. increase in the activity of expansive soils, can result in significant increase in wall penetration depth. Compared with the wall installed in non-expansive soil, the wall penetration depth can increase more than 85% and 125% for low and marginally expansive soils, respectively. Within the plasticity index range considered during this study, the wall penetration depth can increase as much as 190% which is for the plasticity index of 50%.

##### 4.2 Wall bending moment

The effect of expansive soils and potential swell pressures on wall maximum bending moment is shown in Figure 8. The results show that wall bending moment increases as the plasticity index of soil increases. While the presence of marginally expansive soils with fully reached swell potential can result in approximately 105% increase in wall bending moment, an increase of up to 170% can occur for soils with plastic index values of 50%, i.e. highly expansive soils.

Figure 5. Lateral pressure distribution due to swelling of expansive soil.

Figure 6. Soil and swell pressures acting on the wall.

Figure 7. Effect of expansive soils on wall penetration depth.

Figure 8. Effect of expansive soils on wall bending moment.

### 4.3 Anchor force

The effect of expansive soils and potential swell pressure on anchor force is presented in Figure 9. The results show that the anchor force increases as the plasticity index of soil increases, similar to the wall penetration depth and bending moments. However, the presence of expansive soils has the most significant effect on the anchor forces. This is because of the fact that the anchor is located closer to the top of sheet pile wall and the swell pressures are higher closer to the ground surface due to more fluctuations in soil moisture content in this zone. Within the range of parameters considered, an increase in the anchor force can be as much as 240% (when plasticity index is 50%) compared to the condition where the wall is installed in non-expansive soil.

## 5 SUMMARY AND CONCLUSIONS

The design of retaining walls usually specifies cohesionless soils as a backfill material behind the wall, however, in-situ retaining walls, such as anchored sheet pile walls, are installed in existing soils. Expansive soils exist in many locations around the world, and the design of anchored sheet pile walls needs to consider the effect of soil swell pressures when these walls are installed in these soils.

In this paper the effect of expansive soils and swell pressures on anchored sheet pile walls, in terms of wall penetration depth, wall bending moment, and anchor force were investigated. The swell pressures were determined using the soil plasticity index, based on earlier studies. For the cases studied and range of soil properties considered, the analysis results show that the effect of expansive soils on anchored sheet pile walls can be significant,

even if the soils at the site are low to marginally expansive. For soils with the plasticity index of 50%, indicative of highly expansive soils, and for wall geometry and soil conditions considered during this study, the analysis results show that the wall penetration depth increased 190%, wall bending moments increased 170%, and anchor force increased 240%, compared with the wall design when soils at the site are non-expansive. The maximum increase was observed in the anchor force, because higher swell pressures develop closer to the ground surface due to the seasonal changes in moisture content. It should be noted that the swell pressures determined using the plasticity index values represent the maximum potential swell pressures, i.e. upper limit, and these pressures may not develop during each seasonal changes.

# Performance of Soil Nails in Weathered Granite and Fill

## Performance de renforcement par clouage du granite altéré et du remblai

Chow C.-M., Chee-Meng, Tan Y.-C.

G&P Geotechnics Sdn Bhd, Kuala Lumpur, Malaysia ([www.gnpgeo.com.my](http://www.gnpgeo.com.my))

**ABSTRACT:** Soil nail is increasingly common in Malaysia for infrastructure works where high cut slope is often formed to accommodate road alignment, facilities, etc. In recent years, soil nailing has also proven to be a viable, cost-effective and environmental friendly alternative solution for deep excavation of basement to replace conventional solutions using vertical retaining wall such as contiguous bored pile, secant pile or diaphragm wall. Applications of soil nail for basement construction of up to 30m deep have been successfully designed and constructed where performance of the soil nailing works have been verified based on monitoring results. Design assumptions for the skin friction between the soil and grouted body of soil nail were also verified using instrumented preliminary and working pull-out tests on the soil nails. This paper discusses results of the pull-out tests on the soil nails and based on analysis of the test results, recommendations on the skin friction applicable for soil nail design are presented.

**RÉSUMÉ :** Les clous de sols sont de plus en plus communs en Malaisie pour les travaux d'infrastructure où une forte pente de talus est souvent créée pour le tracé de la route, pour accueillir les installations, etc. Ces dernières années, le clouage de sol s'est également avéré être une solution alternative viable, rentable et écologique pour remplacer les solutions classiques utilisant un mur de soutènement vertical tels que les pieux forés contigus, les pieux sécants ou les parois moulées pour les excavations profondes des travaux de fondations. Les applications du clouage de sol dans la construction d'excavations de plus de 30m de profondeur ont été correctement conçues et mises en œuvre et leurs performances ont également été vérifiées sur la base de mesures répétées. Les hypothèses de calcul des efforts d'adhérence entre le sol et les clous de sols avec injection ont également été vérifiées par des tests d'arrachement. Cet article présente les résultats des tests d'arrachement sur des clous de sol et sur la base de l'analyse de ces résultats, propose des recommandations sur la capacité en de scellement à prendre en compte lors de la conception des clous de sol.

**KEYWORDS:** Soil nail, skin friction, pull-out tests, deep excavation.

### 1 INTRODUCTION

Soil nails are increasingly common in Malaysia for infrastructure works where high cut slope is often formed to accommodate road alignment, facilities, etc. Soil nail is advantageous compared to other retaining wall system as the soil nails are installed directly onto the final slope/wall profile and as such, minimises earthworks compared to conventional retaining wall. Furthermore, soil nails installation also does not require heavy machineries compared to system such as contiguous bored pile (CBP), diaphragm wall/secant pile. Malaysia's experiences in soil nail design and construction have been discussed by Chow & Tan 2006 and Chow & Tan 2011.

In recent years, the use of soil nails as alternative solution to vertical retaining wall for basement excavation is also gaining popularity and has been successfully designed and constructed for basement excavation of up to 30m deep. This paper discusses the design and construction of a soil nailed slope for basement excavation of a commercial development in Mont' Kiara, Kuala Lumpur, Malaysia with excavation depth of up to 20m.

### 2 GENERAL GEOLOGY AND SUBSURFACE INFORMATION

The site is underlain by the Kuala Lumpur Granite formation. The granite rocks are generally whitish grey and dark grey in colour except certain parts with iron stained markings that gives orange and dark red colours to the rocks. The texture and composition of the granitic rock generally ranges from coarse to very coarse-grained.

A total of twenty nine boreholes were carried out at the site to facilitate retrieval of undisturbed soil samples for laboratory testing (e.g. Atterberg limits tests, Isotropically Consolidated Undrained Triaxial – CIU tests, etc.) and also in-situ tests such as Standard Penetration Tests (SPT). The interpreted borehole profiles relevant to the soil nail slope showing the SPT-N values, major/minor components of soil and Rock Quality Designation (RQD) for rock are shown in Figure 1. Some of the materials near to the surface, especially for materials with low SPT 'N' values (< 5) are filled materials.

Generally, the subsoil consists mainly silty SAND and sandy SILT with Liquid Limit (LL) ranging from 25% to 71% and Plastic Limit (PL) ranging from 15% to 42% and can be classified as low to high plasticity silty/clayey materials.

A total of eleven Isotropically Consolidated Undrained Triaxial (CIU) tests and four Direct Shear Box tests were carried out to determine the shear strength of the soil. The shear strength parameters of the subsoil adopted for design are  $c'=3.5\text{kPa}$ ,  $\phi'=30^\circ$ .

### 3 DESIGN OF SOIL NAIL SLOPE FOR BASEMENT EXCAVATION

The soil nail slope with retained height of up to 20m is designed to ensure minimum long-term factor of safety of 1.4 as the soil nail slope will be permanent.

Figure 1. Borehole profiles relevant to soil nail slope.

Critical to the design of the soil nail slope is the assumptions on the skin friction between the ground and the grouted body of soil nail and as such, a series of instrumented pull-out tests on preliminary soil nails (non-working soil nails) were carried out at site to verify the design assumptions. The soil nails adopted at site generally consists of 4m to 18m length soil nails with 16mm to 32mm diameter galvanized high yield reinforcement (yield strength = 460N/mm<sup>2</sup>) slotted inside a 150mm diameter hole formed by open hole construction (without temporary casing) and filled with Grade 30 non-shrink grout.

### 3.1 Soil nail pull-out tests

A total of six numbers of instrumented pull-out tests on preliminary soil nails (non-working soil nails) were completed at the time this paper is prepared and the details of the pull-out tests are summarized in Table 1. All the soil nails are 6m length with 5m grouted length and 1m ungrouted length (free length) at the top. Typical set-up for the pull-out tests is shown in Figure 2 while details of the instrumented preliminary soil nails are shown in Figure 3.

Figure 2. Typical set-up for pull-out tests.

tests on preliminary soil nails (non-working soil nails).

Nail No.	Bar Diameter (mm)	Maximum test load achieved (kN)	Nearest borehole
Y-7 (RL 75.19)	25	175.0	BH-15
W/X-16 (RL 71.40)	25	140.0	BH-13
Y-10* (RL 73.24)	25	131.2	BH-15, NBH-3
Y-13* (RL 74.50)	25	148.8	NBH-3
Y-7* (RL 73.24)	25	78.8	BH-15
Y-1/2 (RL 74.00)	32	286.0	NBH-7

Note:

1. Different maximum test load is achieved primarily due to various site issues such as improper test set-up where the dial gauge has reached its maximum travel distance, malfunctioning of the load cell, etc. and not due to inadequate bond strength of the soil.
2. \* - Results ignored due to improper preparation of free length at the soil nail head which interferes with instrumentation results.

Figure 3. Typical details of instrumented preliminary soil nail.

#### 4 RESULTS OF INSTRUMENTED PULL-OUT TESTS

The test procedures and testing sequence of the soil nails are in accordance with FHWA 1998 and the loading schedule is summarised in Table 2. The pull-out test results showing the mobilised skin friction vs nail movement are shown in Figures 4 to 6.

Table 2. Pull-out tests loading schedule (FHWA 1998).

Load	Hold Time (minutes)
0.25 DTL	10
0.50 DTL	10
0.75 DTL	10
1.00 DTL	10
1.25 DTL	10
1.50 DTL (Creep Test)	60
1.75 DTL	10
2.00 DTL	60
Repeat cycle if test load increased to 3.00 DTL	

Note:

1. DTL – Design test load
2. Test load limited to maximum 80% yield strength of nail reinforcement

The longer holding time of 60 minutes at 1.50 DTL and 2.00 DTL is to monitor creep movement. The acceptance criteria is total creep movement of less than 2mm per log cycle of time between the 6 and 60 minute readings and the creep rate is linear or decreasing throughout the creep test load hold period.

Figure 4. Pull-out test results for nail Y-7.

Figure 5. Pull-out test results for nail W/X-16.

Figure 6. Pull-out test results for nail Y-1/2.

From the pull-out tests, the following observations could be made:

- The ultimate skin friction is mobilised at relatively small nail movement of approximately 4 to 6mm which is about 3-4% of the diameter of the drilled hole.
- Only nail Y-1/2 demonstrates the expected behaviour where initially, more load is transferred to the upper part of the nail until the upper part reaches the ultimate skin friction and thereafter, more load is transferred to the lower part of the nail.
- Other nails (Y-7 and W/X-16) also demonstrated behaviour where initially, more load is transferred to the upper part of the nail. However, the mobilised skin friction for the upper part of the nail has rather unexpectedly continued to increase after the initial drop. This is unexpected and is possibly due to interference from the shotcreted slope surface where the pull-out tests were conducted. It is possible that the shotcreted slope surface restricts the expansion of the soil particles during testing and contributed to the increase in mobilised skin friction for the upper part of the nail.
- The SPT-N values at the level of the tested soil nails typically range from 5 to 13 (average about 10) and the mobilised skin friction recorded range from 50 to 140kPa. This indicate a conservative correlation of skin friction can be 5x SPT-N for soil nail design in weathered granite or fill.
- Results of the pull-out tests also indicate the equation proposed by HA 68/94 (see Eq. 1) underpredicts the mobilised skin friction considerably.

$$Q = \sigma'_n \tan \phi' + c' \text{ (kN/m}^2\text{)} \quad (1)$$

where

$\sigma'_n$  = average radial effective stress  
 $\phi', c'$  = soil shear strength parameters

## 5 CONCLUSIONS

A series of instrumented pull-out tests were carried out for a proposed basement with excavation up to 20m deep supported using soil nailed slope. The pull-out test results indicate a conservative preliminary correlation for skin friction between the ground and the grouted soil nail of 5x SPT-N can be adopted for soil nail design in weathered granite or fill.

Further pull-out tests at deeper layers of the subsoil are currently being carried out at site and the results will be presented in the future. Some improvement to the current test procedures will also be carried out such as hacking a larger area of the shotcreted surface surrounding the test nail in order to ensure the results are not affected by the shotcreted slope surface.

## 6 ACKNOWLEDGEMENTS

The Authors acknowledge the contributions of Mr. Lim Fang Liang and Mr. Tong Han Seng for their hard work and dedication as part of the geotechnical design team of the project.

# Effects on adjacent buildings from diaphragm wall installation

## Effets sur des bâtiments adjacents liés à l'installation de parois moulées

Comodromos E.M., Papadopoulou M.C.  
*Dept. of Civil Engineering, University of Thessaly, Greece*

Konstantinidis G.K.  
*Manager, Attiko Metro S.A., Greece*

**ABSTRACT:** A new approach for simulating the excavation and construction of subsequent panels is proposed to investigate the effects from the installation of diaphragm walls on the surrounding soil and adjacent buildings. The method has been combined with a 3-D nonlinear analysis and a constitutive law providing bulk and shear modulus variation, depending on the stress path (loading, unloading, reloading). The effects on an adjacent building have been investigated by applying a full soil-structure interaction analysis including the whole building. Contrary to lateral movements, which mostly take place at the panel under construction, it was found that the effect of settlements covers a larger area leading to a progressive settlement increase. The effect highly depends on the distance from the panel under construction. Settlement profiles and settlements at specific points as increasing with subsequent panels installation are given providing the ability of specific monitoring guidelines for the upcoming construction of the diaphragm wall in front of the building.

**RÉSUMÉ :** Une nouvelle approche pour simuler l'excavation et la construction des panneaux subséquents est proposée pour étudier les effets liés à l'installation de parois moulées adjacents sur les bâtiments et le sol adjacents. La méthode a été associée à une analyse 3-D non linéaire et une loi de comportement qui permet la variation des modules de déformations en fonction des chemins des contraintes. Les effets sur un bâtiment adjacent ont été étudiés en appliquant une analyse d'interaction sol-structures pleine, qui inclut l'ensemble du bâtiment voisin. Contrairement aux mouvements latéraux, qui principalement prennent lieu à partir du panneau en cours de construction, il a été constaté que l'effet des tassements couvre une plus grande région, conduisant à une augmentation progressive de tassements. Les effets dépendent fortement de la distance au panneau en cours de construction. Les profils des tassements et tassements aux points spécifiques augmentant progressivement avec l'installation des panneaux sont donnés en face de l'immeuble où la paroi moulée est en cours de construction.

**KEYWORDS:** diaphragm walls, soil-structure interaction, multi-stage analysis, buildings settlements.

### 1 INTRODUCTION

It is widely accepted that the process of installing diaphragm walls can result in potentially significant soil displacements and cause substantial reductions in horizontal stress. Depending on the soil profile, the diaphragm wall configuration (length and construction sequence) and the close existence of adjacent buildings with poor foundations may render the effects of diaphragm wall installation considerable. Field monitoring confirms that ground movements resulting from diaphragm wall installation could be a significant component of the overall displacement (Burland and Hancock 1977, Tedd et al. 1984, Symons and Carder 1993), while centrifuge tests verified the development of the effect as well (Powrie and Kantartzi 1996). Recent field evidences recorded during the on going construction of subway stations in Thessaloniki demonstrated that the component of ground movements resulting from the diaphragm wall installation may be higher than 50% of the overall displacements. It is therefore evident that the simplistic assumption of a 'wished-in-place' wall (installation without any change in stress and cinematic field) commonly applied for design purposes is rather questionable.

The aim of the present paper is to investigate the effect of a diaphragm wall installation to adjacent buildings with relatively poor foundations. The sequential installation of each individual diaphragm wall panel installation was simulated by a substitution of the parameters of excavated elements with those corresponding to the bentonite slurry and later on by the

concrete tremied into the panel. Valuable qualitative and quantitative conclusions regarding the variation of the effects to the adjacent building have been drawn.

### 1 INSTALLATION PROCEDURE MODELLING

With the aim of minimising disturbance and increase stability during the excavation process, rotary drilling machines for slot excavation have been used in Thessaloniki's underground stations with poor soil conditions. Figure 1, on the left side, shows a rotary drilling machine equipped with cutting wheels and a reverse circulation system. On the right side of Figure 1 the numerical simulation of the excavation process is illustrated. The soil from the surface level down to the upper limit of the rotary wheels (line A), is replaced by a material simulating the bentonite slurry. Appropriate, very small values are attributed to the bulk and the shear modulus of the material. Within that zone the stresses are initialised to the values hydrostatically defined from the weight of bentonite slurry. This simulation process ensures that stresses within this zone remain always equal to the hydrostatic conditions no matter the deformation level. However, in the area occupied by the rotary cutters (area between line A and line B) the development of static hydrostatic pressure is not evident. For this reason, in that zone the stresses are not initialised hydrostatically and only internal gravitational stresses are considered. Within this zone the material (cuttings with bentonite slurry) has higher unit weight and is stiffer than bentonite slurry. The zone undertakes the pressure from the

surrounding elements depending on the internal gravitational stresses, the stiffness and the shear resistance of the surrounding soil elements, and the arching developed around the trench. This complicated mechanism provokes a redistribution of stresses and the surrounding soil elements undergo some deformation. As a result horizontal displacements at the wall/soil interface are governed by the ability of the soil to move in response to the reduction in lateral stresses during the wall installation. The above mechanism leads to a temporary reduction of the horizontal stresses in the surrounding excavation faces, which however increase to the hydrostatic bentonite slurry pressure in the next stage of excavation. When the excavation of a panel is accomplished concrete is cast in place using tremie pipes. The same numerical process is applied to simulate the panel completion, i.e. appropriate values are attributed to the bulk and the shear modulus of the material simulating wet concrete, while, stresses are initialised to the values hydrostatically defined from the weight of wet concrete. When equilibrium is attained, regular concrete values are attributed to bulk and the shear modulus to the panel. The above simulation process is repeated over the entire depth of the panel.

The aforementioned simulation process reflects the construction of a single panel and is applied to all panels in a diaphragm wall. However, the response of each particular panel is greatly influenced by the construction sequence. Obviously when constructing a subsequent panel, with already completed adjacent panels, the effect of arching is strengthened due the high resistance of these elements. As a result a stress increase is observed not only at the adjacent soil, but also on neighbouring panels that have already been casted. Thus over the period of wall construction there will be a progressive transferring of load back and forth laterally, either from a primary panel to the adjacent soil or, as the wall progresses, from new panels to panels previously casted. It can be realised that when accurate prediction of displacements and stresses redistribution are demanded, a profound 3-D nonlinear multi-stage numerical analysis is required.

Figure 1. Schematic illustration of the proposed approach for simulating a single panel excavation

## 2 NUMERICAL SIMULATION

### 2.1 Project description

The station of Analipsis, 210 m long and 16.4 m wide, is considered as one of the most critical of the underground of Thessaloniki. With the exception of the surficial layer the soil conditions are relatively good. However, the fact that the diaphragm wall is located very close to adjacent buildings with poor foundations, in many cases, renders the construction of the diaphragm wall extremely demanding. According to the guidelines of the German code DIN 4126, the critical zone around the trench excavation extends up to a distance of 70% of the pile length. For this reason a relatively small typical panel length  $L = 2.8$  m was applied and a rotary cutting machine was selected to perform the ongoing excavation of the panels. The

thickness of the panels is  $t = 1.20$  m, its depth is  $H = 44.0$  m and the basement of the station is 28.0 m below the ground surface.

### 2.2 Soil model and material properties

The ground conditions at the site together with the soil properties of each soil layer, derived from the carried out geotechnical investigation and the evaluation of in-situ and laboratory tests are presented in Table 1. The groundwater level was encountered at 5.0 m below the ground level. Pressuremeter tests were carried out at the area to assess the in situ horizontal stresses and, according to the evaluation of the results, a constant value of  $K_0 = 0.54$  has been adopted.

Bearing in mind the crucial effect and the necessity for settlements predictions to the adjacent buildings, a constitutive law with double yielding (FLAC 3D) has been applied in the present study. The model includes a volumetric yield cap surface in addition to Mohr-Coulomb shear and tensile failure envelopes. The cap surface is independent of the shear strength and it consists of a vertical line on a plot of shear stress vs mean stress with a trace on the mean stress axis defined as cap pressure  $p_c$ . Any violation of the cap surface produces volumetric plastic strain following a piecewise-linear law prescribed in a user-supplied table. The tangential bulk and shear moduli evolve as plastic volumetric strain takes place according to a special law defined in terms of a constant factor,  $R$ , which is the ratio of elastic bulk modulus,  $K_e$ , to plastic bulk modulus,  $K_t$ . The relevant values adopted are given in Table 1.

The concrete diaphragm wall behaviour was considered as an isotropic linear elastic. Linear elastic behaviour was attributed to the bentonite slurry with infinitesimal deformation values. The shear strength of bentonite slurry with unit weight of  $11 \text{ kN/m}^3$  is of the order 50 Pa (DIN4126). A reasonable value for the slurry shear modulus is three hundred times the shear strength,  $G_{sl} = 15 \text{ kPa}$ , while the Poisson's ratio was taken equal to 0.49. The application of these values to the analysis produced stresses within the bentonite computational domain equal to hydrostatic gravitational state, ensuring that appropriate hydrostatic pressures were developed at the trench faces. A higher value of unit weight ( $12.5 \text{ kN/m}^3$ ) has been attributed to cutting products mixed with bentonite slurry and similarly the shear modulus has been taken equal to 25 kPa. Taking into account that the construction schedule, the time period between adjacent panels installation, particularly the primary panels, is quite enough for any excess pore dissipation an effective stress analysis was applied.

Table 1. Geotechnical properties of soil layers.

Layer	Fill	A1a	A1b	A1c	B
Depth (m)	0 - 3	3 - 10	10 - 35	35 - 40	40 - 60

### 2.3 Simulation procedure

The effective numerical simulation of typical construction procedure for a cast in situ diaphragm wall must reflect the stages and the mechanisms developed during the excavation and throughout the completion of the wall. The first step was to establish the in-situ state of stresses. The construction of a single panel was simulated in 22 stages during which the excavation was advanced in 2.0 m. Within each stage the soil in

the excavation zone was replaced by cutting-bentonite, while the area above the zone being excavated was replaced by bentonite. The end of the excavation was followed by wet concrete placing and the value of  $E_{wc} = 1,000$  MPa was attributed to Young's modulus and  $\nu_{wc} = 0.49$  to Poisson's ratio. The last stage of analysis corresponded to concrete hardening. The same process was applied to all panels under consideration. The most critical location in the area of the station corresponds to poor building foundation conditions very close to the diaphragm wall. The analysis is therefore focused on that. Prior to the currently presented full soil-structure interaction analysis including a 6-storey building, numerical analyses of a single panel construction and of a wall and an adjacent foundation verified the proposed simulation process as well as the constitutive law and the values for the parameters. Figure 2 shows the foundation plan of the adjacent building together with the location of the diaphragm wall and a curtain of micropiles used to minimize the effect of panels' installation. Further to the bay number of each panel the figure shows the panel type (primary, P, or secondary, S) and the order of installation in the circles on the right side of each panel. The foundation consists of individual footings connected with  $0.20 \text{ m} \times 0.50 \text{ m}$  reinforced concrete beams. The foundation level is at 3.0 m from the ground surface. The F.D. mesh included 89,000 3-D elements, 4,272 shell elements and 225 beam elements. The dead weight of the building has been explicitly introduced by the gravity of each element while a uniform load of 5 kPa has been applied to each slab to simulate all other permanent and variable loads. After the establishment of the initial stresses, the installation of the micropiles was introduced followed by the installation of the 9 panels according to the previously described approach. The sequence of installation is presented in Figure 3.

Figure 2. Individual footings of a 6-storey building together with the diaphragm wall and the micropiles

Figure 3. Sequence of panel installation

### 3 NUMERICAL RESULTS

The contour values for soil settlements, the building floors' settlements and the axial forces of the building columns developed after the completion of the first element (element no 8) are illustrated in Figure 4. For visibility reasons the figure is given in a section at the building face and a cross section at the middle of the building. It can be seen that the maximum soil settlement is located around the excavated panel and is of the order of 2.4 mm. The maximum settlement of the building is located at its corner nearby the excavated panel and the contours show a uniform reduction with distance from that point.

The sequential construction of the next panels provokes the maximum effect in front of each panel, as it has been expected, but at the same time contributes to a progressive increase of settlements in a widespread zone. When the primary panels are installed, an increase of settlements to the value of 4.2 mm is occurred. The soil settlements progressively decrease with the distance from the diaphragm wall and are almost zero at the backside of the building. The completion of the wall with the rest 4 secondary panels does not encounter significant increase to the maximum value of the soil settlements. The final value of maximum settlement is 5.3 mm and the same value is developed at the external side of the building close to the diaphragm wall. From the comparison of the axial forces variation throughout the construction of the panel arises that the panels' installation does not practically affect them.

Figure 4. Soil and building settlement contours together with column axial forces after the completion of the first panel (bay no 8)

Figure 5a illustrates the variation of the horizontal displacements with depth below the external boundary of a footing at the front side of the building (cross section 'C-C'). The values are not exceeding the order of 1.0 mm and this is mainly due to the existence of the micropiles. The construction of the panels with bay no 8 and 9 (first and second in construction sequence) are relatively too far from that point and they do not provoke any horizontal displacement at the point under consideration. The panel with bay no 5 is just in front of the point and this explains the important movement of the displacement field during the construction of this panel. Similar are the results in the case of the point below the footing at the edge of the external footing at section 'D-D', Figure 5b.

The most important effect to the adjacent building is the anticipated settlements, the angular distortion that will develop to the foundation and if that last could be capable of provoking any notable bending moment to the foundation elements. Figure 6 illustrates the progressive increase of the settlements across the section 'C-C'. On the same figure the location of the diaphragm wall and the foundation of the building are shown.

The construction of every panel contributes to a progressive increase of settlements, with the maximum influence experienced when the primary panel close to the cross section is installed. This explains the maximum difference observed when panel no 4 is installed. The maximum settlement is developed at the end of the construction of all panels, its value is of the order of 5.5 mm and occurs at the front side of the building.

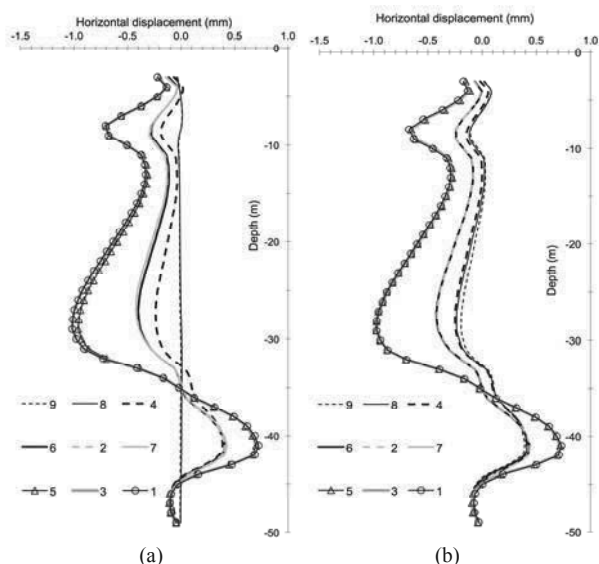

Figure 5. Profile of horizontal displacements below the external footing at (a) the mid-face, point j, and (b) the end-face of the building, point k

Figure 6. Development of settlement profile with panel sequence construction at cross section 'C-C'

It is worth noticing that the settlement values estimated from the 3-D analysis are leading to an angular distortion of 1:5,000. This value is considerably lower than the limits provided by CIRIA and the CFEM.

An effective design of complex retaining structures, with closely adjacent buildings, includes instrumentation and monitoring to ensure the safety of the construction and control the effect on the adjacent buildings. These data will be available when the diaphragm wall at this area will commence and histograms giving the contribution to cumulative settlements of each particular panel can be drawn. It is therefore extremely helpful to give these histograms resulting from the 3-D analysis and follow up the values as the wall is constructed. Figure 7 illustrates the numerically established cumulative settlements after the completion of each panel, at the characteristic points, i, j, k, m and n. The location of each panel corresponds to relative position from left to right, while the installation sequence is given on the top of the histograms.

It can be seen that the final settlements at the front face of the building (points i, j and k) are of the same magnitude and that the values provided for the points far from the diaphragm wall (points m and n) are drastically lower and with no practical effect on the building. It is clearly evident that Figure 7 can be efficiently used to compare settlements during the up coming

construction and provide alarm signal in case of significantly higher settlements values.

Figure 7. Predicted development of cumulative settlements at points i, j, k, m and n at the end of each panel construction

#### 4 CONCLUSION

In this paper the effects from the installation of diaphragm walls have been investigated using a new approach for simulating the excavation and construction of subsequent panels. The method has been combined with a 3-D nonlinear analysis and a constitutive law providing bulk and shear modulus variation, depending on the stress path (loading, unloading, reloading). It has been observed that the most significant effect in front of a given panel occurs during the installation of that panel and that the effect on stress reduction and lateral movements in front of the subsequent panels is rather limited. The method has been used to estimate the effects on an adjacent 6-storey building by applying a full soil-structure interaction including the whole building. Progressively increased with subsequent panels installation settlement profiles are given along the building foundation. Moreover, settlements at specific points where leveling captures have been installed are given in cumulative form. The predictions indicate that the angular distortion of the building remains under the required limits of serviceability and at the same time provide the guidelines for the monitoring of the upcoming construction of the diaphragm wall in front of the building.

# Prise en compte des effets de bord dans un massif renforcé par inclusions rigides

## Modeling edge effects at the periphery of a rigid inclusion reinforced soil volume

Cuira F., Simon B.  
TERRASOL, Paris, France

**RÉSUMÉ :** En périphérie d'un massif de sol renforcé par inclusions rigides il se développe une interaction entre la zone renforcée et la zone non renforcée. Ces effets de bord rendent inapplicables les modèles limités à l'étude d'une cellule élémentaire au sein d'un réseau infini d'inclusions qui adoptent l'hypothèse d'un cisaillement nul sur la frontière de la maille étudiée. Le modèle exposé de type biphasique exprime les équations d'équilibre dans deux domaines apposés, « inclusion » et « sol », en introduisant à la fois le cisaillement interne qui se développe entre l'inclusion et le sol tributaire et le cisaillement externe qui se développe sur tout ou partie de la frontière de la maille, lorsque celle-ci est située en périphérie de la zone renforcée par inclusions. Les cisaillements sont pris en compte en exploitant la notion de loi de transfert t-z appliquée au déplacement relatif entre les domaines considérés. La résolution s'appuie sur une discrétisation 1D des deux domaines et une formulation éléments finis. Différents exemples de semelles sur inclusions sont présentés dont les résultats s'avèrent en bon accord avec ceux de modèles numériques 3D, beaucoup plus complexes à mettre en œuvre. L'évaluation de la méthode se poursuit en exploitant les résultats de modèles physiques en centrifugeuse.

**ABSTRACT:** At the periphery of a soil volume reinforced by rigid inclusions, interaction between the reinforced soil and the unreinforced soil cannot be neglected. Such edge effects prevent use of the commonly used unit cell model which assumes no shear at the model outer boundary. The proposed model, a simplified form of a two-phase model, expresses equilibrium within two side by side domains « inclusion » and « soil » by introducing shear between inclusion and the tributary soil volume within the cell on the one hand and shear along all or part of the outer “soil” domain boundary, on the other hand, when cell under study is at periphery of the reinforced volume. Shear is taken into account through use of t-z transfer curves based on the domain relative displacements. A 1D discrete model of both domains is used together with a finite element formulation. This is applied to different cases of footings over soil reinforced by rigid inclusions. Results agree well with those obtained by other 3D numerical models, which remain a far more difficult task. Further evaluation is planned using the results of centrifuge test models.

**MOTS-CLÉS:** renforcement du sol, inclusions rigides, semelle sur inclusions, modèle analytique, effets de bord.

**KEYWORDS:** soil reinforcement, rigid inclusions, shallow foundations, analytical modelling, edge effects.

## 1 INTRODUCTION

Le renforcement par inclusions rigides a vu son intérêt largement reconnu pour les ouvrages étendus de type remblais ou dallages (locaux industriels). Le dimensionnement s'appuie généralement sur des modèles de calcul réduits à l'étude d'une cellule élémentaire représentant le comportement d'une maille courante centrée sur une inclusion et incluant le volume de sol et la fondation d'ouvrage afférents (Cuira et Simon, 2009, Simon, 2012). Le caractère répété du motif permet de considérer que le cisaillement est nul au bord du modèle, ce qui en simplifie considérablement la construction. Ces modèles apportent tous les éléments nécessaires au dimensionnement des ouvrages en partie courante ; leur validité a été largement éprouvée dans le cadre du projet national ASIRI (2012) par la confrontation des résultats obtenus avec ceux d'expérimentations en vraie grandeur, de modèles physiques ainsi que de modélisations numériques avancées. Ils sont en revanche insuffisants pour traiter des zones périphériques où les cellules placées au bord sont en interaction avec des cellules intérieures mais aussi avec le massif extérieur non renforcé : l'hypothèse de symétrie permettant de considérer un cisaillement nul aux bords du modèle n'est plus applicable. La validité de ces modèles se heurte également au cas des ouvrages d'emprise limitée tels des semelles sous poteaux ou voiles porteurs, pour lesquels la prise en compte des phénomènes de bord devient là encore une nécessité absolue.

La modélisation de ces configurations particulières (bord d'ouvrage étendu ou ouvrage d'emprise limitée) nécessite en toute rigueur des modèles en trois dimensions dont les limites doivent être étendues largement au-delà du volume de sol renforcé, à la différence des modèles de cellule élémentaire. Une telle modélisation est incontestablement mal adaptée à des études courantes, appelées de surcroît et en dépit du caractère

non exceptionnel des fondations concernées, à examiner un grand nombre de cas de charges. Les Recommandations ASIRI (2012) ont ainsi détaillé plusieurs méthodes simplifiées pour traiter ces configurations dans le cas d'un chargement vertical avec des outils classiques du calcul des fondations. Toutes ces méthodes nécessitent cependant une procédure par étapes.

Cette communication présente la généralisation d'une de ces méthodes qui permet de s'affranchir d'un calcul par étapes, en traitant simultanément les interactions internes se développant au sein du massif renforcé et externes se développant aux bords de celui-ci avec le sol environnant non renforcé. L'équilibre mécanique du volume renforcé est ainsi exprimé en combinant des lois d'interface sol/inclusions (internes) et sol/sol (externes), toutes basées sur les déplacements relatifs afférents.

## 2 ASPECTS THEORIQUES

### 2.1 Principe

On considère le cas d'une cellule élémentaire représentant une maille quelconque (courante ou périphérique) centrée sur une inclusion. La cellule est soumise à un chargement vertical et est décomposée en deux domaines complémentaires : le domaine « inclusion » constitué par l'inclusion elle-même et les volumes de sol qui la prolongent jusqu'aux limites inférieure et supérieure du modèle, et le domaine « sol » constitué par le volume de sol complémentaire au domaine « inclusion ». L'interaction entre les deux volumes est supposée entièrement décrite par le cisaillement vertical  $\tau_{int}$  qui se développe sur leur frontière verticale définie par le périmètre de l'inclusion noté  $P_{int}$ . En périphérie de la cellule, l'interaction éventuelle avec le sol environnant non renforcé est supposée entièrement décrite

par un cisaillement vertical extérieur  $\tau_{ext}$  comme le schématise la figure ci-dessous.

Figure 1. Modèle généralisé de la cellule élémentaire – vue en coupe.

Le cisaillement extérieur  $\tau_{ext}$  est supposé se développer sur une fraction  $\beta \times P_{ext}$  ( $0 \leq \beta \leq 1$ ) du périmètre extérieur total  $P_{ext}$  de la cellule comme le schématise la figure ci-dessous.

Figure 2. Modèle généralisé de la cellule élémentaire – vue en plan.

Les deux domaines sont assimilés à deux cylindres concentriques de sections équivalentes. On désigne par  $S_p(z)$  la section du domaine « inclusion » à la profondeur  $z$ . La section du domaine « sol » s'en déduit à l'aide de la relation :  $S_s(z) = S_{maille} - S_p(z)$  où  $S_{maille}$  désigne l'aire totale de la maille.

## 2.2 Mise en équation

On désigne par  $y_p(z)$  et  $y_s(z)$  les tassements respectifs des domaines « inclusion » et « sol ». La combinaison des équations d'équilibre et de comportement des cylindres équivalents aux deux domaines conduit au système d'équations (1), où  $E_p(z)$  et  $E_s(z)$  représentent respectivement les modules de déformation verticale des domaines « inclusion » et « sol ». Pour le domaine « sol », le tassement  $y_s(z)$  est supposé uniforme à toute profondeur  $z$  et  $E_s(z)$  est assimilé au module équivalent pour l'amplitude de chargement calculée.

$$\text{Domaine inclusion} \quad E_p S_p \frac{d^2 y_p}{dz^2} = \tau_{int} P_{int} \quad (1)$$

$$\text{Domaine sol} \quad E_s S_s \frac{d^2 y_s}{dz^2} = -\tau_{int} P_{int} + \beta \tau_{ext} P_{ext}$$

L'interaction entre les deux domaines est décrite au niveau de chaque couche par une fonction de transfert exprimant la dépendance du cisaillement  $\tau_{int}$  avec le déplacement relatif entre les deux domaines :

$$\tau_{int} = f(y_p - y_s) \quad (2)$$

L'interaction éventuelle entre la cellule et le sol environnant non renforcé est décrite par une fonction de transfert reliant le

cisaillement extérieur  $\tau_{ext}$  au déplacement absolu du domaine sol :

$$\tau_{ext} = f(y_s) \quad (3)$$

La combinaison des équations (1), (2) et (3) conduit à un système global à 4 équations et 4 inconnues :  $y_p$ ,  $y_s$ ,  $\tau_{int}$  et  $\tau_{ext}$ .

## 2.3 Résolution

Le système précédent est complété par les conditions aux limites suivantes :

- charge totale appliquée en tête du modèle  $Q_p(0)+Q_s(0)$ ;
- fraction de charge transmise en tête du domaine inclusion  $E_{QP} = Q_p(0)/[Q_p(0)+Q_s(0)]$  ;
- loi de mobilisation de l'effort de pointe avec le déplacement relatif.

En présence d'un élément de fondation rigide en surface (radier ou semelle), la valeur de  $E_{QP}$  est établie en recherchant l'égalité des tassements en surface  $y_p(0)$  et  $y_s(0)$ , ce qui est justifié par le fait que les déformations de l'élément structurel de surface sont négligeables devant celles du sol.

La résolution numérique du système est menée à l'aide d'une formulation en éléments finis. Chacun des deux domaines est discrétisé selon un maillage unidimensionnel avec des éléments à deux nœuds et un degré de liberté par nœud. Dans le cadre de cette discrétisation, le système d'équations précédent s'écrit sous la forme d'un système matriciel équivalent, ce qui simplifie la résolution. La non-linéarité des courbes de transfert implique une procédure itérative visant à assurer la compatibilité en tout point entre cisaillement et déplacement.

## 2.4 Mise en œuvre pratique

### 2.4.1 Choix du paramètre $\beta$

L'introduction du paramètre  $\beta$  dans le modèle de la cellule élémentaire permet d'aller au-delà de la configuration particulière d'une maille courante où les conditions de symétries justifient l'hypothèse d'un cisaillement nul en périphérie du modèle ( $\beta = 0$ ). Le choix d'un  $\beta \neq 0$  implique la prise en compte d'un cisaillement extérieur entre la cellule et le sol environnant non renforcé, sur une partie du périmètre extérieur de la cellule. Dans le cas d'une maille carrée (figure ci-dessous), cela peut être par exemple représentatif d'une cellule située au bord du massif renforcé ( $\beta = 0,25$ ), le cas d'une cellule située à l'angle ( $\beta = 0,5$ ), le cas d'une semelle sur deux inclusions ( $\beta = 0,75$ ) ou une inclusion unique ( $\beta = 1$ ).

Figure 3. Choix du paramètre  $\beta$  pour le cas d'une maille carrée.

## 2.4.2 Fonctions de transfert

Ces fonctions de transfert sont utilisées pour caractériser la mobilisation des cisaillements interne ( $\tau_{int}$ ) et externe ( $\tau_{ext}$ ) ainsi que les réactions en pointe. On utilise pour cela les lois bilinéaires du type proposé par Frank et Zhao (1982) caractérisées par deux paramètres : un paramètre de pente ( $K_i$  ou  $K_p$ ) et une valeur de contrainte limite ( $q_s$  ou  $q_p$ ).

Pour le cisaillement interne et la mobilisation des réactions en pointe, ces lois sont construites directement à partir des paramètres pressiométriques.

Pour le cisaillement extérieur  $\tau_{ext}$ , la valeur de contrainte limite  $q_s$  peut être reliée à la contrainte verticale dans le sol non renforcé  $\sigma_{v0}$  par une relation du type  $q_s = k \tan \delta \cdot \sigma_{v0}$ . Les valeurs choisies pour  $q_s$  et le paramètre de pente peuvent être ajustés de manière à retrouver par le modèle du type exposé, appliqué au cas d'une inclusion de section nulle, un tassement identique à celui de la semelle superficielle rigide sur sol non renforcé calculé par la méthode pressiométrique (Frank, 1999).

## 3 APPLICATION SIMPLE : CAS D'UNE SEMELLE SUR UNE SEULE INCLUSION

### 3.1 Paramètres d'entrée

L'exemple étudié est celui d'une semelle carrée de 1,33 m de côté, renforcée par une seule inclusion de diamètre 40 cm placée dans l'axe. Deux situations sont étudiées : le cas d'une semelle en contact direct avec l'inclusion (mode « fondation mixte »), et le cas d'une couche de forme intercalaire de 50 cm d'épaisseur (mode « inclusion rigide »). La figure ci-dessous présente la coupe du calcul et les données géotechniques utiles.

Figure 4. Cas d'une semelle sur une seule inclusion - Coupe de calcul.

Dans le cas d'une maille unique, le paramètre  $\beta$  est pris égal à 1,00 : le cisaillement extérieur avec le massif de sol non renforcé se développe sur tout le périmètre. Les fonctions de transfert sont constituées selon la démarche décrite en §2.4.2 : en particulier, pour le cisaillement extérieur, le calage du paramètre de pente  $K_i$  conduit à une valeur équivalente de  $K_i = 2,7$  MPa/m. Pour le mode « inclusion rigide », le domaine inclusion est prolongé dans le matelas : la loi d'interface entre les domaines inclusion et sol sur la hauteur du matelas est construite en considérant un module pressiométrique  $E_M = 10$  MPa et un frottement unitaire limite égal à  $k \tan \delta \cdot \sigma_s$  avec  $k \tan \delta = 1$  -et  $\sigma_s$  la contrainte verticale moyenne dans le domaine sol, sur la hauteur du matelas.

Les résultats du calcul sont comparés à ceux d'un traitement en éléments finis sous PLAXIS (modèle axisymétrique équivalent). Dans ce modèle, tous les sols ont un comportement élasto-plastique parfait avec un critère de rupture de Mohr Coulomb : les paramètres d'entrée sont ceux de la Figure 4. Le

choix des paramètres, et notamment ceux décrivant le comportement en pointe (module de déformation et paramètres de cisaillement), a été validé au préalable par calage des courbes de chargement axial d'une inclusion isolée chargée directement en tête (sans semelle), calculées respectivement par un modèle PLAXIS ou un modèle analytique à l'aide des lois de Frank et Zhao.

### 3.2 Sans matelas de répartition : mode « fondation mixte »

La première situation étudiée est celle d'un contact direct entre la semelle et l'inclusion (fondation mixte). Une partie de la charge totale  $Q$  appliquée sur la semelle est reprise par le sol, mais le frottement mobilisé sur la hauteur de l'inclusion demeure positif : la charge maximale dans l'inclusion est obtenue en tête. La figure ci-dessous présente les résultats obtenus selon un diagramme Effort – Tassement. Deux courbes sont représentées : celle du tassement de la semelle en fonction de la charge appliquée (Courbe 1), et celle du tassement de la semelle (= tassement en tête de l'inclusion) en fonction de l'effort maximal dans l'inclusion (Courbe 2). Les résultats se révèlent en bon accord avec ceux de PLAXIS.

Figure 5. Effort sur la semelle et effort maximal dans l'inclusion en fonction du tassement en tête - cas d'une fondation mixte.

### 3.3 Avec matelas de répartition : mode « inclusion rigide »

Dans cette situation, une couche de forme sépare la semelle de l'inclusion. La principale différence avec le cas précédent est l'apparition d'un frottement négatif : l'effort maximal dans l'inclusion n'est pas obtenu en tête mais au niveau du plan neutre identifié ici vers 1,0 m de profondeur. La même concordance peut être observée avec PLAXIS.

Figure 6. Effort sur la semelle et effort maximal dans l'inclusion en fonction du tassement en tête du modèle - cas d'une inclusion rigide.

#### 4 CAS D'UNE SEMELLE SUR QUATRE INCLUSIONS RIGIDES

La situation choisie correspond à une étude numérique conduite dans le cadre du projet ASIRI. Une semelle carrée de côté 2,8 m repose par l'intermédiaire d'un matelas de répartition d'épaisseur 0,5 m sur un sol compressible renforcé par 4 inclusions de diamètre 0,34 m. Le sol compressible repose sur un substratum rigide et est légèrement surconsolidé (surconsolidation de 10 kPa).

Cette configuration a fait l'objet d'une étude paramétrique détaillée à l'aide du logiciel Flac 3D, couvrant un large éventail de cas de charge appliqués à la semelle (Dias et Simon, 2012). La comparaison concerne le cas d'un chargement de la semelle par un effort vertical centré  $Q = 1568$  kN.

Figure 7. Cas d'une semelle sur quatre inclusions - Coupe de calcul.

La méthode exposée a été appliquée à un modèle représentant un quart de la semelle en adoptant pour le paramètre  $\beta$  la valeur 0,5. Les lois d'interaction sont construites selon la formulation de Frank et Zhao en adoptant les valeurs  $K_t$  et  $K_p$  calculées avec  $E_M = 2,5$  MPa et en ajustant les valeurs limites relatives au cisaillement  $\tau_{int}$  pour respecter la relation  $q_s(z) = K \tan \delta \cdot \sigma_s(z)$  où  $\sigma_s(z)$  désigne la contrainte verticale dans le domaine sol à la cote  $z$  et celles concernant le cisaillement  $\tau_{ext}$  pour respecter la relation  $q_s(z) = K \tan \delta \cdot \sigma_{v,0}'(z)$  où  $\sigma_{v,0}'(z)$  désigne la contrainte verticale initiale dans le massif non renforcé à la cote  $z$ . Le facteur  $K \tan \delta$  a été pris égal à 0,3 pour le cisaillement intérieur comme celui extérieur.

La Figure 8 présente les tassements calculés dans les domaines « inclusion » et « sol » en fonction de la profondeur.

Figure 8. Profils de tassement des domaines « inclusion » et « sol » et comparaison à celui calculé dans l'axe du modèle Flac3D.

Le plan neutre s'établit 1,5 m sous la base du matelas. Le tassement dans le domaine « sol » se révèle proche de celui obtenu dans l'axe de la semelle par le modèle Flac3D.

La Figure 9 présente la distribution des efforts  $Q_s(z)$  et  $Q_p(z)$  avec la profondeur sous le sommet de la semelle ; l'effort  $Q_p(z)$  dans l'inclusion est maximal au niveau du plan neutre. La valeur atteinte se révèle d'un ordre de grandeur comparable à celle du modèle Flac3D, même si celui-ci révèle le plan neutre à une profondeur supérieure.

Figure 9. Effort axial dans les domaines « inclusion » et « sol » et comparaison à celui calculé dans une inclusion du modèle Flac3D.

La figure ci-dessus présente également l'évolution de l'effort total [ $Q_s(z) + Q_p(z)$ ] avec la profondeur : celui-ci varie de 392 kN en tête du modèle (seul un quart de la semelle a été modélisé) à 224 kN à la base. La dissipation observée ( $392 - 224 = 168$  kN) est liée au cisaillement extérieur représentant les interactions avec le sol environnant non renforcé.

#### 5 CONCLUSION

La méthode analytique exposée permet de prendre en compte les effets de bord qui sont à considérer autour d'un massif de sol renforcé par inclusions rigides. La comparaison des résultats ainsi obtenus à ceux issus de modèles 3D éléments finis ou différences finies, beaucoup plus complexes à mettre en œuvre s'avère tout à fait encourageante. L'évaluation de la méthode se poursuit sur des résultats de modèles physiques en centrifugeuse.

# Influence of facing vertical stiffness on reinforced soil wall design

## Influence de la rigidité verticale du parement dans la conception des murs en sols renforcés

Damians I.P., Lloret A., Josa A.  
*Universitat Politècnica de Catalunya (UPC) – BarcelonaTech*

Bathurst R.J.  
*Royal Military College of Canada*

**ABSTRACT:** Current design practices for reinforced soil walls typically ignore the influence of facing type and foundation compressibility on the magnitude and distribution of reinforcement loads in steel reinforced soil walls under operational conditions. In this paper, the effect of the facing vertical stiffness (due to elastomeric bearing pads placed in the horizontal joints between panels) on load capacity of steel reinforced soil walls is examined in a systematic manner using a numerical modelling approach. Numerical modelling was carried out using the commercial finite element program PLAXIS. The numerical model was verified against measurements recorded for an instrumented 6 m-high wall reinforced with steel strips. The influence of the facing stiffness and backfill-foundation stiffness combinations on the vertical load through the facing and on the magnitude and distribution of the reinforcement loads was examined. For walls subjected to operational (working stress) conditions at end of construction, the numerical results confirm that the vertical stiffness of the facing and soil-stiffness combinations can have a great effect on the vertical facing loads and on the magnitude and distribution of the load mobilized in the soil reinforcement layers.

**RÉSUMÉ:** Les pratiques actuelles de conception des murs en sol renforcé ignorent généralement l'influence du type du parement et de la rigidité de la fondation sur l'ampleur et la répartition des charges de renforcement. Dans cet article, on utilise une approche par modélisation numérique pour examiner systématiquement l'effet de la rigidité du parement vertical (due à la présence de cales en élastomère placées dans les joints horizontaux entre panneaux) sur la capacité de charge des murs renforcés sol/acier. La modélisation numérique a été réalisée à l'aide du code commercial Éléments Finis PLAXIS. Le modèle numérique a été validé sur des mesures enregistrées lors de l'expérimentation d'un mur d'une hauteur de 6 m et renforcé par des bandes d'acier. Le modèle permet de tester l'influence de différentes combinaisons entre la rigidité du parement et celle du remblai-fondation sur les valeurs des charges verticales dans le parement et les efforts dans les éléments de renforcement. Pour les murs travaillant en conditions opérationnelles (sous efforts de service) à la fin de leur construction, les résultats numériques confirment que ces combinaisons ont un grand effet sur les charges verticales et la distribution des efforts mobilisés dans les couches de renforcement.

**KEYWORDS:** reinforced soil retaining walls, steel strips, facing panels, finite element modelling.

### 1 INTRODUCTION AND GENERAL APPROACH

The mechanical behaviour of reinforced soil walls is complicated due to the mechanical complexity of the component materials (including soil type/arrangement), their interactions, wall geometry, and the influence of method of construction. Most reinforced soil walls are designed assuming that the wall foundation is rigid and/or does not influence the magnitude and distribution of reinforcement loads under operational conditions. This assumption may not apply to walls constructed over compressible foundations. This paper describes the results of a series of numerical simulations that were carried out on a 6-m high wall with precast concrete panels with metallically reinforced soil and constructed with backfill (reinforced soil and retained fill) and foundation soils having different stiffness, and different number of horizontal joints (i.e. different height of the panel units) along the facing elevation.

The program PLAXIS (PLAXIS 2008) was used to carry out the numerical simulations. The reference case for model calibration is the instrumented 6 m-high precast panel facing wall reinforced with steel strips reported by Chida and Nakagaki (1979). All the results in the present study correspond to operational (working stress) conditions at the end of the construction.

### 2 NUMERICAL MODEL

#### 2.1 General

The PLAXIS global geometry, structural components, and the numerical mesh to simulate the performance of the reference instrumented case are illustrated in Figure 1.

Figure 1. PLAXIS numerical model

## 2.2 Materials properties

### 2.3.1 Soil

Material properties for the soil zones (backfill and foundation) are summarized in Table 1. Two different stiffness of the backfill were considered to represent different scenarios due to the effects of compaction. The more compressible soil case (with assumed  $E_{backfill} = 10$  MPa) does not imply that poorly compacted soils should be used in the construction of these types of structures, but was used to ensure detectable differences between simulation outcomes. Moreover, the first meter of reinforced soil in contact with the facing is commonly constructed with less compaction energy and hence was assumed to have one half the stiffness of the fully compacted soil. Two other cases were assumed for the foundation soil; nevertheless, the actual foundation stiffness for the reference wall case was not reported by Chida and Nakagaki. The stiffness combinations in Table 1 result in four boundary cases to be examined.

Plane-strain boundary conditions were considered for the selection of the internal friction angle of the soils. The soil material properties also define the strength and stiffness of the interfaces between the soil and the structural elements (panels and reinforcement) using a reduction factor ( $R_i$ ), which is the ratio of interface shear strength to shear strength of the surrounding soil. The values chosen for this factor in each case (soil-facing and soil-reinforcement) are based on reported data and actual mechanical behavior of these interactions.

Table 1. Model properties of the soil materials

Parameters	Foundation	Backfill	
		> 1.0 m from face	< 1.0 m from face
Unit weight (kN/m <sup>3</sup> )	20	18	18
Cohesion (kPa)	1	1	1
Friction angle (°)	36	44	44
Dilatancy angle (°)	6	14	14
Elastic modulus (MPa)	10 – 1000	10 & 100	5 & 50
Poisson's ratio	0.3	0.3	0.3
Interface reduction factor	1	1	0.3 & 0.6

### 2.3.2 Reinforcement

Reinforcement elements were modelled using the “geogrid” PLAXIS elements as continuous sheets that have only axial stiffness and can transmit load to the surrounding soil through interface shear ( $R_i$  parameter). The equivalent linear-elastic axial stiffness of the geogrid element for each layer of reinforcement elements is computed as follows:

$$(EA)_{geogrid} = E_{reinforcement} A_{reinforcement} \frac{n_{reinforcements}}{L_{panel}} \quad (1)$$

Where:  $E_{reinforcement}$  is the stiffness modulus of the reinforcement layers (200 GPa for steel);  $A_{strip}$  is the cross-sectional area of one strip (100 × 2.3 mm);  $n_{strips}$  is the number of strips along one panel (two strip-units), and  $L_{panel}$  is the panel width assumed as 1.5 m. The resulting axial stiffness of the geogrid element is about 60 MPa/m. Other analyses considering different axial stiffness modulus equivalent to other steel reinforced types (e.g. bar mats with axial stiffness about 40 MPa/m) do not generate significant variations from the results presented in this study.

### 2.3.3 Facing-beam elements

The facing was defined by PLAXIS “beam” elements, and is comprised of the panels and the elastomeric bearing pads. The bearing pads are installed in the horizontal joints between contiguous vertical panels and are used in practice to prevent concrete-to-concrete panel contact.

Material properties for the concrete facing panels and horizontal joints are summarized in Table 2. The material type, dimensions and number of bearing pads can vary between projects (Neely and Tan 2010). The same Equation 1 can be used to obtain the parametrical values of the bearing pad elements (Damians et al 2013). In the present analyses, two EPDM (ethylene propylene diene monomer (M-class) rubber) bearing pads were assumed in each horizontal joint between per panel width.

Table 2. Model properties of the beam elements

Parameters	Panels	Bearing pads (EPDM)
Axial stiffness (MN/m)	6.0	0.1
Bending stiffness (kN/m <sup>2</sup> /m)	11	0.3
Weight (kN/m/m)	4.5	0.2
Poisson's ratio	0.15	0.49

## 3 RESULTS

### 3.1 Numerical and reported physical data comparison

Numerical predicted vertical loads at the base of the facing panels and the reinforcement loads were compared to values reported by Chida and Nakagaki (1979) during calibration of the numerical model.

#### 3.1.1 Vertical loads under facing

Damians et al. (2013) have shown from a review of instrumented case studies that the vertical load at the base of a precast facing wall with steel reinforced soil elements is greater than the self-weight of the panels. The vertical load under facing is a combination of facing self-weight, soil-panel shear and reinforcement down-drag loads, which generate reported load factors from 1.8 to 4.7 times the self-weight of the panels in steel reinforced soil walls (a value of 2.1 is computed for the reference wall reported by Chida and Nakagaki). It should be noted that the studied cases are restricted to steel reinforced soil walls. However, there are similar data for an instrumented full-scale 6-m high geosynthetic-reinforced soil wall with incremental concrete panels constructed in the laboratory (Tariji et al. 1996); the computed vertical load factor is 2.2 for this structure.

Figures 2a and 2b summarize results that take into account the effect of the backfill and foundation stiffness scenarios and the backfill-facing interface shear strength ( $R_i$  value of 0.3 and 0.6).

The data show that the larger  $R_i$ -value assumed results in a range of total vertical facing loads that vary from the reported value of 53.3 kN/m for the reference case. Assuming a value of  $R_i = 0.3$  generates four stiffness scenarios that include the measured case study value more accurately (modifying the  $E_{backfill}$  from 100 to 10 MPa when  $E_{foundation}$  is 1000 MPa, or modifying  $E_{foundation}$  from 1000 to 10 MPa when  $E_{backfill}$  is constant at 100 MPa).

Typically, the recommended interface shear strength factor values are about 0.6 times the shear strength of the surrounding soil. However, analysis of a wall reported by Runser et al. (2001) showed that a value of  $R_i = 0.3$  was gave more accurate

predictions (Damians et al. 2013). This value was adopted in the current study.

### 3.1.2 Reinforcement loads

In Figure 3 are shown the results of the reinforcement tensile loads obtained from numerical modelling and comparison with measured data for selected strips at different elevations. The reinforcement length considered in this study is 0.6 – 0.7 times the total wall height. Steel strips with lengths from 4.0 to 5.0 m were used in the reference case study, so all locations along any reinforcement layer are normalized with the respect to the layer length.

The presented results show good agreement between the numerical model results and measured data. The backfill-foundation stiffness combination results give different tensile-load distributions in the reinforcement layers. The effect of the less-compacted soil near the facing can be clearly detected with the discontinuity at a normalized distance from 0 to 0.25.

Figure 2. Total vertical loads under the facing assuming soil-facing interface reduction factor  $R_i = 0.3$  (a), and  $R_i = 0.6$  (b)

### 3.2 Influence of vertical facing stiffness

As noted earlier, the vertical facing stiffness was modified by changing the number of horizontal joints along the facing height of the wall. The reported case (base-case) had three horizontal joints (four panels of 1.5 m-height). Three other cases were considered to investigate the effect of the vertical facing stiffness (see Figure 4).

Figure 5 shows the numerical model reinforcement tensile-loads with respect to the number of horizontal joints. The values correspond to the maximum load ( $T_{maximum}$ ) of all the reinforcement strips, its related strip, and the normalized

distance of  $T_{max}$  to the facing in the strip. Reported values obtained from Chida and Nakagaki (1979) are also shown.

First, it can be noted that there is little difference in the predicted  $T_{max}$  value with respect to the backfill and foundation stiffness combinations (less than 4 kN/m in the case with more divergence, i.e.  $E_{backfill} = 100$  MPa and  $E_{foundation} = 10$  MPa combination). All the  $T_{max}$  values (numerical and measured) are located at the bottom zone of the wall (all at the layer located at 1.13 m, except the numerical case with  $E_{backfill} = 100$  MPa and  $E_{foundation} = 10$  MPa). With respect to their location in the reinforcement (normalized distance from the facing), all the  $T_{max}$  values are located between 0.3 and 0.5.

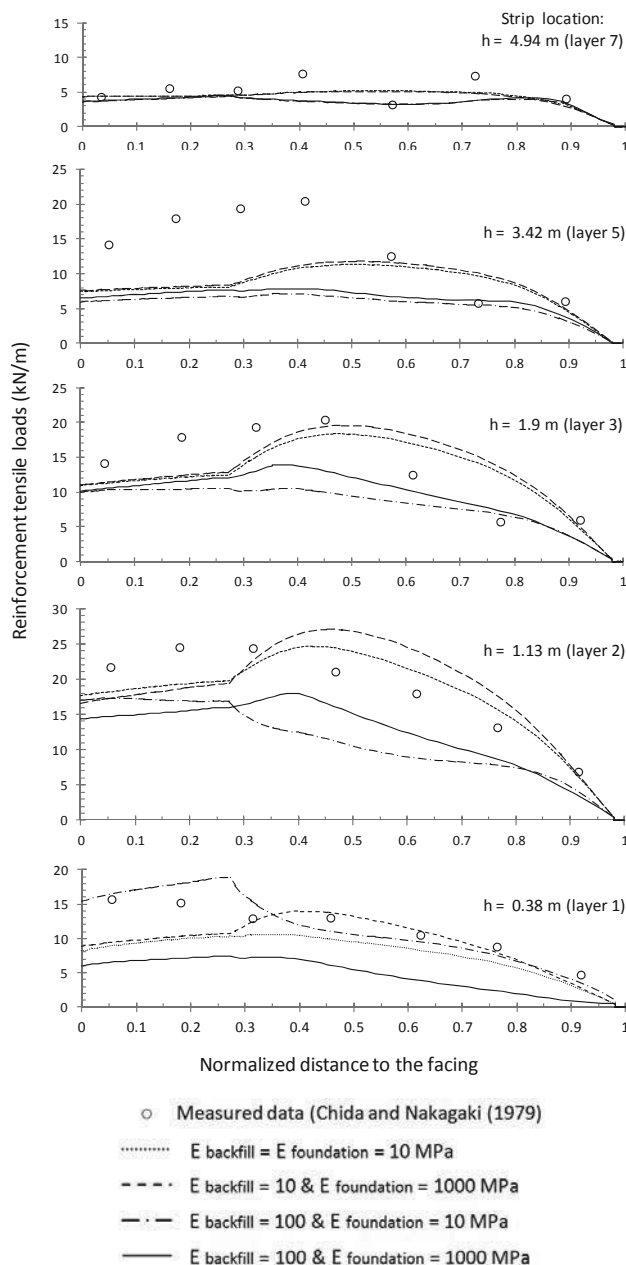

Figure 3. Tensile-load distribution of the wall reinforcements at the end of construction. (Normalized distance = distance to the facing of a stress i-point / total length of the reinforcement)

Figure 4. Schema about the horizontal joint options considered

Figure 6 shows the effect of the foundation stiffness and the vertical facing stiffness on the total vertical loads at base of the facing. Three additional foundation stiffness cases are considered here in order to obtain more data points. It can be observed that higher values of the foundation stiffness (elastic modulus) generate lower values of the total vertical load under the facing. If the total vertical load under the facing with respect to the number horizontal joints is analyzed (Figure 6), a significant influence of the vertical facing stiffness on the results can be noted. This influence is less relevant if the lowest modulus of the backfill soil is assumed (i.e.  $E_{backfill} = 10$  MPa, which generates a range of about 3 kN/m between boundary cases). If the backfill soil is assumed with higher stiffness value ( $E_{backfill} = 100$  MPa), the variation of the vertical load is more significant with a range of 15 kN/m for the single joint case, and 20 kN/m for the four joint case.

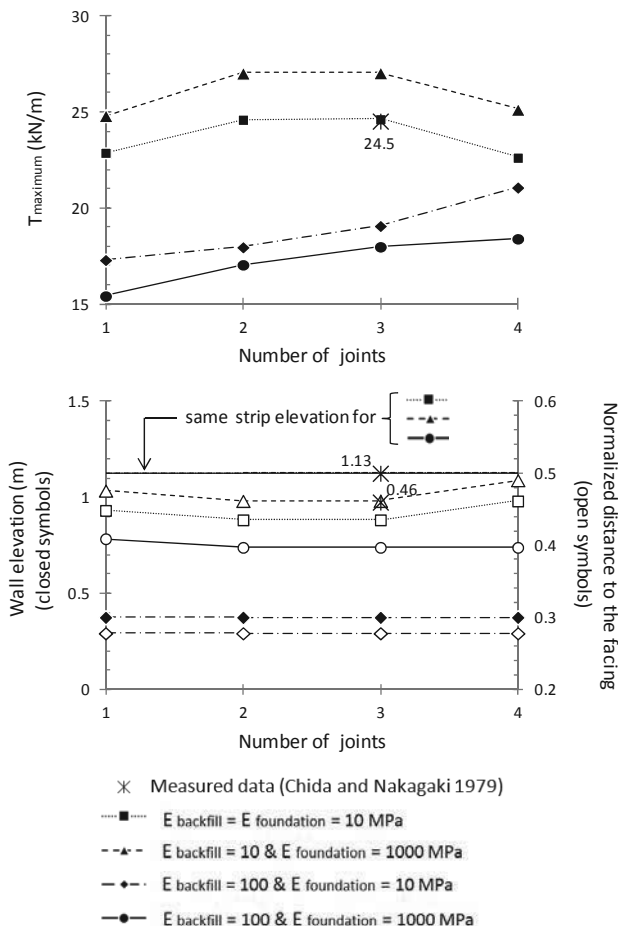

Figure 5. Maximum reinforcement loads ( $T_{max}$ ) with respect to the number of horizontal joints and backfill-foundation stiffness combination (upper figure), and the  $T_{max}$  location in the backfill (reinforcement layer and distance to the facing; bottom figure)

4 CONCLUSIONS

The mechanical behaviour of reinforced soil walls is complicated due to the mechanical complexity of the component materials, their interactions, wall geometry and soil type/arrangement, in addition to the unquantifiable effects of construction method and quality. Nevertheless, current design methods are typically based on classical notions of soil and reinforcement ultimate strength. Furthermore, internal stability design using conventional analytical solutions assumes that the compressibility of the foundation soil does not influence reinforcement loads.

The numerical simulation results in the current study demonstrate, first, that vertical loads at the base of the facing are affected directly by the backfill and foundation stiffness scenario and the soil-facing interface shear strength; second, there is a significant variation of reinforcement tensile load results depending on the combination of the backfill and foundation stiffness values; and third, the vertical stiffness of the facing (represented by the number of horizontal joints along the facing, that can be also be understood as different thicknesses of the bearing pad elements) produce significantly different effects on the vertical facing load and the reinforcement tensile loads. These three outcomes cannot be predicted for walls under operational (working stress) conditions using current strength-based design methods for the calculation of reinforcement loads.

# Earth Pressure from Strip Footings on an Anchored Sheet Pile Wall

## Poussée des terres provenant de semelles filantes sur un mur de palplanches ancré

Denver H., Kellezi L.

*GEO-Danish Geotechnical Institute, Lyngby, Denmark*

**ABSTRACT :** A strip footing is frequently situated near a sheet pile wall. Assessment of the extra pressure on the wall generated by a footing causes theoretical problems for the designer. The distribution of this pressure depends in fact on many parameters. Besides the location and magnitude of the load a characterization of the soil and the wall is necessary for a rational design. Furthermore, the movement of the wall has a significant impact on the pressure. In this paper an anchored wall is investigated where the movement in failure is a rotation about the anchor point. The problem is solved by means of different analytical methods compared with solutions by finite element modeling applied to a number of representative examples. These comprise different strengths for the cohesion-less soil and different load scenarios. After a discussion of the results a simple calculation procedure is proposed.

**RÉSUMÉ :** Une semelle filante est souvent située à proximité d'un mur de palplanches. L'évaluation de la pression supplémentaire sur la paroi générée par la semelle provoque des problèmes théoriques pour le concepteur. La répartition de cette pression dépend en fait de nombreux paramètres. Outre l'emplacement et l'ampleur de la charge, une caractérisation du sol et du mur est nécessaire pour une conception rationnelle. De plus, tout déplacement de la paroi a un impact significatif sur la pression. Dans cet article, une paroi ancrée est étudiée lorsque le déplacement amenant à une défaillance consiste en une inclinaison autour du point d'ancrage. Le problème est résolu par le biais de différentes méthodes d'analyse que l'on compare aux solutions de modélisation d'éléments finis, appliquées à de nombreux exemples représentatifs. Celles-ci comprennent différentes forces pour un sol sans cohésion ainsi que différentes configurations de charge. Une simple procédure de calcul est proposée après la discussion des résultats.

### 1 INTRODUCTION

Sheet pile wall design methods in Europe generally rely on simplified earth pressure theories where the failure mechanism of the soil is in fact not compatible with the wall deflections. The Danish design method of sheet pile walls is based on Brinch Hansen's earth pressure theory, which assumes plastic behaviour for the wall and the soil. The computer program SPOOKS, which is a product from GEO-Danish Geotechnical Institute, is successfully used for sheet pile wall design in Denmark and abroad. The program calculates the required driving depth, the maximum bending moment and the anchor force for a user defined failure mode of the wall and the adjacent soil. The wall may be either anchored or free and either hinged or fixed in an anchor point. In the limit state a yield hinge in the wall with an ultimate positive moment may develop below the anchor level.

When excavating close to an existing building the effect of the partial distributed loads, from for example strip foundations (two dimensional (2D) conditions), or plate foundations (three dimensional (3D) conditions), are usually implemented in the sheet pile wall plastic design by means of the elasticity theory and the principle of superposition, where the extra earth pressure simply is added to the plastic solution. It is however not correct in the plastic design to separately calculate the active earth pressures from partial distributed loads without taking into account the active pressure from the unit weight of the soil.

The objective of the present paper is to supplement an earlier investigation for a free wall, Denver & Kellezi (2011), with establishment of an empirical relationship to estimate the extra earth pressure on an anchored sheet pile wall from a strip load behind the wall. This relationship is compared with solutions from finite elements (FE) results. The additional pressure is found as the difference between the combined pressure from self weight of the soil and the strip footing and the pressure

from only the self weight. In an attempt to assess the additional pressure on the wall, different approaches are investigated:

- Analytical calculations by the theory of plasticity on a suitable rupture figure.
- Empirical solutions inspired by Coulomb's theory.
- Numerical modelling by the FE method.

### 2 GENERAL

The earth pressure calculation on a wall is here illustrated by the Danish method denoted as Earth Pressure Calculation. This method has been proposed by J. B. Hansen (1953) and is extensively used in Denmark. The pressure on the wall ( $e$ ) is calculated as a sum of three terms as given in equation (1).

$$e = \gamma' d K_\gamma + q K_p + (c K_c) \quad (1)$$

These terms and the other parameters used in the calculation are:  $\gamma'$  the effective unit weight of the soil;  $K$  the earth pressure coefficient (different for the three terms);  $c$  the cohesion of the soil;  $p$  the surface load behind the wall, and  $d$  the depth along the wall from the soil surface. The last term is enclosed in parenthesis as this paper deals only with frictional soil.

In the Danish method the wall is considered composed of several rigid parts interconnected by yield hinges. Each part is assumed to rotate about a point and the earth pressure coefficients are functions of the position of this point and the direction of rotation (besides the friction angle of the soil,  $\varphi$ ). Examples of anchored walls with yield hinges are shown in Figure 1, and examples of rupture figures used for calculation of  $K$  are shown in Figure 3. The result of each calculation is the total force on the wall and the point of application. The normal component of this force ( $E$ ) is distributed along the wall. A part of  $E$  is applied near the top as a Prandtl rupture zone.

Figure 1, Anchored wall in failure composed of one or more rigid segments connected by yield hinges in failure. This paper deals with failure mode a) marked with rectangular.

A pressure jump near the top is then applied to ensure that the effect of the distribution (in terms of total force and moment) corresponds with the rupture figure. The method has been described in detail by Mortensen & Steinfeldt (2001) and results of calculated examples are compared with FE calculations.

### 3 COMPUTER PROGRAM ‘SPOOKS’

Although J. B. Hansen has developed a complete set of diagrams to find the values of  $K$ , the earth pressure calculation for a specific design situation is rather time consuming. To this end GEO-Danish Geotechnical Institute has made a commercially available computer program named ‘SPOOKS’.

Here, apart from the geometry of the excavation, the soil conditions and water tables, only a selection of the total wall movements (as shown in Figure 1) is necessary as input. The results are a distribution of both earth and water pressures, curve of bending moments along the wall, tip level, and anchor force. All together ready for the final design of the sheet pile wall profile and anchor. However, this program has no facility to include a partial surface load.

### 4 THEORY OF PLASTICITY

A method to assess the extra soil pressure caused by a partial load has been introduced by J.S. Steinfeldt and B. Hansen (1984). The Danish method to calculate the earth pressure coefficient from a relevant rupture line has been adopted. A circular rupture line is used as an appropriate choice for a rotation about a point at the anchor level. The stresses from the rupture line are determined by the Kötter’s differential equation. The total force is found by integration of this equation presented by Brinch Hansen (1953) and shown as the resulting force ( $F_o$ ) and moment ( $M_o$ ) about the centre of the circle as shown in Figure 2 where the significance of the variables is indicated.

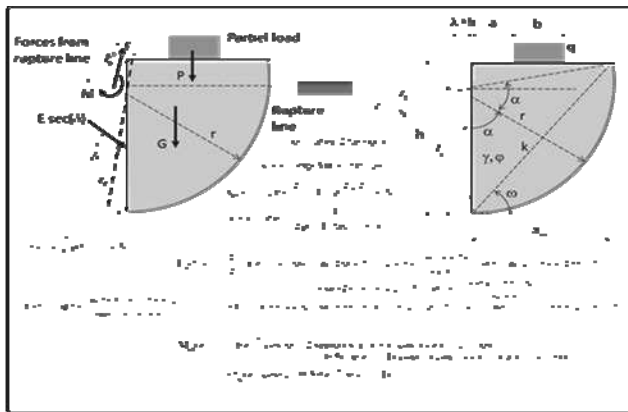

Figure 2, Analytical method where circular rupture figure is applied. Negative values of  $\phi$  and  $\delta$  shall be applied as the rupture is active.

It should be mentioned that  $t_c = \sqrt{q^2 + \tau^2}$  where  $t_c$  refers to the starting point of the integration where the rupture circle meets the soil surface and  $\sigma$  and  $\tau$  are coordinates to the yield point in the Mohr’s circle. The function  $q(\lambda)$  refers to the value of  $q$  in the point where the circle meets the surface. ( $q$  beneath the load

and 0 otherwise). The three unknowns ( $\lambda$ ,  $E$ , and  $z_p$ ) are finally found by the three equilibrium equations.

Figure 3, Rupture figures with different rotation points ( $\rho$ : relative height from the bottom of the wall). The figures are drawn for  $\phi = 30^\circ$ ,  $c = 0$  and rough wall rotating clockwise. The pure line rupture is investigated analytically in this paper (shaded in the figure).

This method (Figure 3 shaded) is in detail introduced and discussed by the authors and the results of a large number of load scenarios are presented in their paper.

### 5 EMPIRICAL METHOD

It is usual practice to apply a soil pressure derived from the distribution for the uniformly loaded surface. A minor part of this distribution is then used situated to a depth interval defined by inclined lines through the soil.

In Figure 4 a method of this kind often used in Denmark is shown. However, a tail below the lower line has been in this method proposed by K. Mortensen (1973) who has pointed out the complexity of the problem assuming a smooth wall that rotates anti-clockwise about a point below the tip of the wall. Consequently, the upper part with the even distribution is given by an active Rankine rupture figure. The tail is probably inspired by calculations by Coulomb’s method where the lower part is more dependent of other parameters than  $a$  and  $b$ .

Figure 4, Empirical method based partly on the Coulomb’s earth pressure theory.

As this method is often used also for other movements, en lieu of other procedures it is adopted here as an example of an empirical solution.

### 6 ELASTIC SOLUTION

An elastic solution developed by Boussinesq (1885) is often used because of its simplicity as shown in Figure 5. Besides the theory of elasticity a smooth vertical wall without any movement is assumed. This method is often questioned as the resulting distribution is too large and situated much too high on the wall with respect to results from model tests and calculations based on the Coulomb’s method.

This is also the authors experience when the movement of the wall is anti clockwise about a low point in the wall. However, if the movement is a clockwise rotation about the anchor (as in this paper) the assumptions for an elastic solution are more justified.

Figure 5, Elastic solution by Boussinesq (1885)

7 FINITE ELEMENT METHOD

In order to validate the method a number of load scenarios have been calculated by the FE program Plaxis 2011.

A 2D mesh pattern has been generated using triangular finite elements (15-noded). Sand is modeled in drained conditions using the Mohr-Coulomb constitutive model. The sheet pile wall is assumed weightless and with a large stiffness to prevent any interaction of stresses caused by deformation of the wall. The initial geostatic conditions are calculated first. Mesh sensitivity analyses have been carried out and an optimal mesh pattern with respect to element size and obtained accuracy has been chosen for the final analyses.

Plaxis plastic analyses (small deformation theory) and Updated Mesh (large deformation theory) have been applied to estimate the effect of the wall movement on the results. The calculations are carried out in different ways considering the impact the staged construction (excavating after, before or at the same time with the load application) has on the results.

Some different load scenarios are modeled and calculated to illustrate the problem. The loads / pressures applied over the foundations are chosen in such a way that the foundation bearing capacity is satisfied. The load scenarios are shown in Table 1.

Table 1, Load scenarios calculated

No	φ	a	b	q	No	φ	a	b	q
	(deg)	(m)	(m)	(kPa)		(deg)	(m)	(m)	(kPa)
1	30	1	2.5	125	6	40	1	2.5	713
2	30	1	1	50	7	40	1	1	285
3	30	2.5	1	50	8	40	2.5	1	285
4	30	5	1	50	9	40	5	1	285
5	30	0	∞	50	10	40	0	∞	285
h = 12 m    γ = 14 kN/m <sup>3</sup> c = 0 kPa    rough wall									
Height to rotation point:    h <sub>p</sub> = 9.6 m									

A unit weight has been applied to the soil to provide a realistic stress distribution near the top of the wall. Interface elements are applied along the wall. However, the soil strength at the interface has not been reduced as a rough wall is considered. The influence of the load on the wall has thus been derived as the difference between results of calculations of the wall with load and unit weight and with unit weight alone.

A rigid anchor is applied at a depth corresponding to 0.8\*h referring to the bottom of excavation or the height of the wall h.

The anchor point ensures a rotation around this point during failure (Figure 6).

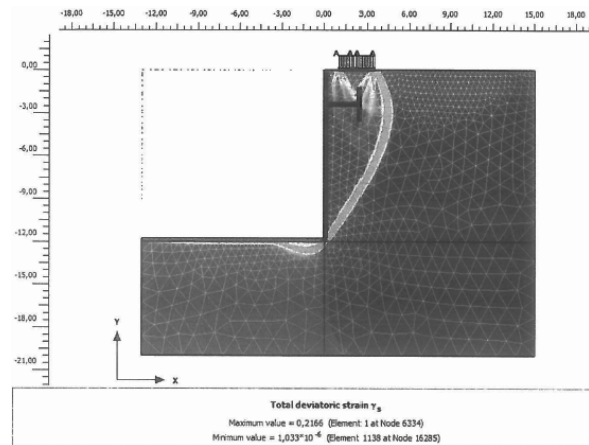

Figure 6 FE model example, (φ=30° a=1.0 m b=2.5 m or a/b=0.4 p=125 kPa).

A complete presentation of the results is not included due to lack of space. The normal pressure (e) on wall from the soil, and the soil plus load, and the additional pressure from the load derived as their difference (Delta e) are derived from the interface zone as given in Figure 7 and 8 for both soil types considered. The FE results are used as benchmarks for the accuracy of the other methods and shown relative to those in the discussion.

Figure 7 FE models results (φ=30°)

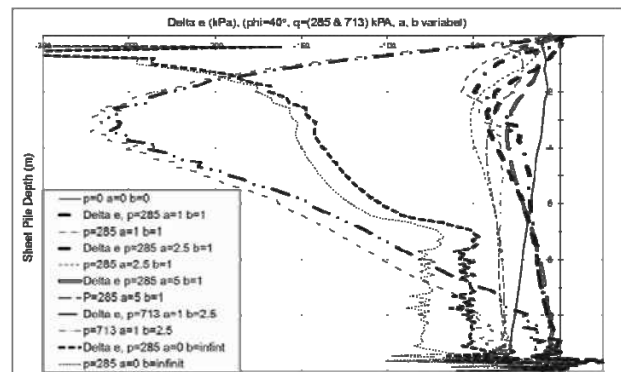

Figure 8 FE models results (φ=40°)

8 DISCUSSION OF CALCULATIONS

It was expected that a study of the theory of plasticity would yield a deeper insight into the problem and provide useful results. However, our calculations have produced rather scattered results. The calculations presented by Steinfeldt & Hansen do by no means suggest simple relations to the input

parameters. Their recommendation is also to make a computer code using the detailed described procedure and solve the problem in question explicitly. The resulting force from the integration along a rupture line consists together with simple zone ruptures the backbone of the Danish earth pressure theory, and should by no means be questioned here.

It should be mentioned that the procedure involves two calculations: (i) a calculation with both  $P$  and  $G$  (Figure 2), and (ii) a calculation with  $G$  alone. The influence of  $P$  is found by a subtraction of the two vectors. As  $G$  is great compared to  $P$  the latter is poorly determined and also problems with the validity of supposition as assumed here will distort the result.

Another problem is connected with the integration of the Kötter's equation. The only contribution to a change of the ambient stress condition is caused by the unit weight. However, the rupture line will pass through domains in the soil much differently affected by the partial loaded surface.

In every case the method will not provide the distribution of the pressure which is imperative especially to determine the moment in the wall in the anchor level.

### 9 PROPOSED PROCEDURE

When a procedure to assess the influence of a partial loaded surface it should be taken into consideration that the proposed distribution should converge to the distribution usually applied for a fully loaded surface.

The procedure proposed is:

- Calculate the elastic distribution ( $e_e(z)$ ) using the equations in Figure 5.
- Calculate the distribution usually used for a fully loaded soil surface. Use only the part of this distribution corresponding to the uniform part of the distribution ( $e_p(z)$ ) shown in Figure 4.
- The final distribution is:  $e(z) = W * e_p + (1-W) * e_e(z)$ , where  $W$  is a weight function  $W = 1.5 * (F - 0.167) - 2 * (F - 0.5)^3$  and  $F = 0.8 * b/h$ .

### 10 VERIFICATION

The benchmark for the verification is chosen as the results of the FE calculations. As before mentioned it is difficult to characterize the distributions by simple means. We have here focused on the usage of the distribution: (i) to calculate the anchor force ( $A$ ), and (ii) to calculate the moment in the wall in the anchor level ( $M$ ).

Figure 9, Accuracy of the methods (Empirical, Proposed vs. FE).

The anchor force is estimated as the part of the distribution above the depth  $z$  equal to double the height of the wall above the anchor. This procedure excludes the results found by the theory of plasticity to be represented. The quantities  $\ln(A/A_{FE})$  and  $\ln(M/M_{FE})$  are made where the denominators are the results from the FE calculations. These quantities are plotted against each other in Figure 9 for load cases (1-4) and (6-9).

When a quantity is greater than zero, the predicted value is on the safe side. When a quantity is 1 the corresponding ratio is 2.7. If  $A$ , or  $M$  is zero the quantity is minus infinity but plotted on the frame of the diagram.

A study of Figure 9 shows that the proposed procedure is superior to the empirical procedure and the fit is surprisingly accurate taking into account the complexity of the problem.

In order to offer a qualitative impression of the results a single distribution from the FE calculations is shown in Figure 10. This distribution is supplemented with distributions from two other methods (Empirical and Proposed).

Figure 10, Normal pressure distribution ( $e$ ) from FE calculations compared with other methods (Empirical, Proposed) for a single load, (Load Case 8).

### 11 CONCLUSION

A procedure to calculate the pressure distribution has been proposed and has proved an excellent fit with results from FE calculations. The procedure is based on the theory of elasticity where the assumption of an immobile wall is justified by the high rotation point. The result converges to the usually applied when the entire surface is loaded.

# Top-Down Construction Alongside Of Bosphorus – A Case Study

## Construction en « Top-Down » le long du Bosphore – Une étude de cas

Durgunoglu T., Kulac F., Ikiz S., Akcakal O.  
*Zetas Zemin Teknolojisi A.S., Istanbul, Turkey*

**ABSTRACT:** Hatice Sultan and Fehime Sultan Residences are two historical Ottoman waterfront mansions placed on the European shore of Bosphorus in Istanbul. Within the restoration campaign of these mansions, it is planned to add four basement levels under the complete plot with the exception of preserved two corners where Hatice Sultan Residence and an old and large tree exist. The depth of the excavation needed for the basements is about 24 m below ground surface of which 21.20 m will be below groundwater level. The excavation should take place just 75 m far from the southwest pylon of the Bosphorus Suspension Bridge. Soil profile consists of uncontrolled fill, marine alluvium layer and bedrock which is sloped towards the seaside with a varying inclination. Steel propping system was set forth by the geotechnical design group of the Client, though this method was eliminated later during the bidding stage, because it was found impractical due to their obstacle in basement construction. The method of top-down construction of the basement levels with permanent diaphragm wall and bored piles socketed into bedrock was agreed to be realized by the Client based on the alternative proposal given by the foundation subcontractor during the bidding stage. THY -Do&Co JV Ortakoy Hotel Project is an interesting case-study where a challenging supporting system is being implemented near the Bosphorus in very poor soil conditions, under high seismicity.

**RÉSUMÉ :** Les Résidences de Hatice Sultan et de Fehime Sultan sont deux yalis Ottomanes historiques situées sur la côte Européenne du Bosphore, à Istanbul. Le projet de rénovation de ces yalis prévoit d'ajouter quatre étages en sous-sol sous l'ensemble du terrain, à l'exception de deux zones préservées où sont situés la Résidence de Hatice Sultan et un arbre centenaire. Une excavation de 24m sous le niveau du terrain naturel est requise pour la réalisation des sous-sols dont environ 21,20 m sous le niveau de la nappe phréatique. L'excavation aura lieu à tout juste 75 m du pylône sud-ouest du Pont sur le Bosphore. Le profil du sol est constitué de remblais non contrôlés, de couches d'alluvions marins reposant sur un substratum rocheux s'enfonçant avec une inclinaison variable en allant vers le Bosphore. Cependant, le design initial du client basé sur la mise en œuvre d'un système de soutènement en acier a été plus tard écarté car ne permettant pas la réalisation ultérieure des niveaux de sous-sol. La méthode de construction en « top-down » utilisant une paroi moulée et des pieux forés ancrés dans le substratum rocheux a finalement été sélectionnée par le Client, sur la base de la proposition alternative remise par le sous-traitant lors de l'appel d'offres. Le Projet de THY - Do&Co JV Ortakoy Hôtel est une étude de cas intéressante pour lequel un soutènement a dû être mis en œuvre à proximité du Bosphore, avec des conditions de sol très difficiles et en prenant en compte de forts risques sismiques.

**KEYWORDS:** Top-Down Construction

## 1 INTRODUCTION

Fehime Sultan and Hatice Sultan Residences are one of the historical Ottoman waterfront mansions constructed alongside the Bosphorus. These residences were constructed in the second half of the 19th the Century by Sultan Abdulhamid II as a wedding present for two daughters of Sultan Murat V. Later on, Fehime Sultan Residence was given as a gift to Gazi Osman Pasha for his success in Plevne Defense against Russian Army. During the Turkish Republic period this mansion served as a primary school and unfortunately was seriously damaged in a recent fire in 2002. On the other hand Hatice Sultan Residence served as an orphanage and then as private swimmers club in the later periods. The plot has been recently purchased by Turkish Airlines - Do&Co JV on BOT basis and is planned to be restored and developed to serve as a boutique hotel. Ruins of the Fehime Sultan Residence have been transferred to the restoration workshop. This beautiful and historical mansion is planned to be re-constructed using its original fragments. Within this restoration campaign, it is also planned to add four basement levels under the complete plot with the exception of two corners where Hatice Sultan Residence and an old and large tree exist. This deep excavation is agreed to be implemented with the Top-Down construction method because of the poor soil conditions, high ground water table and important

neighboring infrastructures. On the date of the paper submission, the diaphragm wall construction was just finalized. Therefore, only findings and implications of design and methodology together with diaphragm wall construction are presented within this paper.

## 2 PROJECT DESCRIPTION

Fehime Sultan and Hatice Sultan residences are located in district of Ortakoy alongside of Bosphorus and approximately 75 m away the southwest pylon of the Bosphorus Suspension Bridge in Istanbul (Figures 1a and 1b). Within the restoration campaign of these residences four basement floors are planned to be constructed in the entire plot. The periphery of the basement floors encloses the plot limit, except two corners on where Hatice Sultan residence and a historical tree exist (Figure 2). Basement excavation will be realized under Fehime Sultan residence location at the left in Figure 2 because ruins of this residence as a result of fire have been removed to restoration workshop area before the commencement of the works. The perimeter of the excavation plot is about 372 m and the area of the plot is approx. 6064 m<sup>2</sup>. Site elevations are varying between +1.00 m to +3.00 m. Excavation elevation is 21.20 m below the

sea level and maximum excavation depth is approximately 24 m.

Figure 1a and 1b. General View of the Site Figure and Location of the Site in Istanbul

Figure 2. Periphery of the Excavation (photo after the fire of 2002 and before the start of the restoration campaign)

During the bidding stage, top-down construction proposed by the foundation subcontractor was considered as a suitable method under the existing conditions. Typical cross section of the basement structures through the perpendicular direction to the seashore is given in Figure 3. It is planned to use the diaphragm walls as permanent periphery walls of the basement floors, construct the bored piles as permanent columns of the underground structure and integrate the foundation and slabs with the permanent wall and columns during the top-down construction method. This choice resulted in the necessity to develop special details for ground water isolation and continuity of the structural elements.

Figure 3. Section of the Basement Structure in Perpendicular to the Seashore

### 3 GEOTECHNICAL MODELLING

Within the soil investigations ten boreholes were implemented with a maximum length of 50 m. Two of the boreholes adjacent to the seaside were implemented with 45° inclination and length of these boreholes was 100 m. Also within the geophysical measurements, MASW and microtremor studies are implemented in the site to obtain the geodynamic modeling of subsoils.

Soil profile consists in sequence from top to down as of uncontrolled fill, marine alluvium and bedrock. Dyke, sandstone and shale are the commonly encountered rock types at the site. According to the results of vertical boreholes at the site bedrock is located between 13.50 m and 27.20 m under the sea level. Therefore length of the diaphragm wall and bored piles are chosen variable from one location to another in accordance to

encountered bedrock elevations. Typical soil profile is given in Figure 4.

Figure 4. Typical Soil Profile

Simplified average drained shear parameters of the alluvial soil layers based on the field and laboratory testings are given in Table 1. Ground water table is located within 1.0m to 3.0m below the ground surface.

Table 1. Soil Properties

Layer	$\gamma$ (kN/m <sup>3</sup> )	$\phi'$ (°)	$c'$ (kN/m <sup>2</sup> )
Uncontrolled Fill and Marine Alluvium	18	28	1
Weathered Rock	22	33	20
Bedrock	24	33	50

### 4 PRELIMINARY DESIGN

The preliminary retaining system has been proposed by a geotechnical design group employed by the Client prior to the tender, which consisting a peripheral diaphragm wall and tubular steel struts. Diaphragm wall thickness was considered as 800 mm and planned to be used only temporarily during the excavation. To support the diaphragm wall, four rows of steel struts are proposed to be implemented. The spacing between the struts was 5.0 m in vertical and 8.20 m in horizontal directions. Typical cross section of the tender design is given in Figure 5.

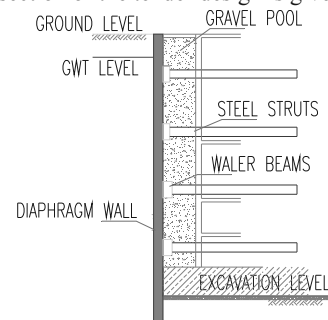

Figure 5. Tender Design Typical Cross Section

Complete underground structure were planned to be constructed 21.20 m below the water table. As a result, the uplift of the underground structure is one of the critical issues for the design.

### 5 PROPOSED ALTERNATIVE DESIGN

During the bidding stage the applicability towards the construction of underground structure and the cost of the tender design was examined. One of the drawbacks realized was that the space between the steel tubular struts was very limited to implement the excavation works in a safe and efficient manner. As a result, alternative top-down construction method was proposed to eliminate the implications of steel struts. Further, in order to eliminate the gravel filled between the walls; namely

gravel pool, proposed in the preliminary design, uplift loads are proposed to be taken by tension piles under the foundation.

As described in the previous sections, the site is located in a densely populated urban zone and there are important neighboring infrastructures around the plot. In order to minimize the lateral displacements to be realized during excavation implication of the proposed top down procedure was very effective and superior compare to strutted excavation.

In the proposed top down method permanent diaphragm walls and piles are to be constructed prior to excavation works. Later ground level r. c. floor will be constructed except the part behind the Hatice Sultan residence (Figure 6).

Figure 6. Top Down Construction Area

Soil under the ground level floor will be excavated phase by phase until the bottom elevation of foundation. In parallel to excavation works 1st basement r. c. floor will be constructed. The part of limited excavation plot behind the Hatice Sultan Residence will be supported with steel struts to provide space for ramps which will be used for the transportation of the excavated material. Top down construction steps will continue similarly as 2nd basement floor 3rd basement floor and foundation respectively (Figure 7).

Figure 7. Top Down Construction Steps

Groundwater seepage into the excavation site is evaluated by seepage analysis and optimum socket length in to the bedrock is determined as 5.0 m. Also settlements due to the lowering groundwater table are estimated and found to be less than 18 mm which is considered as tolerable for the existing structures.

Bored piles are designed to be used as compression and tension members depending on the loading conditions. Therefore, piles which will act as permanent columns of the underground structure are extended into the bedrock having minimum socket length of 6.0 m based on the result of pile tension test conducted at the site in order to satisfy the most critical tension loading condition under the uplift forces. Tension capacity of the piles are estimated and taken into account against uplift forces.

In the top down construction, floor and foundation reinforcements will be integrated into the permanent diaphragm wall and piles with the aid of additional link reinforcements

which are already placed in these elements. Details of these link reinforcements are given in the next section.

After the top down construction steps the limited area behind the Hatice Sultan Residence will be constructed with conventional method from bottom to top in parallel to dissembling the steel struts. Special water-proofing works will also be implemented under the foundation and on the constructive inner wall during the down to top construction steps.

## 6 CONSTRUCTION STAGE OF DIAPHRAGM WALLS

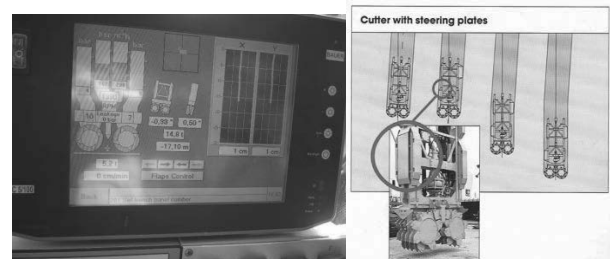

At the time of paper submission, diaphragm wall construction was just completed and preparations have been realized to initiate the piling works. Therefore only diaphragm wall construction stage would be covered within the paper.

To implement the diaphragm wall in required socket lengths in the bedrock formation, hydrofraise machine was mobilized for this project having 81 kNm max. torque per gear box, and 25 rpm max. revolution, with a max cutting depth capacity of 70m (Figure 8).

Figure 8. Diaphragm Wall Machine, Hydrofraise-Cutter

Another reason of implementing the hydrofraise-cutter machine was to provide a better verticality control during the construction of the permanent diaphragm walls. The verticality was monitored parallel to diaphragm wall excavation and direction of the cutter controlled with the help of the flaps on the edges (Figures 9a and 9b).

Figures 9a and 9b. Verticality Control System

During the soil investigations encountered maximum UCS values of the bedrock are given at the Table 2 below.

Table 2. Unconfined Compression Strength (UCS) values- Mpa

UCS Value	Intrusive Dyke		Sandstone		Shale Sandstone	
	Min.	Max.	Min.	Max.	Min.	Max.
	0.7	65	3.6	160	1.0	67

The distribution of the UCS values with the depth is given in Figure 10.

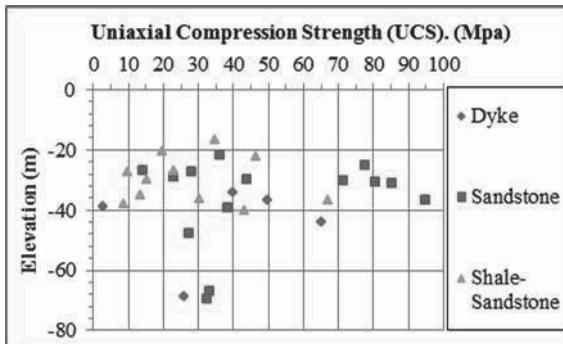

Figure 10. Unconfined Compression Strength (UCS) Values with Depth

The socket length of the diaphragm wall is variable due to the variability of the lithology of bedrock. It is estimated that the minimum 5.0 m socket length in the rock formation will be required. With the utilized hydrofraise cutter diaphragm wall machine, it was possible to construct approximately 2.65 m/day on plan (equals to 60 m<sup>2</sup> diaphragm wall per day) in average.

To integrate the slabs and foundation with the diaphragm walls additional link reinforcements are placed in the reinforcement cage (Figure 11). It is planned to chip the concrete on these elevations to bend the additional reinforcement into the slab and foundation elements.

Figure 11. Additional Link Reinforcements on the Slab Elevations

Prior to diaphragm wall construction on the seaside, it was planned to implement sheet piles at the shore to remove the large quay stones at the back side and to prevent the negative fluctuation effect of the sea during the diaphragm wall construction. Sheet piles also contribute to the overall stability of the quay under the weight of heavy diaphragm wall machine. Sheet piling application is presented in the Figures 12a and 12b.

Figures 12a and 12b Sheet Piling

## 7 CONCLUSIONS

Within the restoration campaign of two beautiful historical mansions from Ottomans alongside the Bosphorus namely Hatice Sultan and Fehime Sultan, four basement floors was planned to be constructed with a maximum excavation depth of 24 m. Tender design for the retaining system of this excavation was temporary diaphragm walls supported with steel tubular struts. Due to the lack of enough spacing between the struts, applicability of the excavation works to achieve the desired speed was found to be questionable. Therefore an alternative system of top down construction method was proposed during the bidding stage. Prior to the excavation, it is proposed to construct the diaphragm wall and bored piles which will be also part of permanent structure of the basement so a remarkable saving and speed together with additional safety could be provided to the project. Another benefit of this system was also allowing extension of bored piles which are also columns of the basement into the bedrock to have desired tension resistance against uplift. This design gave a chance to eliminate the gravel pool proposed in preliminary design and provided additional space in basement floors. Integration of diaphragm wall, slabs and foundation is realized with additional link reinforcements and these reinforcements are placed in their for seen locations during the cage preparation. Sheet piles implemented also successfully prior to the seaside diaphragm wall construction in order to eliminate the negative effect of sea. In spite of the high UCS values it was possible to construct the diaphragm walls socketing 5.0 m deep into the bedrock with high capacity hydrofraise – cutter diaphragm wall machine at a reasonable rate. It is concluded that with the implication of top down construction method, part of this challenging project is completed successfully in economical, safe and timely manner.

## 8 ACKNOWLEDGMENT

We would like to extend our great appreciation to Mr. Hamdi Topcu, Chairman of Executive committee of Turkish Airlines and Mr. Atilla Dogudan, Chairman of Do-Co Corporation. The coordination and cooperation of Guryapi Construction Company are also gratefully acknowledged.

# Experiences with SBMA ground anchors in spanish soils

## Etude expérimentale avec les tirants d'ancrage SBMA dans le sol espagnol

Fernandez Vincent J.M.

Universidad de Buenos Aires, Universidad Catolica Argentina, Geotecnika SRL

**ABSTRACT:** The load transfer mechanism of steel, subjected to axial tension, adhered to a soil or rock through a cement grout is not through a uniform stress distribution. This results from the general incompatibility between the modulus of elasticity of steel, grout and soil, causing the phenomenon known as progressive debonding, as it causes the increase of the load of the anchor. The investigation of this phenomenon, the development of this knowledge and its application to industry has resulted in the SBMA System. This system applies much more efficiently the bond stresses available in the field through the use of various units within a single anchor borehole. We present brief guidelines for their design, and case histories within different geotechnical units in Spain.

**RÉSUMÉ :** Le mécanisme de transfert de charge d'un tirant en acier, soumis à une traction axiale, scellé dans le sol ou le rocher par un coulis de ciment ne se fait pas avec une répartition uniforme des contraintes. Ceci résulte de l'incompatibilité générale entre le module d'élasticité de l'acier, le coulis et le sol, provoquant un phénomène de décollement progressif et d'augmentation de la charge de l'ancrage. L'étude de ce phénomène, le développement d'un savoir et son application à l'industrie sont synthétisés dans le système SBMA. L'utilisation de plusieurs éléments dans un seul forage permet d'augmenter l'efficacité de l'ancrage. La communication présente des directives de conception, et des cas historiques dans différentes unités géotechniques en Espagne.

**KEYWORDS:** design – ground anchor – multiple anchor - load transfer – efficiency factor – fixed length

**MOTS CLES:** Conception, tirants, ancrage multiples, charge de transfert, facteur d'efficacité, longueur de scellement

### 1 INTRODUCTION.

Anchor design codes allow engineers to assume load is distributed uniformly through the length of an anchor, but experts acknowledge that the ultimate load is not proportional to the anchor's fixed length.

Anthony D. Barley's (1995, 1997, 2003) research and development for over a decade confirmed and extended existing independently works coming to the same conclusion of the non-uniformity of the distribution of adhesion in the fixed length anchor, but finally introducing the efficiency factor for calculating the length of the fixed length of an anchor considering this phenomenon. This research was then applied to the development of a new technology for ground and rock posttensioned anchors called Single Bore Multiple Anchor (SBMA).

In 2004 this technology was introduced in Spain, in which the author was responsible. This was done with the technical support of A. Barley.

### 2. DESCRIPTION

The system involves the installation of multiple units in a single anchor borehole. Each unit has its own single tendon, his own free length, length of bulb and is loaded using its own tensioning unit. The tensioning of all anchor units is performed simultaneously by a hydraulic jacks synchronized equipment that ensure that the load applied to the various units is always the same. The sum of the loads of the various units loads totaled the anchor total of the SBMA. With the design conception, there is no theoretical limitation on the overall bond length used (the sum of the fixed lengths of the various units), while for the conventional anchors little increase is expected load over fixed lengths of 8 to 10 meters.

Another advantage of the system is the opportunity to take account of the varying strata within the ground, as each anchor

within a bore can be designed for different ground conditions. Experts agree that the SBMA system is most effective in weak soils either to enhance capacity or to reduce the total number of anchors. However, they are not economically viable where the structural loading requires only low load anchors at wide spacings.

Figure 1. Adhesion stress distribution in several efficient units

### 3. DESIGN

#### 3.1 Efficiency factor

The relationship between the stiffness of the fixed anchor (controlled by the steel tendon) and the stiffness of the ground governs the rate of progressive debonding as an anchor is loaded and hence affects fixed length efficiency.

The nonlinearity of the mobilization of the value of the grout/ground bond stress ( $\tau_{ult}$  vs.  $\tau_{res}$ ) along the fixed length could be accounted by the efficiency factor for ground anchors.

$$f_{eff} = 1.6 \cdot L^{-0.57} \quad (1)$$

Figure 2. Bond stress distribution in the fixed length for different stages of a load test until failure. The area A is the failure load of the fixed length of the anchor. (Barley and Ostermayer, 2003).

Figure 3. Efficiency factor for Ground Anchors, Steel and GRP Soil Nails (Barley, 1997)

The ultimate geotechnical capacity of the anchor ( $T_{ult}$ ) is:

$$T_{ult} = (\pi \cdot d \cdot \tau_{ult}) \cdot f_{eff} \cdot L \quad (2)$$

This formula does not apply to granular soils where the capacity to borehole diameter ( $d$ ) it is not linear and has to be established by meter of fixed length.

All load transfer mechanisms from tendon to grout induce bursting forces in the grout of one degree or another. Generally, the greater the mechanical locking effect (end plate or major deformations) the greater the bursting forces. It follows that the shorter the tendon bond length the greater the mechanical locking to allow the potential transfer of full tendon load capacity. However, this can only be effected where the ground or strong rock will provide adequate confinement of the grout column to prevent bursting failure. So to reduce the inefficiency in load transfer (entire fixed length in shear and tension) it is appropriate to utilize tendon bond lengths long enough to eliminate the risk of bursting failure yet as short as possible to gain maximum efficiency from grout/ground bond (Figure 4).

The high values of bond stress at the grout/ground interface results from the dilatancy effects of the soil in the shear zone, and interlocking at the rough interface, all as a consequence of an increase in radial normal stress.

Figure 4. Probable bond stress distribution in compression and combined shear and tension.

### 3.2 Preliminary tests

Where preliminary trial anchors are tested to failure, each unit anchor yields its own value of ultimate bond capacity and hence more intensive data than conventional test anchors. The in situ testing of many of these multiple anchors with variable unit lengths has therefore recently extended the knowledge and

understanding of the tendon/grout/ground bond mechanism. The SBMA system has been utilized in permanent anchors and temporary anchors (including those with removable tendons).

Test anchors of length 2.5 to 5 metres may easily be taken to failure to establish the ultimate bond stress of that length and then the fixed length of production anchors accurately, designed to provide the required factor of safety. In the trials it is important to control the grouted length tested.

Figure 5. Trial research test with multiple synchronized hydraulic jacks in Parking La Vega, Murcia, 2005.

## 4. CASE HISTORIES

### 4.1 La China Stormwater management pond (Madrid)

In carrying out the excavation depth of 15.0 meters, were implemented temporary SBMA anchors of 2000 kN design load, using four units in the soil strata called "Peñuela" (gypsum with interbedded clays). The system was used always in combination with an injection unit located in each bulb known in spanish specification as IR that involves a postgrouting procedure and each units had 3x0,6" steel strand.

Research trials conducted according to the standard UNE 1537, allowed to change the original traditional ground anchors design, for less multiple anchors with increased load and efficiency.

Figure 6. Section of diaphragm wall with trial anchor test TA2.

Figure 7. Load-deformation curve of trial test unit TA2-A.

#### 4.2 Parking La Vega (Murcia)

For the excavation of a parking 16.0 meters deep, with 9.0 meters of water thrust, one row of temporary SBMA anchors of 1900 kN were executed using four units in a dense gravel. This bearing layer was underlying clays and silts with medium consistency supported by a diaphragm wall thickness of 0.80 m. This solution as an alternative to a 0.60 m thick wall and two levels of traditional anchors.

Figure 8. Section of diaphragm wall with trial anchor test TA1.

Figure 9. Load-deformation curve of trial test unit TA1-B.

#### 4.3 Palacio de los Congresos (Cartagena)

The Cartagena Convention Centre, located next to the port, run an excavation depth of 13.0 meters, with 10.0 meters of water

pressure. The containment wall was formed by a diaphragm wall 1.00 m thick and 2000 kN temporary anchors, bulb units in both compact red clays, and gravelly dense sands according to the geotechnical profile of each sector, and combinations of both soils in the same anchor. The inclination of the anchors was 30 to 40 degrees to the vertical, in order to avoid obstacles and achieve the desired geotechnical units.

Figure 10. Investigation test in trial SBMA anchor in the port zone.

Figure 11. Section of port zone. Diaphragm wall with trial anchor.

Figure 12. Load-deformation curve of trial test unit 55-B.

#### 4.4 El Corte Ingles (Albacete)

In the execution of the excavation depth of 14.0 meters, were implemented temporary anchors SBMA of 1200-1800 kN

design load, using three and four units in clays and silts of medium consistency, supporting a diaphragm wall of 0,80 m thickness with a water head of 10 meters. They were employed four rows of anchors, the first line with traditional anchors and the other three with SBMA.

In the preliminary research trials, within the present cohesive soils ( $N_{SPT} < 8$ ), the distribution of the adhesion along the fixed lengths tested was close to linear. The same is known of loose granular soils.

Figure 13. General view of the jobsite at design excavation level.

Figure 14. Execution of acceptance tests in El Corte Ingles

Within the reference work, we tested the use of multiple removable anchors as a modern solution to urban problems of public land use. This anchor also employs several units, each consisting of a single tendon lubricated and encapsulated in its entire length, which is bent in a special chair 180 degrees. The chair has a steel bar and the whole performs as a compression anchor, which transfers the load to the cement grout and ground. Thereof the anchorage capacity determines the number of units. The cable of each unit is then removed by pulling one of its ends. The complete withdrawal of steel anchors once their useful life is due, freeing of "pollution" of the ground for future use (subway/metro, underground pipes, buildings with deep foundations or basements, etc.)

Figure 15. Removable SBMA units, schematic arrangement.

Figure 16. Removing an anchor unit with a force of 50-150 kN.

## 5. CONCLUSIONS

SBMA ground anchors are currently the most advanced technology for greater efficiency in the use of high adhesion capacity of the ground by the technologies currently employed in the execution of post-tensioned anchors. This system increases the limit loads traditional anchors used in soils, and innovation in paradigms hitherto employed in reference to the design and implementation of the fixed length of an anchor.

The efficiency factor should be complemented with more test data from different soil units with different consistency or relative density; so further detailed test trials research for the better understanding of each geotechnical unit is to be done. Meanwhile, there is experience accumulated in the countries where this technique has been being used the last 20 years.

# Computed and observed ground movements during top-down construction in Chicago

## Mouvements de terrains calculés et observés en construction descendante à Chicago

Finno R.J., Arboleda L., Kern K.

*Department of Civil and Environmental Engineering, Northwestern University, Evanston, IL, USA*

Kim T.

*Korea Railroad Research Institute, Uiwang, Korea*

Sarabia F.

*AECOM, Vernon Hills, IL, USA*

**ABSTRACT:** Two detailed case studies of deep excavations in Chicago made with top down techniques are presented. The importance of considering all aspects of the construction process when estimating ground movements is emphasized. Detailed construction records were maintained at both sites. Inclinometers located within the walls, close to the walls and 7 m from the wall provided lateral movements throughout construction. Ground surface settlements were obtained by optical survey of several hundred observation points at each project. In addition, one of the projects included 88 strain gages installed in the floor slabs to measure time dependent responses of the concrete slabs used as lateral support for more than four years. The movements are presented in relation to construction activities and causes of incremental movements are identified. The lateral movements that arose from cycles of excavation and bracing accounted for approximately one-quarter and one-half the total movements at the two sites. Of these, field performance data and results of numerical simulations showed that approximately 40% of the movements arose from the time-dependent responses of the concrete floor slabs.

**RÉSUMÉ :** Deux études de cas détaillées d'excavation profondes réalisées à Chicago en construction descendante sont présentées. L'accent est mis sur l'importance de prendre en considération tous les aspects du procédé de construction. Des registres de construction détaillés ont été maintenus sur les deux projets. Des inclinomètres situés dans les murs, à proximité des murs et à 7m du mur ont mesuré les déplacements horizontaux tout au long de la construction. Les affaissements de surface ont été observés à l'aide d'un relevé topographique optique comprenant plusieurs centaines de points pour chaque projet. De plus, l'un des projets comprenait 88 jauges de déformations installées dans les dalles de plancher pour mesurer les réponses dans le temps des dalles de béton utilisées comme supports latéraux pendant plus de quatre ans. Les mouvements sont mis en relation avec les activités de construction et les causes des mouvements progressifs sont identifiées. Les mouvements latéraux causés par les cycles d'excavation et de contreventement ont représenté environ la moitié et le quart des mouvements totaux sur les deux projets. Pour ceux-ci, les résultats des tests sur le terrain et des simulations numériques ont montré qu'environ un tiers des mouvements était causé par les réponses dans le temps des dalles de planchers en béton.

**KEYWORDS:** Excavation, top-down support, ground movements, clays, time-dependent concrete response

## 1 INTRODUCTION

Use of top down construction has increased as more developers have seen the benefit of taking the excavation portion of a project off the critical path. Top down methods use permanent walls and flooring systems as temporary support and thus the support systems are very stiff. Yet, there are conflicting data concerning whether resulting movements are smaller than those associated with bottom-up methods. For example, Long (2001) observed no discernible difference in the performance of internally supported, anchored, or top-down systems based on examination of 296 excavation case studies. Kung (2009) reported results of 26 excavations made through Taipei silty clay which showed the maximum lateral wall deflection induced by the top-down methods were 1.3 times larger than that induced by bottom up methods. These observations are surprising given that the floor slabs are in theory much stiffer than either cross-lot braces or ground anchors, and that it is not possible to overexcavate the soil – i.e., make a deeper cut than planned so that the support system is essentially more flexible than planned in design - during construction since one must cast each floor on the ground.

This paper summarizes two case studies of deep excavations in Chicago made with top down techniques. Detailed construction records were maintained at both the Block 37 and One Museum Park West (OMPW) projects. Performance during construction is illustrated with results of inclinometers

located close to the walls and optical surveys of points on the ground adjacent to the excavations. In addition, one of the projects included 88 strain gages installed in the floor slabs to measure for four years the time-dependent responses of the concrete slabs used as lateral support. The movements are presented in relation to construction activities at both sites and causes of incremental movements are identified. It is shown that the movements that occurred during cycles of excavation and bracing are small, and about 40% of these movements are attributable to the time-dependent responses of the concrete slabs. The importance of considering all aspects of the construction process when evaluating movements is emphasized.

## 2 SUBSURFACE CONDITIONS

The subsurface conditions at the two sites are summarized in Figure 1 which shows the natural water contents and undrained shear strengths found from results of site investigations at each location. The surficial layer is an urban fill material consisting of sandy soils and construction debris. Underlying the fill material is a sequence of glacially deposited clays. The first two layers are soft to medium stiff clays which are very similar mineralogically, but exhibit different geotechnical characteristics due to the type of glacial deposition. The Blodgett stratum underlies the urban fill and was deposited in a

supra-glacial environment, which include glaciolucustrine clays and melt-out and flow tills (Chung and Finno, 1992). Because of this complicated depositional environment, the Blodgett generally has variable geotechnical characteristics, including water content, strength and stiffness. A desiccated crust is often present on top of the Blodgett stratum. At these sites, the crust is relatively thin, and in some cases is not present at all. Underlying the Blodgett stratum is a medium stiff clay, called the Deerfield stratum. This stratum exhibits much more uniform geotechnical characteristics than the Blodgett because the Deerfield was deposited as a basal melt-out till or a waterlain paratill. The stiff Park Ridge clay underlies the Deerfield layer. It is generally a little more overconsolidated than the upper clays, with an OCR of about 1.5. A deposit locally known as “hardpan” is found beneath the Park Ridge stratum. The soils in the hardpan are very stiff to hard and consist of silty clays to clayey silts and contain occasional lenses of sandy soils. These soils are basal tills and overconsolidated.

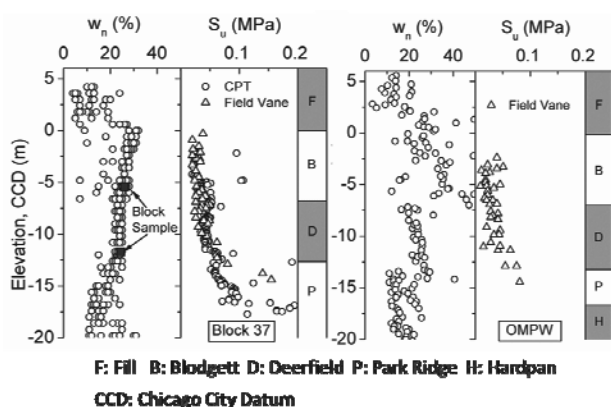

Figure 1. Subsurface conditions

### 3 BLOCK 37 PROJECT

Lateral support for the Block 37 excavation consisted of a 0.9 m thick reinforced concrete slurry wall and four levels of reinforced concrete floor slabs. After installation of the slurry wall, existing foundations from previous buildings were removed. These potholing activities were extensive near the north end of the excavation, and excavations reached as deep as 6 m. After the abandoned foundations and walls were removed, the excavations were backfilled.

Thereafter the excavation progressed in stages to the levels of the four basement floors (B1, B2, B3 and B4). Because the “ground” slab was placed after slab B1, the slurry wall was cantilevered with an unsupported length of about 7 m before any lateral support was placed. Thus this excavation deviated from an ideal top-down construction system because the lateral support was not installed prior to any significant excavation. The contractor made the decision to delay placement of the ground surface slab on the basis of construction expediency. A complete description of the activities at the site and performance of the excavation is found in Kern (2011).

#### 3.1 Ground movements during construction

The development of ground movements during construction is summarized in Figure 2. The optical survey points and inclinometer were located adjacent to the north wall of the excavation. The settlements are typical of the maximum values measured along this side of the excavation. The horizontal movements were taken from an inclinometer located 1 m behind the slurry wall near its center and were taken from elevation – 9 m CCD. Lateral movements versus depth will be discussed in the next section. Also shown on the figure is a record of the

construction activities so the causes of the movements are apparent.

Figure 2. Settlements and lateral movements at Block 37

The maximum settlement and lateral movement observed at this section was 36 mm. As is apparent from the figure, significant ground movements developed during both the potholing activities and the first portion of the excavation when the large cantilever stage existed as the contractor excavated to the B1 slab level. These activities caused about 60% of the settlements that developed throughout the entire construction process. This large percentage was caused by the contractor’s decision to start the top-down process after the first level basement was constructed. The removal of the old foundations and slabs also contributed to the relatively large movements observed along this wall.

#### 3.2 Lateral movements adjacent to wall

Typical distributions of lateral ground movements with depth are shown in Figure 3 for inclinometers located 1 m and 7 m from the wall. These inclinometers were installed prior to any construction at the site and thus indicate the complete lateral response. The large influence of the potholing and initial cantilever stage of the excavation is seen clearly in the results.

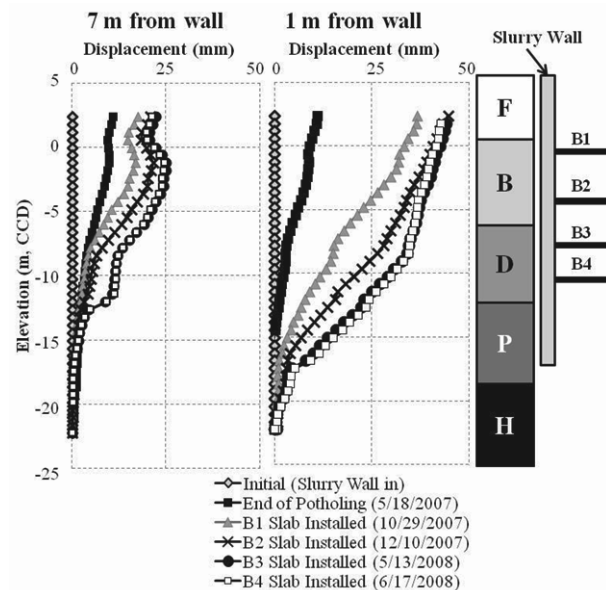

Figure 3. Lateral ground movements at Block 37

### 4 ONE MUSEUM PARK WEST PROJECT.

The One Museum Park West project involved constructing a 53-story reinforced concrete tower with a central core and four or five basement levels that extended approximately 15.3 m

below grade. The central core was excavated using a circular cofferdam, consisting of a sheet-pile wall and horizontal ring beams for internal bracing. The construction of the tower core was performed in a conventional “bottom-up” manner. The basement was constructed with steel beam reinforced concrete secant pile walls using top-down construction procedures. After leveling the site, the perimeter wall was installed and caisson foundations constructed. After the central core cofferdam was built, the excavation of the remainder of the site is being made with “top-down” construction methods. The perimeter secant pile wall is utilized as a permanent load bearing wall. Lateral bracing is provided by 4 or 5 levels of permanent floor slabs, depending on the location within the structure. After the ground level slab was cast integrally with the slurry wall, excavation proceed top-down by excavating to the bottom of the second level floor slab, casting that slab integrally to the slurry wall, and repeating the process until the final excavation depth was reached. Detailed descriptions of the construction and performance of this project are found in Sarabia (2012) and Arboleda (2013).

The development of ground movements during construction is summarized in Figure 4. Again, both settlements and lateral movements are represented in the figure. In this case, only the settlements provide a complete record of the ground response during construction. The inclinometers were located within 1 m of the secant pile wall at all locations, and were damaged as the wall was installed. Replacement inclinometers were initialized prior to the start of top-down excavation, so these data do not reflect deformations that developed as the wall and caissons were installed, or as the central core cofferdam was constructed. The data for the lateral movements were taken from the location of the maximum lateral movement recorded by the inclinometer, in this case, from elevation -8 m CCD. The settlements are typical of the maximum values measured along the west side of the excavation. Also shown on the figure is a record of the construction activities so the causes of the movements are apparent.

Figure 4. Settlements and lateral movements at OMPW

The maximum settlement observed at this section was 150 mm and the maximum lateral movement was 30 mm. As is apparent from the figure, significant ground movements developed throughout construction. The portions of the settlements that occurred during different phases of construction are summarized in Table 1. The activities before the top down portion of the project started resulted in 75% of the total settlements observed during construction.

Table 1. Settlements during construction activities

Construction activity	Settlement (mm)
Secant pile wall installation	11
Caisson installation	12
Water main relocation	5
Central cofferdam construction	12
Top-down construction	13

## 5 WALL MOVEMENTS DURING EXCAVATION

The lateral deformations that were recorded at OMPW only reflect those that occurred during top-down construction. Data from an inclinometer located in the middle of the west wall are shown on Figure 5. Also shown on the figure are the lateral movements that developed at Block 37 during the top-down phase of that construction, i.e., those after slab B1 was cast.

Figure 5. Lateral movements during top-down excavation only

The trends in these data reflect expected responses for an excavation made using top-down methods with very stiff walls and supports. Very little lateral movement is observed at the uppermost slab which was cast at the ground surface. The normalized maximum horizontal movements (movement/depth of excavation) were 0.14% and 0.2% at the Block 37 and OMPW sections, respectively. These values are more in line with what one would expect from a very stiff excavation with no overexcavation. However, it is clear that movements developed at both sites as a result of other construction activities or procedures that were not employed with the goal of minimizing ground movements. When using precedent for a first order estimate of expected ground movements for a top-down procedure, these data provide useful estimates. One should not indiscriminately use performance data without considering all activities that occurred during construction.

## 6 TIME-DEPENDENT RESPONSES OF FLOOR SLABS

The concrete floor slabs that serve as lateral bracing for these two projects were cast integrally with the support walls. As such, the floor slabs contracted as the concrete cured and crept under load. This time-dependent component of movement contributed to the wall deformations and analyses were conducted to evaluate the magnitude of this effect. Eighty-eight vibrating wire strain gages were cast into the OMPW slabs at four levels and at five sections so as to directly measure the strains in the slab that developed over time. Detailed descriptions of the instrumentation and results of analyses are given in Arboleda (2013).

To illustrate the influence of the time-dependent properties of concrete on the lateral movements of the secant walls, 3D

finite element simulations of the top-down construction process were conducted using SAP2000. The nonlinear time-dependent concrete effects of shrinkage, creep and variation of the modulus of elasticity with time were considered in the analysis. The analysis was performed in a step-by-step basis for the entire construction sequence using nonlinear stage construction without geometric nonlinearity.

Figure 6 shows the model after the first basement level was placed. The reinforced concrete columns and caissons were modeled as frame elements whereas the basement slabs, secant walls, foundation mat, corewalls, and interior shear walls were modeled as thin shell elements. The cross section of the secant walls consisted of concrete elements with embedded wide flange sections (W24, W33) and was modeled using an equivalent thickness based on the transformed section. Structural loads were applied, but lateral earth loads were not.

Figure 6. Model for time-dependent slab response at OMPW

The concrete was assumed isotropic with compressive strength taken from the as-built structural drawings and verified with the concrete reports provided by the contractor. The time-dependent behavior of concrete was included only for the basement slabs. The concrete properties were calculated based on standard concrete practice methods defined in ACI (2011) for a Poisson ratio of 0.2. The nonlinear variation of shrinkage with time was based on average values of the standard concrete practice codes: ACI 209, CEB-FIP 1990, AASHTO LRFD 2010, AS3600-2009, and NEN 6720.

The results of the analyses are given in Figure 7, where both the computed time-dependent movements of the walls at the end of each slab placement stage are compared to the total lateral movements of an inclinometer 1 m behind the wall. The lateral movements shown correspond to those that developed after the excavation to the first slab level was made, so that one can directly see the contributions of the time-dependent movements to the lateral deformations. About 40% of the lateral movements can be attributed to the time dependent effects of the concrete slabs.

## 7 CONCLUSION

Based on the results of the data and analyses summarized herein, the following conclusions can be drawn regarding these two excavations:

Figure 7. Computed time-dependent and observed lateral movements after slab B4 placed at OMPW

1. Top-down excavations in clays can be expected to result in normalized horizontal movements of approximately 0.15 to .2% when the uppermost slab is placed close to the ground surface so as to minimize the cantilever movements associated with the excavation process.
2. Of these “top-down” movements, approximately 40 % could be attributed to the time-dependent response of the concrete floor slabs.
3. Other construction activities or expedient excavation procedures led to movements that constituted 60 to 75% of the total movements that developed during construction. Use of precedence in estimating ground movements must be tempered by a realization of other site activities that can lead to ground movements.

**ABSTRACT:** Geogrids made of geosynthetics can replace conventional building materials like concrete. In this article, goal and scope, basic data and the results of a comparative life cycle assessment of concrete reinforced retaining walls (CRRW) and geosynthetics reinforced retaining walls (GRRW) are described. One running meter of a three meters high retaining wall forms the basis for comparison. The two walls have the same technical performance and an equal life time of 100 years. The GRRW has a lower demand of steel and concrete compared to the CRRW. The product system includes the supply of the raw materials, the manufacture of the geotextiles and the concrete, the construction of the wall, its use and its end of life. The life cycle assessment reveals that the GRRW causes lower environmental impacts. The cumulative greenhouse gas emissions of 300 m CRRW are 400 t and 70 t in case of GRRW. The use of an environmentally friendlier lorry in a sensitivity analysis and monte carlo simulation confirm the lower environmental impacts caused by the construction of a GRRW compared to a CRRW. More than 70 % of the environmental impacts of the geogrids production are caused by the raw material provision (plastic granulate) and the electricity demand in manufacturing.

**RÉSUMÉ :** Géogrids peuvent remplacer les matériaux conventionnels comme le béton. Cet article contient une description de la définition de l'objectif et du champ d'étude, de l'analyse de l'inventaire et des résultats d'un analyse de cycle de vie comparative d'un épaulement géotextile et conventionnel. La comparaison est faite sur un mètre courant d'un épaulement de trois mètre d'hauteur. Les deux alternatives ont les mêmes propriétés techniques et la même durée de vie de 100 ans. Les systèmes contiennent la provision des matériaux, la fabrication des géotextiles et du béton, la construction, l'utilisation et l'évacuation de l'épaulement. L'analyse de cycle de vie démontre qu'un mètre courant d'un épaulement géotextile cause moins d'impacts environnementaux qu'un mètre courant d'un épaulement de béton. 300 mètres d'un épaulement de béton entraîne 400 t CO<sub>2</sub>-eq, celui de géotextile 70 t CO<sub>2</sub>-eq des émissions des gaz à effet de serre. L'utilisation des camions avec les émissions réduites ne change pas les résultats. Une simulation « monte carlo » confirme la stabilité des résultats. La provision des matériaux et l'électricité utilisé dans la fabrication de la couche de filtre géotextile sont des facteurs primordiaux (plus que 70 %) en ce qui concerne les impacts environnementaux du géogrid utilisé dans l'épaulement géotextile.

**KEYWORDS:** retaining wall, slope retention, geosynthetics, concrete, geogrid, life cycle assessment, LCA

**MOTS CLÉS :** épaulement, géotextile, géogrid, béton, analyse de cycle de vie, ACV

## 1 INTRODUCTION

Geosynthetic materials are used in many different applications in civil and underground engineering, such as in road construction, in foundation stabilisation, in landfill construction and in slope retention. In most cases they are used instead of minerals based materials such as concrete, gravel or lime.

Environmental aspects get more and more relevant in the construction sector. That is why the environmental performance of technical solutions in the civil and underground engineering sector gets more and more attention.

The European Association for Geosynthetic Manufacturers (E.A.G.M.) commissioned ETH Zürich and Rolf Frischknecht (formerly working at ESU-services Ltd.) to quantify the environmental performance of commonly applied construction materials (such as concrete, cement, lime or gravel) versus geosynthetics (Stucki et al. 2011).

In this article, the results of a comparative Life Cycle Assessment (LCA) of slope retention are described. The slope retention is either provided by a concrete reinforced retaining

wall (CRRW) or a geosynthetics reinforced retaining wall (GRRW).

The environmental performance is assessed with eight impact category indicators. These are Cumulative Energy Demand (CED, Frischknecht et al. 2007), Climate Change (Global Warming Potential, GWP100, Solomon et al. 2007), Photochemical Ozone Formation (Guinée et al. 2001a; b), Particulate Formation (Goedkoop et al. 2009), Acidification (Guinée et al. 2001a; b), Eutrophication (effects of nitrate and phosphate accumulation on aquatic systems, Guinée et al. 2001a; b), Land competition (Guinée et al. 2001a; b), and Water use (indicator developed by the authors). The calculations are performed with the software SimaPro (PRé Consultants 2012).

## 2 GEOSYNTHETIC VERSUS CONCRETE RETAINING WALL

It may be necessary in some cases, especially in the construction of traffic infrastructure, to build-up very steep walls. For such walls, supporting structures are necessary. The retaining walls need to meet defined tensile and shear

strengths. Retaining walls can be reinforced with concrete or geogrid made of geosynthetics.

The functional unit is defined as the construction and disposal of 1 m slope retention with a 3 meters high wall, referring to a standard cross-section. Thus, the functional unit is independent of the length of the wall.

Polyethylene and PET granules are used as basic material of the geogrid. The geogrid has to achieve a long-term strength of 14 kN/m. A scheme of both types of retaining walls are shown in Fig. 1.

Figure 1. Scheme of the concrete reinforced retaining wall (CRRW, left) and the geosynthetics reinforced retaining wall (GRRW, right)

Some important key figures of the construction of a reinforced retaining wall are summarized in Tab. 1. The information refers to one meter of slope retention infrastructure and a time period of 100 years. Diesel is used in building machines for the excavation of the foundation and the compaction of the ground. The NMVOC emissions shown are released from the bitumen used to seal the concrete wall. The use of recycled gravel is not considered, since usually no onsite recycled gravel with specific properties is available when building reinforced retaining wall for the first time.

Tab. 1 shows specific values of the retaining walls for both alternatives. The material on site is used as fill material, wall embankments and cover material in case of a GRRW. A drainage layer made of gravel with a thickness of at least 30 cm behind the concrete lining is necessary. To be consistent with the CRRW, a gravel layer thickness of 80 cm is assumed in both cases. Round gravel is used for drainage purposes.

Table 1. Selected key figures describing the two constructions of one meter reinforced retaining wall

	Unit	CRRW	GRRW
Concrete	m <sup>3</sup> /m	1.60	-
Lean mix concrete	m <sup>3</sup> /m	0.24	-
Structural concrete	m <sup>3</sup> /m	2.10	0.31
Reinforcing steel	kg/m	153	-
Gravel	t/m	4.3	4.3
Bitumen	kg/m	2.84	-
Three layered laminated board	m <sup>3</sup> /m	0.01	-
Geosynthetic	m <sup>2</sup> /m	-	39.2
Polystyrene foam slab	kg/m	0.25	-
Polyethylene	kg/m	1.74	2.02
Diesel in building machine	MJ/m	11.6	53.9
Transport, lorry	tkm/m	701	265
Transport, freight, rail	tkm/m	33.2	6.9
Land use	m <sup>2</sup> /m	1.0	0.6
NMVOC	g/m	20	-

The difference between the CRRW and GRRW lies in the amount of concrete, steel and bitumen used, the energy con-

sumption that is related to the slope retention used (material transportation, excavation etc.), and the use of geosynthetics.

In a sensitivity analysis, it is analysed how the results of the slope retention change, when a low emission Euro5 lorry (>32 t) is used for the transportation of the materials to the construction site instead of an average European lorry (>16 t).

### 3 MANUFACTURING OF THE GEOGRID

Data about geosynthetic material production are gathered at the numerous companies participating in the project using pre-designed questionnaires. The company specific life cycle inventories are used to establish average life cycle inventories of geosynthetic material.

The data collected include qualitative information of system relevant products and processes from the producer, information from suppliers of the producer (where possible) as well as data from technical reference documents (e.g. related studies, product declarations, etc.). Average LCI are established on the basis of equally weighted averages of the environmental performance of the products manufactured by the participating companies.

The primary source of background inventory data used in this study is the ecoinvent data v2.2 (ecoinvent Centre 2010), which contain inventory data of many basic materials and services. In total, data from 5 questionnaires concerning the production of geosynthetic geogrids used in slope retention applications are included. The quality of the data received is considered to be accurate. The level of detail is balanced in a few cases before modelling an average geosynthetic layer.

Tab. 2 shows important key figures of the production of an average geosynthetic geogrid

Table 2. Selected key figures referring to the production of 1 kg geosynthetic layer used in slope retention

	Unit	Value
Raw materials	kg/kg	1.02
Water	kg/kg	0.86
Lubricating oil	kg/kg	7.30*10 <sup>-5</sup>
Electricity	kWh/kg	0.73
Thermal energy	MJ/kg	1.24
Fuel for forklifts	MJ/kg	0.13
Building hall	m <sup>2</sup> /kg	6.32*10 <sup>-6</sup>

### 4 LIFE CYCLE IMPACT ASSESSMENT

In this section the environmental impacts of 1 m slope retention with a height of 3 m over the full life cycle are evaluated. The life cycle includes the provision of raw materials as well as the construction and disposal phases.

In Fig. 2 the environmental impacts over the full life cycle of the slope retention are shown. The environmental impacts of the case with the highest environmental impacts are scaled to 100%. The total impacts are divided into the sections wall, raw materials (concrete, gravel, geosynthetic layers, reinforcing steel, bitumen, wooden board), building machine (construction requirements), transports (of raw materials to construction site) and disposal of the wall (includes transports from the construction site to the disposal site and impacts of the disposal of the different materials).

The GRRW (4B) causes lower environmental impacts compared to the CRRW (4A) in all impact categories considered. The non-renewable cumulative energy demand of the construction and disposal of 1 meter CRRW (4A) with a height of 3 meters is 12'700 MJ-eq and 3'100 MJ-eq in case

of GRRW (4B). The cumulative greenhouse gas emissions amount to 1.3 t CO<sub>2</sub>-eq in case of the CRRW (4A) and 0.2 t CO<sub>2</sub>-eq in case of the GRRW (4B). Correspondingly, the cumulative greenhouse gas emissions of 300 m CRRW (4A) are 400 t and 70 t in case of GRRW (4B).

The most relevant aspects concerning the environmental impacts of the life cycle of the CRRW (4A) are concrete, reinforcing steel, transportation and disposal. This order of relevance changes depending on the impact category indicators. The high share of concrete in the global warming indicator can be explained by the production process of clinker. During its calcination process geogenic CO<sub>2</sub> emissions arise. Reinforcing steel consists of 63 % primary steel and 37 % recycled steel. Most environmental impacts of the reinforcing steel arise from the fuel consumption and the emissions during the sinter and pig iron production in the supply chain of the primary steel. Disposal includes the disposal as well as transports from the construction site to the disposal site in case the material is not recycled. Impacts of disposal are dominated by the high amount of concrete which is landfilled. While direct emissions of landfilling concrete are negligible, the construction of the landfill and the transport of concrete to the landfill site are important. The land competition indicator is strongly influenced by the direct land use of the slope retention as well as by the wooden board used in the formworks. Gravel is responsible for a considerable share of the total amount of water used because substantial amounts of water are needed in gravel production.

Concrete, the geosynthetic and transportation mostly cause the highest burdens of the life cycle of the GRRW (4B). The share of the geogrid to the overall impacts is relatively high because on one hand several layers, and thus a considerable amount of geogrid, are required. On the other hand most materials used in the construction of the slope retention are available on-site and thus do not cause substantial environmental impacts (compare Tab. 1). The disposal gains importance in the categories eutrophication and global warming. The global warming impacts of disposal are caused by burning geogrids in waste incineration plants, which leads to fossil CO<sub>2</sub> emissions. Gravel dominates the water use indicator and the direct land use of the slope retention wall during its use is dominating land competition.

The main driving forces for the difference between CRRW (4A) and GRRW (4B) are the higher amount of concrete used in CRRW (4A) as well as the use of reinforcing steel, which additionally leads to higher transport expenditures. With regard to CED renewable and land competition the wooden board additionally increases the difference in total impacts because wood is a renewable resource with a high direct land occupation. Direct land competition is lower for the GRRW (4B) because the sprayed concrete lining is thinner than the CRRW (4A) and the embankment and backfilling area is not considered as occupied land.

The share of the geosynthetic material on the overall environmental impacts is between 3 % and 44 % (water use and CED non-renewable, respectively).

Figure 2. Sensitivity analysis: Environmental impacts of the life cycle of 1 m conventional (4A) and geosynthetic retaining wall (4B). 4AS1 and 4BS1 refer to the sensitivity analysis with a Euro5 lorry transportation. For each indicator, the case with highest environmental impacts is scaled to 100%.

#### 4.1 Sensitivity analysis

In a sensitivity analysis, it is analysed how the results of the slope retention change, when a Euro5 lorry (>32 t) is used for the transportation of the materials to the construction site instead of an average European lorry (>16 t).

Fig. 2 reveals that if a Euro5 lorry with lower exhaust emissions is used for the transportation, the environmental impacts of the GRRW (4BS1) are reduced between 0.1 % and 22.8 % (land competition and eutrophication respectively), whereas the environmental impacts of the CRRW (4AS1) are decreased between 0.2 % and 13.2 % (land competition and eutrophication respectively). The use of a Euro5 lorry leads among others to lower NO<sub>x</sub> emissions, which influences eutrophication. Land competition is obviously not influenced much by using another type of lorry.

#### 4.2 Contribution Analysis Geosynthetic Production

In this section the environmental impacts of 1 kg geogrid are evaluated. The life cycle includes the provision and use of raw materials, working materials, energy carriers, infrastructure and disposal processes. The category geosynthetic in Fig. 3 comprises the direct burdens of the geosynthetic production. This includes land occupied to produce the geosynthetic as well as process emissions (e.g. NMVOC, particulate and COD emissions) from the production process but not emissions from electricity and fuel combustion which are displayed separately. The environmental impacts of the geogrid are shown in Fig. 3. The cumulative greenhouse gas emissions amount to 3.4 kg CO<sub>2</sub>-eq per kg.

Environmental impacts are mostly dominated by the raw material provision and electricity consumption. Raw material

includes different types of plastics. Country-specific electricity mixes are modelled for each company and thus impacts of electricity consumption depend not only on the amount of electricity needed but also on its mix. The higher share of electricity in CED renewable can be explained by the use of hydroelectric power plants in the electricity mixes of several factories. And the relatively high share in eutrophication is mainly due to electricity from lignite. The share of heating energy and fuel consumption for forklifts is between 0.01 % (land competition) and 2.8 % (global warming) and is thus not considered to be of primary

importance. With regard to land competition the geosynthetic production plays an important role. The impacts are dominated by the direct land use, i.e. land which is occupied by the manufacturer plant in which the geosynthetic is produced. Indirect land uses, i.e. land occupation stemming from upstream processes, are significantly lower because no land occupation is reported in the inventories of plastic feedstock and no land intensive products such as wood are used in considerable amounts. Water consumption is included in the working materials. As a consequence, this category bears about 5 % of the total amount of water used.

Figure 3. Environmental impacts of the life cycle of 1 kg geogrid. Geosynthetic includes direct burdens of the geosynthetic production. Raw materials include plastic, extrusion if necessary and additives, working materials include water (tap and deionised) and lubricating oil, other energy includes thermal energy and fuels, infrastructure covers the production plant and disposal comprises wastewater treatment and disposal of different types of waste.

## 5 DISCUSSION AND CONCLUSION

The use of geosynthetics leads to lower environmental impacts of slope retention in all indicators investigated. The specific climate change impact of the construction of the slope retention (1 m slope retention with a 3 meters high wall) using geosynthetics is about 1 ton CO<sub>2</sub>-eq per meter lower compared to a conventional alternative. This difference is equal to about 84 % of the overall climate change impact of the construction and disposal efforts of an entire conventional slope retention system during its 100 years lifetime.

If a Euro5 lorry with lower exhaust emissions than an average fleet lorry is used for the transportation of materials, the environmental impacts of both cases are somewhat reduced regarding some indicators. However, this does not affect the overall conclusions of the comparison.

Slope retentions are individual solutions in a particular situation. The height of slope retention walls and the horizontal loads on it may differ, which may lead to differences in thickness and reinforcement. Thus, generalising assumptions were necessary to model a typical slope retention. Data about on-site material used, gravel extraction, concrete and the use of building machines are based on generic data and knowledge of individual civil engineering experts.

Based on the uncertainty assessment it can be safely stated that the geosynthetics reinforced slope retention shows lower environmental impacts than the concrete wall. Despite the necessary simplifications and assumptions, the results of the comparison are considered to be significant and reliable.

A geosynthetic reinforced wall used for slope retention constitutes a different system compared to a concrete reinforced wall. Nevertheless, both systems provide the same function by enabling the build-up of steep walls. Compared to the conventional slope retention, the geosynthetic reinforced wall substitutes the use of concrete and reinforcing steel, which results between 63 % and 87 % lower environmental impacts.

# Design of inverted T-shaped Cantilever Wall with a Relief Floor

## Conception d'un mur équerre avec dalle de délestage

Ganne P.P., Raucroix X.

Engineering department, BESIX, Gemeenschappenlaan 100, 1200 Brussels, Belgium

**ABSTRACT:** Cantilever walls are widely used as ground retaining structures. The analytical approach of L-shaped and inverted T-shaped cantilever walls results in reliable designs. This paper proposes and discusses an analytical approach for the geotechnical design of inverted T-shaped cantilever walls with relief floor. This approach combines the analytical approaches of inverted T-shaped walls and of relief floors. The resulting analytical approach is verified by numerical simulations of inverted T-shaped cantilever walls with relief floor for 5m till 10m high retaining structures in unsaturated sandy soils, silty soils and alluvial clayey soils. Finally, rules of thumbs for typical dimensions of the inverted T-shaped cantilever wall with relief floor are given, based on experience, analytical calculations and numerical simulations.

**RÉSUMÉ :** Les murs équerres sont communément répandus comme structure de soutènement. D'un point de vue de la conception géotechnique, les méthodes analytiques sont éprouvées. Cet article propose et discute une approche analytique pour la conception géotechnique des murs équerres avec dalle de délestage. Cette approche combine l'approche de dimensionnement analytique des murs équerres avec l'effet d'ombre des dalles de délestage. L'approche analytique proposée est justifiée à l'aide de simulations numériques modélisant des murs équerres avec dalle de délestage reprenant des différences de niveau allant de 5m à 10m et ce, dans des sols non-saturés de nature sableuse, silteuse et alluvio-argileuse. En conclusion, des dimensions typiques de murs équerres avec dalle de délestage sont données, basées sur l'expérience, des calculs analytiques et des simulations numériques.

**KEYWORDS:** inverted T-shaped cantilever wall, relief floor, soil retaining structure, finite element code

### 1 INTRODUCTION

In recent decades, the number of installations of permanent ground retaining structures is drastically increasing. One of the oldest ground retaining structures are the gravity walls. They have a very easy way of realization and are particularly suitable for retained heights of less than 3m. While they can be designed for greater heights, other types of retaining walls such as L-shaped cantilever walls are usually more economical as the height increases.

L-shaped cantilever walls uses the soil upon the heel to stabilize the horizontal soil pressures. One of the disadvantages of the L-shaped cantilever walls is the high ratio between the horizontal loads due to soil pressures and the vertical soil weight, causing a disadvantageous eccentricity of the forces at the base slab. Therefore, the length of the base slab can amount up to 70% (sandy soils) and up to 120% (alluvial clay) of the retaining height. In most projects, the realization of L-shape structure is not possible due to the lack of required space to excavate up to the rear edge of the base slab level with a reasonable slope.

It is usually more economical to design the L-shaped cantilever wall with a toe at its front side: the inverted T-shaped cantilever wall. This increases the moment arm and reduces the disadvantageous eccentricity of the forces in the base slab. The distance between the front of the stem and the back of the heel of the cantilever wall amounts to 50% (sandy soils) or to 60% (alluvial clay) of the retaining height.

In some cases, it is more economical to further reduce the required space between the front wall face and the temporary slope at the back of the structure. In these cases, a relief floor

could be added : the inverted T-shaped cantilever wall with relief floor. In this way, (1) the disadvantageous horizontal soil forces are reduced and (2) the disadvantageous eccentricity of the forces at the base slab could be reduced, generally down to a negligible low value. The distance between the front of the stem and the back of the heel of the cantilever wall amounts only 20% (sandy soils) or to 40% (alluvial clay) of the retaining height.

The construction of the inverted T-shaped cantilever wall with a relief floor itself is in most of the cases of lower economical interest than the inverted T-shaped cantilever wall. Nevertheless, reducing the space between the front of the stem and the heel, increases the available space for the excavation, necessary to reach the level of the base slab. The possible economic benefit may be found in the less expensive temporary excavation method.

The geometry of an inverted T-shaped cantilever wall with a relief floor depends on the conditions of the specific project. Therefore, each realization must be based on thorough geotechnical evaluation of its design, a hydrogeological evaluation, a detailed structural design, an analyses of the construction methodology and a general risk evaluation.

This paper proposes a simplified analytical approach for the geotechnical design of the inverted T-shaped cantilever wall with a relief floor. This simplified analytical approach is checked by numerical simulations for unsaturated sandy soils, silty soils and alluvial clays. Finally, typical dimensions which can be used for predesign estimations are given, based on experience, analytical and numerical calculations.

### 1 ANALYTICAL APPROACH OF A L-SHAPED WALL WITH A RELIEF FLOOR

The envisaged geotechnical structure is an inverted T-shaped cantilever wall with a relief floor. Figure 1 shows a typical section of this construction with a retaining soil height of 8.6m. The foundation level is 0.8m below ground surface, in order to place it under the frost line. In order to study the behavior of this structure, a brief review of the behavior of L-shaped cantilever walls and the influence of a relief floor is given, before the global analytical approach is proposed.

Figure 1. View of the inverted T-shaped cantilever wall with a relief floor of 3.9 m.

#### 1.1 Geotechnical principle of L-shaped cantilever wall

The geotechnical behavior of a L-shaped or an inverted T-shaped cantilever wall is quite complex (Figure 2). When the L-shaped wall fails geotechnically, the failure surfaces E-F, A-D and A-C occur. All these failure surfaces have an inclination of  $\pi/4 - \varphi/2$  from the vertical A-B (further called 'virtual back'). All the soil in the block A-C-D can be described as active Rankine soil. The block A-C-F-E deforms and slides downwards simultaneously. The soil pressure distribution in the block A-C-D is symmetrical about the vertical A-B, on which horizontal soil pressures are present. This theory is confirmed by numerical modeling (e.g. Arnold, 2010).

Figure 2. Soil rupture surface (wing shape : C-A and E-F) of a L-shaped cantilever wall (after Vandepitte, 1979).

It is shown that this complex geotechnical behavior of the L-shaped or an inverted T-shaped cantilever wall is equivalent to the following simplified structure (Rouili et al. 2005; Vandepitte 1979). The wall together with the backfill up to a vertical plane above its heel (A-B i.e. 'virtual back') is treated as a monolithic block. Gravity forces, surface loads and horizontal active soil pressures acting at the virtual back may be assumed. This block is checked against sliding, overturning and

bearing capacity failures in the ultimate limit state (GEO 2000; Frank et al. 2004).

This approach is mathematically equivalent to the consideration of the wall together with the backfill up to the plane A-C (Figure 3).

It has to be stressed that though the two above approaches are equivalent for the design of the L-shaped or an inverted T-shaped cantilever wall, the wing-shaped soil rupture surface is the only physical failure mode.

Figure 3. Alternative design rupture surface C-A-E of a L-shaped cantilever wall (after Vandepitte, 1979).

#### 1.2 Geotechnical principle of a relief floor

Geotechnical constructions sometimes uses a relief floor. If the relief floor is rigidly build-in in the geotechnical construction, it implies three stabilizing effects (Figure 4):

1. the backfill in the area A'-A-B engenders a stabilizing moment against overturning,
2. a reduction of the total horizontal soil pressure, increasing the safety to sliding,
3. a reduced eccentricity of the global force at the base, increasing the bearing capacity.

Figure 4. Four zones of soil pressure distribution A-C, C'-D, D-E and E-F. (after Vandepitte, 1979).

Four zones of horizontal soil pressure can be distinguished:

- Zone 1 : A-C is not influenced by the relief floor.
- Zone 2 : C'-D is totally influenced by the relief floor. The horizontal soil pressure is 0 in C'.
- Zone 3 : D-E is partly influenced by the relief floor. The horizontal soil pressures increases linearly from d to e.
- Zone 4 : E-F is not influenced by the relief floor. The horizontal soil pressure correspond to the active soil pressure, taking into account the surface level A'A and the present surface load.

#### 1.3 Simplified analytical approach of an inverted T-shaped cantilever wall with a relief floor.

The proposed simplified analytical approach combines the theory of the L-shaped cantilever wall and the theory of the relief floor. Two virtual backs are defined : upper virtual back A-B and lower virtual back C'-F (Figure 5).

The wall together with the backfill up to the virtual backs (A-B and C'-F) is treated as a monolithic block. Surcharges and horizontal active soil pressures acting on the virtual backs and gravity forces may be taken into account. On the lower virtual back (under the relief floor level), horizontal soil pressures as described in §1.2 are assumed. This monolithic block is checked against sliding, overturning and bearing capacity failures in the ultimate limit state.

It has to be stressed that the above approach is a simplification of the physical behavior. The physical soil rupture surface does not follow the two virtual backs, but corresponds more with wing-shapes.

Figure 5. Virtual backs as in the analytical approach of an inverted T-shaped cantilever wall with a relief floor.

## 2 NUMERICAL SIMULATION OF INVERTED T-SHAPED CANTILEVER WALL WITH RELIEF FLOOR

For the numerical validation of the inverted T-shaped cantilever wall with a relief floor, two-dimensional finite element code PLAXIS is used. The Hardening soil model in plane strain is used to model the soil (Brinkgreve et al. 2002).

### 2.1 Simulation of excavation stages

Accomplishment of physical modeling, including simulation for gravity stresses is followed with the calculation program. Simulation of the entire inverted T-shaped cantilever wall with relief floor is carried out in a sequence of construction stages. In each construction stage a sufficient number of calculation steps are used to obtain an equilibrium-state:

- Stage 1 : initial situation (gravity loading, soil with temporary cohesion)
- Stage 2 : excavation till bottom level of the cantilever wall (soil with temporary cohesion)

Table 1. Soil parameters of sandy soil, silty soil and clayey soil, as used in the numerical simulations (the stiffness is expressed at a reference pressure of 100 kPa).

	Sandy soil	Silty soil	Clayey soil
$\gamma_{\text{unsat}}$	17kN/m <sup>3</sup>	18kN/m <sup>3</sup>	17kN/m <sup>3</sup>
$E^{\text{ref}}_{\text{oad}}$	22,30.10 <sup>3</sup> kN/m <sup>2</sup>	6.10 <sup>3</sup> kN/m <sup>2</sup>	4.10 <sup>3</sup> kN/m <sup>2</sup>
$E^{\text{ref}}_{50}$	22,30.10 <sup>3</sup> kN/m <sup>2</sup>	9.10 <sup>3</sup> kN/m <sup>2</sup>	8.10 <sup>3</sup> kN/m <sup>2</sup>
$E^{\text{ref}}_{\text{ur}}$	66,90.10 <sup>3</sup> kN/m <sup>2</sup>	36.10 <sup>3</sup> kN/m <sup>2</sup>	40.10 <sup>3</sup> kN/m <sup>2</sup>
$m$	0,50	0,75	1,00
$c^{\text{temp}}$	4kPa	4kPa	4kPa
$c^{\text{perm}}$	0,1kPa	2kPa	4kPa
$\phi^{\text{p}}$	30°	25°	22°

- Stage 3 : construction and back fill of the cantilever wall till level of relief floor (soil with temporary cohesion)
- Stage 4 : Construction and back fill of the relief floor till final level (final situation, permanent soil parameters, SLS)
- Stage 5 : Determination of factor of safety using c-phi reduction (ULS).

The model simulates 100m (length) by 50m (depth) using 4825 elements (15-noded). The elements around the inverted T-shaped cantilever with relief floor are highly refined. The geotechnical behavior is simulated in unsaturated sandy soils, silty soils and alluvial clayey soils (Table 1).

### 2.2 Numerical simulation of an inverted T-shaped cantilever wall in sandy soil

A typical section of inverted T-shaped cantilever wall is simulated (Figure 1), retaining the soil over 8,6 m of height. The used geometry implies a L1 = 3,6m and a Fs = 1,9m (Figure 5). The buried depth of the base slab D is in this case 0,6m. The used type of in situ soil and the backfill soil are in this example the above described 'Sandy soil'.

Figure 6. Horizontal effective soil pressures at the lower virtual back up to 61,3kPa at stage 4 (c-phi reduction of 1,20).

Figure 7. Positions of elements with a Mohr-Coulomb plastic behavior in stage 4 (c-phi reduction of 1,20).

The global geotechnical safety, calculated by the c-phi reduction is 1,20. Figure 7 shows the positions of the elements which are in the plastic zone of the Mohr-Coulomb law. The failure surface underneath the foundation level suggests a failure mode of bearing capacity. As the inverted T-shaped cantilever wall deforms, failure surfaces, inclined at  $\pi/4 - \phi/2$  from the vertical, at the upper and lower virtual backs occur. This corresponds with the described failure 'wings' in § 1.1.

The effective horizontal stresses at the upper virtual back increases from 0kPa up to 29kPa. At the lower virtual back, the effective horizontal stresses increases from 2kPa up to 70kPa. Figure 6 shows that the influence of the relief floor isn't total : the relief floor deforms 3cm downwards, causing a small horizontal effective stress (2kPa) at the top of the lower virtual back. The mean effective vertical stress at the base slab amounts to 228kPa.

### 2.3 Comparison of the numerical simulation with the proposed analytical approach

The inverted T-shaped cantilever wall with a relief floor in § 3.2 is compared with the analytical calculation as described in § 2.3. The geometry and the soil parameters are similar inputs in both approaches.

Remember that the analytical calculations consider active soil pressures. Therefore, the analytical approach assumes a displacement of the structure. In the numerical simulations, this displacement of the structure occurs only in stage 5 ‘c-phi-reduction’. When forces in the analytical calculations are compared to those in the c-phi reduction stage of the numerical simulations, it is important to notify that the actual cohesion  $c'$  and angle of internal friction of the soil  $\phi'$  are reduced.

In the analytical approach, the factor of safety is 3,39 for the overturning failure mode, 1,98 for the sliding and 2,14 for the bearing failure mode. Figure 7 suggests that the failure mode of the numerical model is the bearing capacity (c-phi reduction safety factor = 1,20).

Table 2 shows that the difference of the horizontal forces at the virtual backs in the analytical approach and in the numerical simulations is below 8%. The difference of the vertical force at the foundation amounts to 15%.

Table 2. Comparison of the horizontal and vertical forces at the virtual backs and the foundation in the analytical approach and the numerical simulations.

	Anal. approach	Num. simulation
Horizontal force at upper virtual back	57kN/m <sup>2</sup>	62kN/m <sup>2</sup>
Horizontal force at lower virtual back	230kN/m <sup>2</sup>	211kN/m <sup>2</sup>
Vertical force at foundation	951kN/m <sup>2</sup>	1117kN/m <sup>2</sup>

### 3 PREDESIGN OF L-SHAPED CANTILEVER WITH RELIEF FLOOR

Based on experience, numerical modeling and hand calculations, typical dimensions of reliable inverted T-shaped cantilever walls with a relief floor could be estimated. For sandy soil and a buried depth of 0,8m and 1,3m; the L1 is about 20% to 40% of the retained soil height H; the Fs (as defined in Figure 5) is about 1,5 to 2,5 m (Figure 8).

The level of the relief floor is of less importance for the geotechnical design, as long as the full stress relief is applied on the virtual back of the inverted T-shaped wall. Furthermore, it is good practice to design the level of the relief floor at about the half of the retained soil height.

The type of soil in situ is an important geotechnical parameter, specially for the bearing capacity and sliding failure mode. For inverted T-shaped walls with relief floor, retaining a soil height of 5 m, a buried depth  $D = 1,3m$ ; the length L1 varies from 1m (sandy soil) to 2m (clayey soil) (Figure 9).

Figure 8. Typical distance between the front of the stem and the back of the heel (L1 [m]) of inverted T-shaped cantilever walls with and without relief floor in sandy soils.

Figure 9. Typical distance between the front of the stem and the back of the heel (L1 [m]) of inverted T-shaped cantilever walls with a relief floor in sandy, silty and clayey soils (retained soil height of 5,0m; buried depth of base slab  $D = 1,3$ ).

### 4 CONCLUSIONS

The geometry of an inverted T-shaped cantilever wall with a relief floor depends on the height of the retaining soil, the surcharges, the depth of the foundation base slab, the geotechnical parameters of the soil in situ and of the backfill, the possible length of the toe and so forth.

In the case of unsaturated sandy soils, silty soils and alluvial clayey soils, an analytical approach is proposed and confirmed by numerical simulations. The analytical approach is based on an upper and a lower vertical virtual back. The wall together with the backfill up to the virtual backs are treated as a monolithic block. At the lower virtual back, the horizontal soil pressures are reduced, due to the presence of the relief floor. This monolithic block is checked against sliding, overturning and bearing capacity failures in the ultimate limit state.

For predesign estimations, a typical inverted T-shaped cantilever wall with a relief floor may be considered:

- the distance between the front of the stem and the back of the heel is about 20% to 40% of the retained soil height,
- the length of the toe is similar to the length of the heel,
- the base slab is buried deeper than the frost line,
- the difference between the length of the relief floor and the length of the heel is about 1,5m to 2,5m,
- the level of the relief floor is about the half of the retained soil height.

Though some general rules of thumbs for the dimensions of an inverted T-shaped cantilever wall with relief floor are given, each realization must be based on thorough geotechnical evaluation of its design, a hydrogeological evaluation, a detailed structural design, an analyses of the construction methodology and a general risk evaluation.

# An Anchored Retaining Wall in CSM

## Un soutènement ancré en CSM

Gomes Correia A., Tinoco J.  
*C-TAC - University of Minho, Guimarães, Portugal*

Pinto A., Tomásio R.  
*JetSJ Geotecnia, Lisboa, Portugal*

**ABSTRACT:** Cutter soil mixing (CSM) is being recently used in Portugal in several applications. This paper describes a solution in cutter soil mixing reinforced with vertical steel profiles IPE270 for a retaining wall with 66 m long and 13 m high constructed in geological formations of landfill materials, Miocene sandy soils and sandstones, with a phreatic level around 8 m depth. This construction is done nearby commercial buildings. The solution is justified against more classical solutions for anchored retaining walls considering the following aspects: feasibility of CSM in the geological and environment conditions, predict behaviour during and post construction, simplicity of construction process, time of construction, economy and quality assurance. Numerical modelling using a commercial program is carried out, based in geotechnical parameters established at the project level, showing a good agreement of the observed data, in terms of horizontal displacements of the wall and also of the safety levels against bending, shear and compression.

**RÉSUMÉ :** La technique « cutter soil mixing » (CSM) a été récemment utilisée au Portugal dans plusieurs applications. Cet article décrit une solution CSM renforcé avec des profilés verticaux IPE270 pour un mur de soutènement avec 66 m de long et 13 m de haut construit dans des formations géologiques de matériaux de remblai, des formations du Miocène de sols sablonneux et des grès, avec un niveau de nappe phréatique autour de 8 m de profondeur. Cette construction se fait à proximité de bâtiments commerciaux. La solution est justifiée par rapport aux solutions plus classiques des murs de soutènement ancrés tenant compte des aspects suivants: faisabilité du CSM dans une vaste gamme des conditions géologiques et de l'environnement, prévoir le comportement durant et après construction, simplicité du processus de construction, le temps de construction, l'économie et l'assurance-qualité. Une modélisation numérique au moyen d'un programme commercial est effectuée avec l'utilisation des paramètres géotechniques établis au niveau du projet, montrant une bonne concordance des données observées, en termes de déplacements horizontaux de la paroi, autant que des niveaux de sécurité contre la flexion, le cisaillement et la compression.

**KEYWORDS:** soil treatment, deep soil mixing, cutter soil mixing, retaining wall.

### 1 INTRODUCTION

Deep Mixing is an in situ soil treatment method that makes use of a technology in which the soil is mechanically mixed with other materials, mainly binders. The composite material will have improved benefits in terms of resistance, compressibility and permeability (Larsson 2003, Bruce 2000). One of the variants of Deep Mixing is the Cutter Soil Mixing (CSM) technique, which produces panel elements with an accurate geometry, vertically and direction. Additionally, low disturbance is induced on the soil and nearby structures, making their use appropriate in urban areas. Furthermore, this technique has shown a great technical versatility and efficiency, as well as economical advantages, including the optimization of the construction schedule (Ameratunga et al., 2009, Capelo et al. 2012, Marzano et al., 2009, Pinto et al. 2011).

This paper describes an innovative solution involving CSM panels combined with a reinforced concrete wall, for a permanent ground anchored retained structure, with about 66 m long and 13 m high constructed in geological formations of heterogeneous landfill materials, Miocene sandy soils and medium weathered sandstones, with a phreatic level around 8 m depth. This construction is done nearby industrial buildings. Consequently their main purpose was to act as a support system maintaining the stability of the excavation against lateral earth pressures, while controlling the deformation and settlement of the surrounding structures (Porbaha, 2000).

The retaining wall uses soil-cement panels with a minimum depth above the excavation level of 4 m and cross-section of 2.4 x 0.5 m<sup>2</sup>, including 0.20 m of overlapping, were built using the

CSM technology. The panels were reinforced with vertical IPE270 (S275JR) hot rolled steel profiles (Euronorm 19-57), spaced in average 1,1m, in order to resist both to the earth and water pressures, as well as to ensure a better control of deformations. The steel profiles were placed inside the panels, before the cement started the curing process. The wall was braced by four (case study) or three levels of permanent ground anchors, applied at the capping beam as well as at the distribution beams, integrated on the reinforced concrete lining wall (Figure 1). As already stated, the soil-cement panels were lined with a reinforced concrete 0.20m thickness wall, connected to the vertical IPE270 profiles with steel cantilevers, allowing the mobilization of the global resistance of both the steel profiles and the lining reinforced concrete wall, acting a Berlin wall combined with CSM panels. The design criteria, verifying Ultimate Limit State and the Serviceability Limit State, as well as the limitation of the water inflow, were established by the support of 2D FEM analysis using commercial PLAXIS<sup>®</sup> software. In this paper a comparison between the control and monitoring parameters with design parameters is done in order to support the discussion about the reliability of both the solution and the construction method.

Figure 1. Representative schema of the solution proposed for the retained wall.

## 2 SITE AND SUBSURFACE CONDITIONS

The local geological conditions were heterogeneous. The excavation works intersected, from the surface, heterogeneous landfills and Miocene medium dense to dense sands and medium weathered sandstones. The ground water table was located about 5m above the final excavation level. Taking into account this scenario, an initial solution of Berlin walls was considered. A more detailed information about the site and subsurface conditions can be consulted in Pinto et al (2013).

## 3 CSM WALL MODELLING AND DESIGN CRITERIA

The modelling work was carried out using the commercial PLAXIS<sup>®</sup> software. The *Hardening-Soil* model was adopted for the different soil layers based in the available geotechnical laboratory and field data and taking into account all the excavation phases. Table 1 summarizes the main soil parameters.

Table 1. Main soil properties for modeling.

Constitutive model: Hardening-Soil	Landfill	Sandy soil (medium)	Sandy soil (dense)
$\gamma_t$ (kN/m <sup>3</sup> )	16	17	19
$E_{50}^{ref}$ (kN/m <sup>2</sup> )	10,000	20,000	35,000
$E_{oed}^{ref}$ (kN/m <sup>2</sup> )	10,000	20,000	35,000
$E_{ur}^{ref}$ (kN/m <sup>2</sup> )	30,000	60,000	105,000
Parameter m	0.5	0.5	0.6
$c'$	0	0	0
$\phi'$ (°)	22	33	35

For the soil-cement material produced by the CSM technology, using a cement consumption ratio of about 600kg/m<sup>3</sup>, the Mohr-Coulomb constitutive model was adopted and the parameters summarized in Table 2 were used.

Table 2. Main CSM panels parameters used in the modeling.

Constitutive model: Mohr-Coulomb	CSM panels
$\gamma_t$ (kN/m <sup>3</sup> )	22
$E_{ref}$ (kN/m <sup>2</sup> )	1000000
$\nu$	0.3
$c'$ (kN/m <sup>2</sup> )	600
$\phi'$ (°)	35

With the purpose to approximate the behavior of the structure to the real behavior, the three configurations shown in Figure 2 were considered: a) two half vertical IPE270 spaced in 1.1 m, b) two half vertical IPE270 spaced in 1.1 m plus lining wall and c) two half vertical IPE270 spaced in 1.1 m plus lining wall and CSM panels.

Figure 2. Configurations adopted in the modeling: a) two half vertical IPE270 spaced in 1.1 m, b) two half vertical IPE270 spaced in 1.1 m plus lining wall and c) two half vertical IPE270 spaced in 1.1 m plus lining wall and CSM panels.

For the structural analysis, load combinations for the Ultimate Limit State and for the Serviceability Limit State were defined according to Pereira (2011). The obtained results of 2D FEM analysis (mesh consisted of plane strain, 15-node elements) in terms of efforts and displacements are illustrated in Figure 3 and Figure 4 respectively.

Figure 3. Efforts diagrams.

Figure 4. Displacement diagrams.

For the verification of the ultimate limit states was assumed a simplified approach. Thus, it was considered that the strength capacity is the individual combination of the strength resistance of the CSM panels, the IPE270 profiles and the reinforced concrete lining wall.

Summarising the main results obtained are the following:

- $M_{Rd}$  (resistant bending moment) = 167 kNm/m > 1.5  $M_{Ed}$  (maximum acting bending moment) = 119 kNm/m;
- $V_{Rd}$  (resistant shear force) = 251 kN/m > 1.5  $V_{Ed}$  (maximum acting shear force) = 207 kN/m;
- $\sigma_{Rd}$  (resistant compression stress of CSM) = 2 MPa (with FS=2) > 1.5  $\sigma_{Ed}$  (maximum acting normal stress) = 1.1 MPa;
- $S_H$  (maximum horizontal displacement) = 22.7 mm at about 10m depth.

Based in these results the following design criteria were established: take into account the resistance and stiffness of both the steel profiles and the reinforced concrete lining wall. The contribution of the CSM panels was considered in order to protect and confine the steel profiles (exploration phase) and to perform as preliminary ground improvement, allowing the execution of the excavation works without any restriction, in each level.

#### 4 QUALITY CONTROL / QUALITY ASSURANCE

##### 4.1 Control of production parameters

One of the major issues of the CSM technology is the high quality control and quality assurance (QC/QA), allowing on real time the monitoring and correction of important parameters, such as: depth, inclination, speed of mixing tools, pressure (ground and binder slurry) on cutter wheels, rate and total volume of pumped slurry (Figure 5).

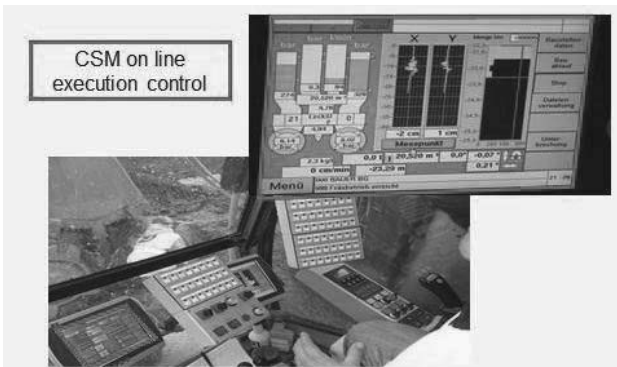

Figure 5. CSM on line execution control.

##### 4.2 Control of mechanical soil-cement properties

The execution control is complemented by a tight quality control and quality assurance, allowing the confirmation of both the main resistance, homogeneity and deformability of the soil-cement (soil-binder) parameters. For this purpose, samples from fresh material (before on suitability tested panels and during construction) and cores from the executed panels (after a certain curing age ranging from 7 to 28 days) were collected in order to access the material homogeneity, as well as to perform laboratorial tests with different ages, mainly unconfined compression strength (UCS) and Modulus ( $E_{s50}$  – secant modulus at 50% of maximum stress of UCS). The results obtained confirm an UCS minimal of 4MPa and a  $E_{s50}$  not lesser than 1GPa, satisfying the design criteria (Figure 6).

Figure 6. Collection of soil - cement fresh cores.

Taking into account the results of the UCS load tests, mainly on the suitability test panels, the following parameters were adopted for the execution of the CSM panels are presented on Figure 7.

Figure 7. Adopted values for the CSM panels execution parameters.

Regarding the QC/QA of the solution, it should also be pointed out the execution of suitability and reception tests for all the permanent ground anchors, allowing the optimization of the anchors grout body length (Figures 8 and 9).

Figure 8. Permanent ground anchor suitability test.

Figure 9. Main results of the ground anchor suitability test.

### 5 CSM WALL PERFORMANCE

The implemented monitoring and observation plan, is shown on Figure 10, including 2 inclinometers and 7 topographic targets.

Figure 10. Monitoring and observation plan.

Figure 11 shows that the maximum displacement was observed at 10 m depth, corresponding to 15 mm (inclinometer I8).

Figure 11. Displacement recorded at the inclinometer I8.

In Figure 12 it is observed that the maximum vertical displacement is 4 mm and that the maximum horizontal displacement is 17 mm.

These results show that the FEM analysis, with the presented input data, has given a good analytical prediction of the observed horizontal displacement, mainly confirming the depth where the maximum horizontal displacement occurred.

Figure 12. Displacement recorded at the topographic target A1.

### 6 MAIN CONCLUSIONS

The case study presented in this paper shows the good performance, mainly low deformations, of an anchored retaining structure, combining CSM panels with a reinforced concrete lining wall, leading to the optimization of both the construction overall schedule and budget in a complex geotechnical and site conditions. It was also shown that the use of commercial FEM software with appropriated input data gives a reasonable prediction of the main displacements, which are critical for the verification of both the ultimate and serviceability limit states, for all the excavation phases.

### 7 ACKNOWLEDGEMENTS

The authors wish to thank to “Fundação para a Ciência e a Tecnologia” (FCT) for the financial support under the strategic project PEst-OE/ ECI/UI4047/2011. In addition, the authors would like to thank the contribution of Ângelo Pereira.

## 1 PRESENTATION

Le projet Odéon à Monaco consiste en la construction d'une tour de 160 m de hauteur sur un versant en forte pente et dans un contexte déjà fortement urbanisé. L'emprise du projet, la topographie, et la construction de 10 niveaux de sous-sol en infrastructures de la tour conduisent à réaliser un ouvrage de soutènement de très grande hauteur, environ 70 m, dont 35 m en parois berlinoises ancrées par tirants actifs et près de 40 m en paroi moulées butonnées par les planchers de sous-sols.

La géologie du site est constituée d'éboulis surmontant des marnes noires de qualité médiocre et des calcaires profonds. La tour elle-même repose sur des barrettes préfondées, permettant la construction selon la méthode « up and down », ancrées en moyenne à 50 m de profondeur sous le niveau du rez de chaussée.

Outre les dimensions tout à fait exceptionnelles de l'excavation, l'enjeu géotechnique majeur consistait à garantir des déplacements des ouvrages avoisinants existants inférieurs à 5 mm, et la méthode observationnelle était imposée pour garantir le succès de l'opération.

La communication présente :

- La conception globale du projet et le dimensionnement des divers éléments de soutènement et fondation ;
- Les modélisations numériques géotechniques 3D qui ont été élaborés à différents stades du projet, intégrant l'ensemble des fondations (parois moulées périmétriques et barrettes, planchers des sous sols) et des soutènements, y compris tirants et pieux des berlinoises, et reproduisant les phases de construction. Ces modèles ont globalement permis de valider les méthodes et phasages de construction ;
- Les performances réellement observées, notamment en termes de déplacements sur les avoisinants, qui ont dans l'ensemble confirmé les ordres de grandeur attendus.

Elle décrit également quelques adaptations du projet qui ont été mises en œuvre dans le cadre de la méthode observationnelle, et qui ont permis de gérer les situations où les déplacements observés sur des bâtiments avoisinants ont dépassés les seuils.

## 2 DESCRIPTION DU PROJET

### 2.1 L'ouvrage et son phasage de réalisation

La tour s'inscrit dans un talus naturel de pente moyenne 25°, qui doit être en conséquence rogné sur un dénivelé de plus de 40 m, entre la cote 110.0 NGM en amont et le niveau de la rue en aval à 67.0 NGM. Elle se compose de 2 parties en forme de pétales ayant respectivement 44 et 48 étages au-dessus d'un parking de 10 niveaux en sous-sol. L'ensemble est fondé sur une paroi moulée périphérique en forme d'auge vue en plan, et sur un réseau de barrettes intérieures. La paroi moulée est prolongée verticalement en superstructure par un voile pour épouser le versant sculpté en amphithéâtre, constituant un socle rigide dont le rôle est capital vis-à-vis de la reprise des efforts liés à la dissymétrie du site.

L'ouverture de la fouille se fait à l'abri de 3 soutènements étagés successifs (Figure 1) :

- Une microberloise de 15 m, avec micropieux  $\phi$  219 ayant une fiche de 8 m et espacés d'environ 1 m ;
- Une berlinoise de 20 m, avec pieux  $\phi$  1000 espacés de 2 m et ancrés d'en moyenne 12 m ;
- Et enfin la paroi moulée de 30 à 40 m de haut renforcée dans certaines zones par des contreforts.

Ces dispositions visent, au fur et à mesure du terrassement, à la constitution de plates-formes de travail de plus en plus larges pour l'utilisation d'un matériel de plus forte capacité permettant la mise en œuvre de soutènements de plus forte inertie.

Ente les cotes 110.0 NGM et 64.0 NGM, les berlinoises et la partie supérieure de la paroi moulée sont ancrées par 18 lignes de tirants de longueur maximum 42 m.

Figure 1 : Vue 3D des soutènements et fondations

A la cote 64.0/67.0 NGM, la dalle de couverture du parking est coulée, après quoi la construction de la tour en up & down peut débuter : il s'agit de construire simultanément la superstructure et l'infrastructure, à raison de trois étages de superstructure pour un niveau d'infrastructure en taube, la paroi moulée et ses contreforts prenant appui sur les dalles de sous-sols coulées à l'avancement et portées par les barrettes de fondations profondées.

## 2.2 Le contexte géotechnique

Géologiquement la structure tectonique régionale est complexe : l'ensemble du versant est constitué d'un système d'écaillés, et au droit du site on rencontre des marnes Cénomaniennes. Ces dernières, qui ont déjà été à l'origine de difficultés lors de la réalisation de grandes excavations à Monaco, constituent l'essentiel des terrains à excaver, avec localement un substratum calcaire, qui remonte à la faveur d'une faille. Notons que la faille du Larvotto se situe légèrement en aval du site.

Le site a fait l'objet d'une importante reconnaissance, avec environ 35 sondages, carottés, destructifs et pressiométriques, sur des profondeurs atteignant couramment 90 m, et jusqu'à 120 m. La Figure 2 montre une coupe transversale, mettant en évidence la couche de colluvions épaisse de 25 m en amont du site, puis les marnes du Cénomaniens, plus ou moins déstructurées, et localement les calcaires profonds.

On notera tout particulièrement la présence de niveaux décomprimés dans les marnes, mis en évidence par leur description sur carottes et par des modules pressiométriques très faibles (< 50 MPa), alors qu'ils sont de l'ordre de 200 à 300 MPa dans les marnes saines. Cette conséquence probable de la tectonique du site a été l'un des enjeux importants du projet de soutènement.

L'hydrogéologie montre une nappe de surface dans les éboulis, suivant la pente à 15-20 m sous le TN et une nappe captive en charge dans les calcaires profonds. Mais les capteurs de pression interstitielle dans les marnes montrent également des valeurs de pression correspondant à la nappe de surface, et ce au moins localement et temporairement : la conception du projet a du également tenir compte de ces fortes charges piézométriques.

Figure 2 : Profil géologique et projet

## 2.3 La conception des soutènements et fondations

La hauteur importante de la tour, et les actions qui en résultent sur les fondations sous l'effet du vent et du séisme, ont nécessité une étroite liaison entre les études de la structure et des soutènements. En effet, la paroi moulée périphérique fonctionne à la fois comme soutènement des terres et comme fondation de la tour. Les effets de renversement sur la tour, notamment sous séisme, mettent en traction la paroi moulée amont. Par ailleurs, en phase de service, la tour doit être calculée sous l'hypothèse d'une détente des tirants des berlinoises, les massifs de terre s'appuyant directement sur le socle de la superstructure.

Pour ces diverses raisons, les soutènements ont fait l'objet de plusieurs vérifications. En phase d'excavation, ils ont été dimensionnés par la méthode classique des calculs au coefficient de réaction, complétée par des calculs de stabilité générale faisant intervenir la longueur des tirants. L'ensemble a été conduit selon des profils transversaux bidimensionnels, malgré le caractère fortement tridimensionnel du projet, conduisant à une approche a priori sécuritaire.

En phase de service, pour vérifier le comportement de la paroi moulée associée à la tour, un modèle 3D structurel des infrastructures a été élaboré, sur lequel ont été appliquées les poussées issues des calculs de soutènement au coefficient de réaction, et les actions propres à la tour (vent, séisme, charges verticales). Afin de prendre en compte l'effet des phases de terrassement sur les sollicitations finales dans la paroi moulée, il a été également introduit un cas de charge élémentaire représentant le décalage de moment et d'effort tranchant dans la paroi entre un calcul phasé et un calcul non phasé négligeant les terrassements. Le modèle de l'infrastructure ainsi étudiée fournit les cartographies d'armatures à prendre en compte dans le dessin des cages de paroi moulée et conduit à un dimensionnement rigoureux et optimum.

La méthodologie de construction de la tour en up & down permet d'assurer la stabilité générale et de maîtriser au mieux les modifications de contraintes dans le massif. En effet :

- En phase de terrassement, le poids de la tour compense partiellement le poids des terres excavées qui sont stabilisatrices vis-à-vis des cercles de grand glissement ;
- Les tassements se produisent au fur et à mesure de la construction et sont compensés par le soulèvement du fond de fouille.

Enfin, malgré le caractère de roche tendre des terrains, un clouage vertical en fibres de verre a été nécessaire devant la paroi moulée amont, afin d'améliorer la butée mobilisable lors des dernières passes de terrassement où la paroi est soumise à

une poussée approchant les 1000 kPa dans les zones de marnes altérées.

### 3 LES MODÉLISATIONS NUMÉRIQUES

#### 3.1 Modélisation 3D globale sous CESAR 3D

Après un premier modèle géotechnique tridimensionnel réalisé par Coyne et Bellier dans le cadre des études de conception, nous avons conduit, dès le démarrage des études d'exécution, une nouvelle modélisation géotechnique 3D de l'ensemble du projet, intégrant les interfaces géologiques, les avoisinants existants et les nouvelles infrastructures, réalisée avec CESAR 3D v5. Le modèle (Figure 5) comporte 57 phases de calcul reproduisant toutes les étapes des travaux depuis l'excavation des premières plateformes jusqu'à l'application des charges de superstructures sur les barrettes de fondations.

Figure 3 : Vue du modèle 3D général

Les résultats mettent en évidence l'effet de voûte lié à la forme de l'excavation et conduisent à des déplacements des avoisinants de l'ordre de 5 mm en déplacement horizontal, et presque toujours inférieurs à 5 mm en soulèvement. Les déplacements calculés les plus importants sont situés près du collège Charles III.

#### 3.2 Modélisation 3D locale sous Plaxis 3D

Suite à un changement de méthode pour réaliser les soutènements au niveau du collège, un autre calcul centré sur ce bâtiment a été réalisé avec Plaxis 3D. Ce modèle « simplifié » (Figure 4) ne comprend que les structures existantes du collège, la variante de soutènement, et une moitié de l'excavation principale. La stabilité de l'ensemble est assurée par les conditions aux limites, et l'effet de voûte est reproduit par une surcharge à l'arrière du modèle.

Les déplacements calculés restent comparables à ceux obtenus précédemment et montrent que la nouvelle solution de soutènement garantit bien la stabilité de l'ensemble.

#### 3.3 Apport des modélisations

Ces modélisations 3D ont permis la prise en compte des effets 3D tels que l'effet de voûte et la validation de systèmes de soutènement complexes, notamment vis-à-vis des déplacements des structures et des avoisinants. Le comportement fortement 3D de l'ouvrage est bien mis en évidence, avec notamment des déplacements des soutènements de l'ordre de 10 mm au maximum, très inférieurs aux 30 mm évalués par les calculs 2D au modules de réaction.

En outre, une approche de la stabilité générale a pu être conduite sur la base du modèle global, en affectant les paramètres de résistance au cisaillement des terrains de coefficients réducteurs partiels, et en vérifiant l'équilibre numérique du modèle avec ses caractéristiques réduites.

## 4 L'APPLICATION DE LA MÉTHODE OBSERVATIONNELLE

### 4.1 Auscultation mise en œuvre

L'auscultation de l'ouvrage et de ses avoisinants est organisée selon 10 profils verticaux (3 à l'amont côté ouest, 3 côté collège au sud, 2 côté Nord et 2 à l'aval côté Est) tel qu'illustré sur Figure 4. Sur chacun de ces profils, les différents instruments de mesures permettent de recouper les informations.

Figure 4 : Vue en plan du projet et des profils d'auscultation

La mise en place du dispositif d'auscultation de l'ouvrage et de ses avoisinants s'est faite de manière progressive :

- En premier lieu, dès le début des travaux, les avoisinants (villas et immeubles aux alentours, collège Charles III, paroi moulée amont du collège) ont été équipés de cibles topographiques ; des inclinomètres profonds ont été réalisés dans le terrain (jusqu'à 80 m de profondeur) à l'amont et autour de l'emprise de la future fouille, et une dizaine de piézomètres a également été réalisée tout autour de la fouille ;
- Puis les ouvrages ont été équipés au fur et à mesure de la réalisation : mise en place d'inclinomètres noyés dans les micropieux, pieux et paroi moulée, de cibles topographiques, d'extensomètres de forages, de cellules dynamométriques en tête de tirants, ainsi que de jauges de contraintes dans les barrettes et certaines dalles. L'auscultation des avoisinants a également été renforcée tout au long du chantier avec l'ajout de cibles complémentaires et de fissuromètres dans les zones ayant subi des déplacements au cours de travaux.

Pour les profils les plus hauts côté amont, 3 séries d'inclinomètres sont placées en recouvrement relatif sur la microberlinoise, la berlinoise et la paroi-moulée, de façon à reconstituer un profil inclinométrique complet intéressant les divers soutènements. Ils sont également équipés d'environ 7 cellules de charges sur les têtes de tirants, réparties sur les 18 lits.

Les cibles topographiques sont elles aussi disposées le long des profils à raison d'une cible toutes les 2 passes de terrassement soit environ une cible tous les 5 mètres, avec une cible en tête de chaque ouvrage.

Les extensomètres de forage sont pour certains ancrés à une profondeur de 60 m à l'arrière du soutènement, au-delà des tirants les plus longs, avec une ancre tous les 10 m.

Inévitablement un certain nombre d'instruments situés dans le terrain à l'amont du projet a été détruit au moment de la réalisation des tirants de la berlinoise, et a dû être remplacé. C'est notamment le cas des piézomètres, qui ont été remplacés le plus souvent par des capteurs de pression interstitielle.

#### 4.2 Choix des seuils

La limite admissible de déplacements des immeubles mitoyens a été fixée contractuellement à 5 mm, avec un seuil d’alerte à 3 mm.

Vis-à-vis des soutènements eux-mêmes, le contrat spécifiait uniquement des critères de déplacements pour le dimensionnement selon la méthode de calcul au coefficient de réaction (calcul 2D) :

- 30 mm pour les parois non joutées par des immeubles ;
- 15 mm pour les points situés à plus de 10 m des fondations des immeubles ;
- 3 à 10 mm pour les points entre 5 et 10 m de ces fondations ;
- 3 mm pour les points situés à moins de 5 m des fondations.

Il faut souligner que les déplacements calculés par les méthodes aux éléments finis (3D) sont largement inférieurs à ceux obtenus par les méthodes 2D.

### 5 LE COMPORTEMENT EN COURS DE TRAVAUX

#### 5.1 En zone courante

On notera tout d’abord que la précision du théodolite automatique est tout à fait remarquable : avec une mesure toutes les trois heures, la précision obtenue est de l’ordre de +/- 0,5 mm, comme cela apparait sur les courbes de suivi topographique. De même la précision des extensomètres de forage est tout aussi remarquable : +/- 0,1 mm. Seule la précision des inclinomètres est plus aléatoire : il apparait que celle-ci dépend fortement de la qualité du scellement, en relation avec la qualité des terrains trouvés et bien sûr de la hauteur de l’inclinomètre. Un post-traitement de type correction de pied, ou autre, améliore nettement la fiabilité des résultats.

En vue de l’analyse des mesures, le Bureau d’Etudes avait transmis, pour les profils types, les courbes de déplacements calculés phase par phase, pour comparaison avec les mesures inclinométriques.

Les mesures montrent, notamment en zone amont, des déplacements inclinométriques de la paroi moulée de quelques millimètres, nettement plus faibles que ceux calculés avec la méthode au coefficient de réaction en 2D, qui atteignaient 10 à 15 mm dans cette zone (Figure 5).

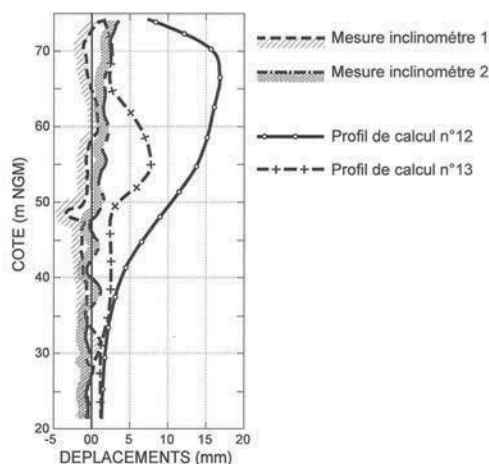

Figure 5 : déplacements calculés et mesurés des parois

Ceci était prévisible, comme le montraient les résultats des calculs numériques 3D, du fait de la géométrie de la fouille beaucoup plus haute que large, qui favorise la formation de voûtes de décharge horizontales, réduisant ainsi la poussée effective sur le soutènement.

D’une façon générale, on peut souligner que les déplacements maximaux  $\delta$  des parois de soutènement restent de l’ordre de 10 mm au maximum, ce qui est remarquable pour un soutènement de hauteur totale  $H = 70$  m :  $\delta/H \approx 0.15/1000^\circ$ .

#### 5.2 Exemple d’écarts par rapport au modèle et adaptations du projet

D’une façon générale, il n’a été constaté que peu d’écarts significatifs entre le comportement observé et les prévisions de déplacements fournies par les calculs.

Les premiers écarts l’ont été dès le début du chantier, lors de la foration des premiers tirants dans les éboulis qui ont conduit à des déplacements centimétriques, dépassant les seuils, sur certains avoisinants. Ces premiers mouvements, attribués à l’effet de la foration et du scellement des tirants dans les éboulis, nous ont conduits à adapter la méthode de forage : abandon des forages à l’air en faveur de méthodes au tricône sous coulis, et forage « Sonic ».

Ainsi, pour la villa Bataglia, située au nord-ouest du projet et qui avait subi des déplacements allant jusqu’à 14 mm, nous avons été conduits à réaliser un soutènement spécifique en aval de la villa : longrines en béton armé de 1 m de haut sur deux niveaux, ancrées par 8 tirants de 15 m de long scellés dans les éboulis, et 3 tirants de 21 m dans les marnes. Ce soutènement a permis d’éviter l’évolution des mouvements jusqu’à la fin des travaux de perforation et d’injection de coulis dans cette zone. A ce jour, soit environ un an et demi après ces travaux, plus aucun déplacement complémentaire n’a été observé.

Un autre écart de comportement structurel a pu être constaté, cette fois-ci sur l’ouvrage en construction : dans la zone située au droit du collège, la paroi moulée se trouvait localement en console maintenue par trois lits de tirants, après un terrassement de 7 m pour le coulage de la dalle RDC. Les déplacements mesurés en tête de la paroi moulée ont atteint 13 mm, supérieurs aux déplacements calculés. Le bureau d’études a alors lancé une rétro-analyse, qui a montré que ces mouvements pouvaient être attribués à une « surcharge » résultant de l’accumulation d’eau derrière la paroi, en relation avec les venues d’eau rencontrées lors de la foration de certains tirants.

Nous avons donc réalisé des drains complémentaires et trois tirants d’ancrages supplémentaires. Lors de la foration des drains complémentaires, il a été constaté un fort débit pendant les premiers jours et une atténuation par la suite. Ce dispositif a permis de stopper les déplacements, en attendant le butonnage par la réalisation des planchers correspondants.

### 6 CONCLUSION

Cet ouvrage, exceptionnel par sa hauteur (70 m de soutènement) et par son environnement imposant des contraintes très strictes de déplacements, a pu être mené à bien grâce à une conception d’origine adaptée, notamment par sa géométrie en voûte et par la méthode de construction en « Top & Down », et par des études alliant des approches traditionnelles négligeant tout effet tridimensionnel, et des modélisations numériques 3D permettant d’évaluer les effets bénéfiques de cette géométrie en reproduisant tous les éléments de soutènement et d’infrastructure et le phasage détaillé de l’opération.

Mais tout autant que la conception, c’est le suivi rigoureux du chantier, conduit selon les principes de la méthode observationnelle, qui a permis d’atteindre les performances attendues (déplacement horizontal en tête de l’ordre de  $0.15/1000^\circ$  de la hauteur), et de traiter à temps les rares, mais inévitables, anomalies de comportement local.

# A Case Study of 3D FE Analysis of a Deep Excavation Adjacent to a Tunnel Construction

Une étude de cas d'une simulation tridimensionnelle d'analyse par éléments finis d'une excavation profonde adjacente à une construction d'un tunnel

Guler E.

*Bosphorus University, Istanbul, Turkey*

Osmanoglu U., Koç M.

*ELC Group Inc. (Royal HaskoningDHV Turkey), Istanbul, Turkey*

**ABSTRACT:** This paper describes the 3D geotechnical FE analysis and design of a deep excavation bracing system. The location is situated in a very dense business area in Istanbul. The maximum height of the excavation is ~23 m to accommodate 7 basement floors. The layout has a non-uniform shape, surrounded with existing high rise structures with multi-basement floors, and an underpass connection to E-5 Motorway. In addition to these, the most outstanding characteristic of this design is the pedestrian tunnel and the shaft that is very close to the excavation pit. Both of these underground structures were being constructed throughout the same construction period as the deep excavation. At the non-anchoring zones adjacent to the tunnel and shaft, steel struts have been used. As a compound engineering service, soil investigation – design – site supervision – geotechnical instrumentation works was carried out. Therefore a comprehensive data for comparison between design results and in-situ performance could be gathered. This paper focuses on the details of the sophisticated 3D FE analysis and the comparison with the in-situ performance of the shoring system.

**RÉSUMÉ :** Ce document décrit l'analyse géotechnique 3D par éléments finis et la conception d'un système de contreventement utilisé dans l'excavation profonde. L'emplacement est situé dans un quartier très dense à Istanbul. La hauteur maximale de l'excavation est de 23 m pour 7 sous-sols. Le site a une forme non uniforme, entouré de structures existantes de grande hauteur avec multi-sous-sols, une connexion souterraine de l'autoroute E-5. En plus de cela, la caractéristique la plus remarquable de cette conception est le tunnel pour piétons et l'arbre qui est très proche de l'excavation. Ces deux structures souterraines ont été construites pendant la même période que la construction de l'excavation profonde. Au niveau des zones de non-ancrage adjacentes au tunnel et à l'arbre, des entretoises en acier sont utilisées. En tant que service d'ingénierie l'étude du sol, - la conception - la supervision de chantier - les travaux en instrumentation géotechnique ont été réalisées. Par conséquent un ensemble de données complètes pour la comparaison entre les résultats de la conception et de la performance in-situ aurait pu être recueillie. Ce document se concentre sur les détails d'une simulation 3D sophistiquée d'Analyse par éléments finis et la comparaison des performances in-situ du système d'étaie.

## 1 INTRODUCTION

The deep excavation retaining system project is located at the European side of Istanbul. The plan view of the site is presented in Figure 1. The depth of the excavation is 23 m. The ongoing construction of a pedestrian tunnel and entrance shaft adjacent to this excavation makes the design of the retaining system complicated. Interaction with this deep excavation work was not considered in the design of the tunnel and shaft. Hence, the shoring design for the deep excavation had to consider the very close tunnel and shaft which were still being constructed and standing with their temporary support systems during the excavation works. Since the interaction between the deep excavation and the simultaneously constructed shaft and tunnel cannot be modeled with only a 2D analysis (plain-strain model), a 3D Geotechnical FE analysis (especially for the shaft location) had to be conducted.

The pedestrian tunnel has a span of 7 m at a distance of 7 m to the piles of the shoring system. The shaft has a diameter of 6 m at 2.5 m distance to the piles of the shoring system. The tunnel and shaft's temporary support system was composing of ~20 cm shotcrete facing and rock bolts. In the tunnel 4 m long rock bolts were used only at the top heading. In the shaft 2 m long radial rock bolts were used. The temporary excavation system of the building is designed with micro piles, pre-stressed anchors and steel struts at non-anchoring zones due to tunnel and shaft. The elevation corresponds roughly to the foundation level of the excavation pit.

The software used in this project were TNO DIANA for 3D modeling and Plaxis V.11 for 2D modeling (for the analysis at the tunnel side).

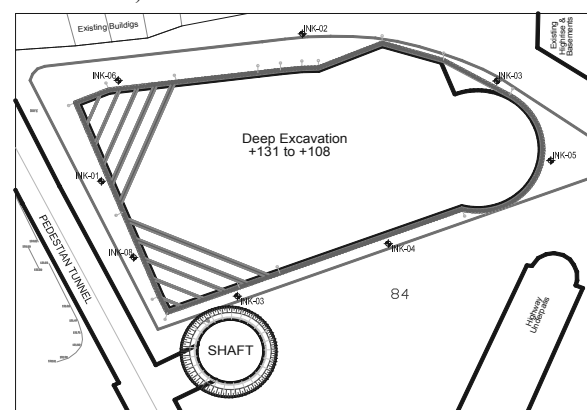

Figure 1. Site layout with surrounding structures

## 2 DESIGN PHASE

The design works were carried out based on the geological & geotechnical data obtained from the site investigations. Surcharge loads were considered wherever necessary.

### 2.1 Geological & Geotechnical Conditions

The geology of the site mainly consists of Carboniferous aged Trace Formation’s intercalation of sandstone – siltstone layers. The bedrock is overlain by weathered particles of the Trace Formation in clay matrix with thicknesses varying between 3 ~ 4 m. Finally the site is covered with artificial fill with a thickness of ~2 m. The bedrock is divided in to two fictitious layers at a depth of 14 m according to the increasing rock mass quality. Except leakage water from the discontinuities and fractures, no groundwater table was encountered at the site. The proposed stratigraphy and the engineering parameters used in modeling are presented in Table 1.

Table 1. Proposed stratigraphy and engineering parameters

Layer	Fill	Residual Zone	Bedrock-1	Bedrock-2
Thickness (m)	2	5	7	-
c (kPa)	0	1	5	10
$\phi$ (°)	25	30	35	38
$\gamma$ (kN/m <sup>3</sup> )	18	20	22.5	23
E (kN/m <sup>2</sup> )	5,000	25,000	100,000	150,000
$\nu$	0.35	0.30	0.28	0.25

### 2.2 Design Philosophy

Since the construction of the pedestrian tunnel and shaft were ongoing at the time, the initiation of the phased construction model had to be started with simulation of these structures. The design work was aiming to find out the effects of the deep excavation on the tunnel and shaft structures. In order to detect the magnitude (after initial phase) and variations of the section forces together with the deformations of the tunnel and shafts’ temporary support system throughout the deep excavation, dewatering and basement construction stages, the shotcrete facing was modeled with shell elements.

The deep excavation support system was designed contiguous (without a gap) to the basement walls that will be constructed after the completion of the deep excavation. This is mainly due to the clients’ demand for minimum space loss. This philosophy turned in to an advantage for the adjacent tunnel and shaft, since every constructed basement floor constituted a rigid support to the shoring system, hence the effects of dewatering stages could be minimized on tunnel and shaft.

Both the 2D and 3D finite elements models were constituted in compliance with in-situ construction steps (tunnel & shaft construction, staged deep excavation procedure, staged basement construction and dewatering of the steel struts).

The steel struts, piles of shoring system, shotcrete facing and the rockbolts were modeled as linear elastic materials. The properties of these linear elastic materials are given in Table 2. All struts used were tubular steel with a thickness of 10.3 mm.

Table 2. Elastic and rigidity variables

Material	E (kN/m <sup>2</sup> )	D Spacing (m)	d Diameter	$\nu$
Micropiles	2.5E7	0.60	30 cm	0.20
Shotcrete	2.0E7	cont.	20 cm	0.20
Steel struts	2.1E8	3	16” ~ 32”	0.28
Rockbolts	1E7	1.5	51 mm	0.28

### 2.3 2D FE Analysis

General approach to model a deep excavation in geotechnical engineering is to execute Limit Equilibrium stability analysis to get the satisfactory factor of safety and a FEA to check the

compliance of deformation criteria. Since 2D FEA is a fast and effective design tool, the same methodology was used for the subjected project.

The 2D FE model at the adjacent tunnel location is given in Figure 2.

Figure 2. 2D FE model from tunnel section

Deformation analyses were carried out with commercial software package of PLAXIS. Mohr Coulomb material model was used for the design based on the expertise of deep excavation designs and their feedback from in-situ performance, in similar geological circumstances which is very widespread in Istanbul.

### 2.4 3D FE Analysis

A 3D FE Analysis had to be conducted in order to simulate the interaction between the deep excavation works and tunnel&shaft. The main goal of the 3D modeling study was to establish an appropriate excavation system and sequence, hence only the related part of the system was focused in the analysis. By this means, the processing time in such a complex model could be reduced to a reasonable level. As it is in 2D FEA, also Mohr-Coulomb material model was used in the 3D FEA. All engineering parameters were kept same.

The 3D FE model is given in Figure 3.

Figure 3. 3D FE model from with nearby tunnel and shaft

## 3 RESULTS FROM THE ANALYSES

The main purpose of this modeling study was to find out the interaction between the tunnel&shaft structures with (and during) the deep excavation works. Therefore, the specific values (bending moments, shear forces, normal forces, and

displacements) are presented in this paper (both from 2D FEA and 3D FEA) in Table 3. The given results for the tunnel and shaft structures are values prior to excavation and final values after completion of deep excavation work.

Table 3. Results of FEA

Result	2D FEA	3D FEA
Deformation of shoring (mm)	7.8	4.2
Deformation of Tunnel (mm)	9 / 3	2.0
Deformation of Shaft (mm)	NA	3.2
Bnd.Moment on Shoring (kNm/m)	97.3	31
Bnd.Moment on Tunnel (kNm/m)	9 / 16.4	8.4 / 8.7
Bnd.Moment on Shaft (kNm/m)	NA	13.9 / 16.1
Shear Force on Shoring (kN/m)	132.4	83
Shear Force on Tunnel (kN/m)	20.2 / 22.5	26.8 / 25.3
Shear Force on Shaft (kN/m)	NA	20.0 / 19.6
Normal Force on Shoring (kN/m)	416.8	366
Normal Force on Tunnel (kN/m)	470.7 / 633.4	545 / 532
Normal Force on Shaft (kN/m)	NA	800 / 666

The result for total deformation from the 3D FEA is presented in Figure 4. The result for total deformation from the 2D FEA is presented in Figure 5.

Figure 4. Total displacement from 3D FEA (max. 4.2 mm)

Figure 5. Total displacement from 2D FEA (max. 7.8 mm)

The result for bending moments (on all shell elements) is presented in Figure 6.

Figure 6. Bending moments from 3D FEA (max. 31 kNm/m shoring, max. 8.7 kNm/m tunnel, max. 16.1 kNm/m shaft).

In addition to deformations and section forces, the axial forces on the steel struts are also calculated and compared with both 2D and 3D FEA. The values are presented (as the envelope values for all construction and demounting stages) in Table 4.

Table 4. Results of Axial Forces in struts

Result	2D FEA	3D FEA
Axial Forces (kN)	263 kN/m	627-765 kN*

\*The assumed length of struts in 2D is 20 m hence the results of 17-23 m struts in 3D model are given. The spacing of the struts in 2D model is 4.0 m, so that the value of 263 kN/m (perpendicular to the surface) shall be multiplied by 3 in order to get the axial perpendicular force of an individual strut.

The results for steel strut axial forces from 3D FEA are presented in Figure 7.

Figure 7. Total strut forces from 3D FEA (max. 885 kN)

#### 4 CONSTRUCTION AND MONITORING PHASE

During construction period, a geotechnical instrumentation program, consisting of inclinometers, optic survey points (for deformation monitoring) and strain-gauges (for axial force and dependently stresses on steel struts), has been carried out. This monitoring program gave reliable data and so it was possible to verify the design results with in-situ performance that has been gathered.

The maximum deformation on the inclinometer at shaft location (INK-07) was measured as ~7 mm. The maximum deformation values received from optical surveys are also ~7 mm at shaft location and ~8 mm at the tunnel location. Inclinometer and optic survey results are presented in Figure 8.

# Suction Caisson Installation in Shallow Water: Model Tests and Prediction

## Installation de caissons à succion en eau peu profonde: essais et prédiction

Guo W.

*School of Civil & Environmental Engineering, Nanyang Technological University, Singapore*

Chu J.

*Department Civil, Construction & Environmental Engineering, Iowa State University, USA*

**ABSTRACT:** Suction caissons have been used as foundations to support mainly offshore structures such as offshore oil rigs in deep water where a large suction pressure can be generated. Studies have been made recently to use this method for near shore foundations in shallow water where the suction that can be applied is much smaller. In this paper, a study on the installation of suction caissons in clay in shallow water using large scale model tests is presented. The model test setup and test results are discussed. The effects of soil plug and side friction are evaluated. An analytical method proposed by Houlsby and Byrne is adopted to predict the penetration versus time relationship. The analytical solutions agree well with the model test results.

**RÉSUMÉ:** Les caissons à succion ont été utilisés principalement pour les fondations de structures offshore en eau profonde permettant de générer de fortes pressions de succion. Cet article présente une étude sur une installation de caisson dans de l'argile à faible profondeur en utilisant un modèle à grande échelle. Les résistances d'arrachement et frottements latéraux sont évalués. La méthode analytique proposée par Houlsby et Byrne est adoptée pour prédire la relation pénétration-temps et donne de bons résultats

**KEYWORDS:** Caisson; Clay; Model Test.

## 1 INTRODUCTION

A research project to use super-size cylindrical structures to form underwater space and at the same time create land on top is being carried out in Singapore. As the seabed soil is mainly soft clay, suction caissons were considered on possible form of foundations to support part of the reclaimed land for buildings or other types of structures to be built on top of it, the foundation types for the offshore structures have to be developed using innovative solutions. The most difficult design condition is when the seabed soil is soft. It would be too costly to treat the soft soil offshore. One innovative solution is to use suction caissons.

Normally suction caissons are large, hollow, cylindrical steel or concrete structures in form of upturned bucket shape, and are penetrated into the seafloor bottom sediments by self-weight and suction pressure. The principle of the suction caisson technique is to apply suction inside a sealed cylindrical caisson to create a downward net force to sink the caisson into the seabed soil. After the suction is removed, the foundation is constructed without treating the soft soil. The suction caisson have been successfully employed in recent years in many projects including mooring anchors (Andersen and Jostad, 1999; Andresen et al., 2011; Randolph et al., 2011; Wang et al., 1975), beak water or sea walls (Chu et al., 2012), offshore platforms (Zhang et al., 2007; Zhang and Ding, 2011) and foundation for wind turbine in deep waters (Byrne et al., 2002; Gavin et al., 2011; Houlsby et al., 2005c).

For caissons used in deep water, the hydrostatic water pressure as provided by the water depth can contribute to suction pressure to compress the caisson into seabed. However, in relatively shallow water, there may not be sufficient suction to allow the caisson to penetrate to the required depth. Another factor affecting the penetration of a suction caisson is the soil plug formed inside the caisson. When a caisson is penetrated into clay, soil will go inside the open ended hollow caisson and form soil plug. The soil plug resists the penetration of the caisson. For this purpose and for the development of suitable design methods, model tests and numerical studies were carried out.

Analytical methods for analyzing the installation process of suction caisson have also been proposed (Andersen et al., 2005;

Chen et al., 2009; Houlsby and Byrne, 2005a, 2005b; House and Randolph, 2001; House et al., 1999; Tran and Randolph, 2008). In the method by Houlsby and Byrne (2005a, 2005b), a constant penetration velocity was assumed. The driving forces and soil resistance were also assumed to be balanced during the whole installation process. This method was adopted to calculate the amount of penetration of suction caisson subjected to a constant driving force. The solution of this method was compared with those from the model tests and good agreement was achieved. Some of the key design parameters were also evaluated based on the model test results.

## 2 MODEL TESTS

### 2.1 Soil Preparation

The soil used for the model tests was consolidated from kaolin slurry. Factory made kaolin powder was used because of its high coefficient of consolidation, low compressibility and commercial availability. The kaolin used was supplied by Kaolin Malaysia Sdn. Bhd. It has a specific gravity of 2.61, a liquid limit of 61% and a plastic limit of 38%.

The kaolin powder was mixed with tap water into a slurry form with water content of 81.3%. After mixing, the desired slurry was transferred to the consolidation tank as shown in Figure 1. Then the top cap and piston were mounted onto the cylindrical tank. A compressed air pressure of 60kPa was applied on top of the piston to consolidate the kaolin slurry for about 10 days. The friction between the piston and the tank wall was 17.35 kN measured by a calibration test before the test. Therefore, the effective consolidation pressure was 37.9 kPa only.

The consolidated water was allowed to drain freely through a drainage valve at the bottom of base plate. In order to consolidate the kaolin slurry faster, a filter layer were designed on the bottom of the tank including two layers of geotextile, fine sand and gravel. The movement of piston was monitored by a laser sensor (Keyence®IL-600). After the consolidation was completed, the air pressure was reduced to zero and the top cap was removed to allow soil samples to be taken for undrained shear strength and water content tests. The water content of the tested soil was 42.7%. The average undrained shear strength

( $S_u$ ) was 13 kPa as measured by lab shear vane method along the tank depth.

Figure 1 Consolidation procedure of kaolin

### 2.2 Caisson Installation

The caisson was made by an inner steel skirt and covered by a layer of concrete with its total height of 400mm, diameter of 205mm and wall thickness of 22.5mm. The Caisson was assembled with a designed piston which made it possible to monitor the process of soil plug during installation tests. The piston consisted of a ‘Teflon’ plate and a steel rod. The plate was 25 mm thick and 150 mm in diameter with steel rod mounted in the middle. A crew with a height of 20 mm was used to strengthen the connection of the rod and the plate. Thus the clear internal skirt length of the caisson reduced from 400mm to 335 mm. The total weight of caisson and piston was 27.2kg.

The vacuum loading system was composed by a vacuum pump (EVISA E25), a vacuum gauge, two bowl vacuum filters, a vacuum tank, and a hose, as illustrate in Figure 2. Note that during suction installation tests, one more absolute pressure transducer was mounted in the caisson cavity to test the vacuum pressure.

The miniature pore water pressure transducers (PPTs) were used in this model test to measure the pore water pressure changes. Such a miniature size was necessary to minimize the influence of the measuring device to the overall soil behavior during model test. Before a model test, all PPTs were calibrated by using water pressure generated in a triaxial cell. The preinstalled positions of the PPTs on the top cap are shown in Figure 2.

The displacement of the piston in the consolidation tank or that of the suction caisson during the model test was measured by laser sensor (KEYENCE IL series) which had an effective measurement range from 20cm to 1.0m. The displacement of piston rod in caisson was also measure by another laser sensor by mounting an aluminum plate on to the rod. The third laser sensor was mounted on the frame to measure the displacement of suction caisson. Two other laser sensors were used to measure the soil movement on caisson sides as shown in Figure 2. This contact-free displacement measuring method offered both reliability and convenience.

### 2.3 Model Test Results

The model test results of caisson penetrated into the soil bed assisted by vacuum pressure was discussed in this section. Since the self-weight was not able to provide enough penetration force for caisson insertion, the caisson was manually penetrated into soil in a short distance to ensure that the applied suction would not leakage. The applied vacuum pressures in Model Test No. 1 and No. 2 during the suction installation are shown in Figure 3. It can be seen that the vacuum pressure increased very slowly

till to the largest magnitude of -80kPa. The displacements of the caisson and soil plug are shown in Figure 4 and Figure 5, respectively. It can be seen that the soil plug was moving upward throughout the installation procedure. At the beginning, the soil plugs increased nearly linearly with the time. At the time of 81s for test No. 1 and 96s for test No. 2, there was a sudden jump in the displacement. This happened because the soil plug was broken suddenly. During this period, the caisson had no penetration.

### 3 ANALYTICAL SOLUTIONS

An analytical method to simulate the penetration procedure for suction caisson in clay has been proposed by Houlsby and Byne (2005b). The friction between internal caisson wall and internal clay and that between external wall and external clay were considered separately by using different friction coefficient (different  $\alpha$  value). The self-weight penetration and suction assistant penetration have been made a clear distinction. As the self-weight penetration is very small in our 1-g model tests, only the suction assistant penetration process is discussed in this paper.

A simplified cross-section of the suction caisson is shown in Figure 6. The vertical coordinates, measured at a depth below the mud line, is set up with  $z$ . The inside, outside and average diameters of the caisson are represented by  $D_i$ ,  $D_o$ ,  $D$  respectively. Therefore,  $D_i = D_o - 2t$  and  $D = (D_i + D_o)/2$  where  $t$  is the thickness of the caisson wall. The total height of the caisson is  $L$  and height embedment into the seabed is  $h$ . The soil plug higher than the mud line inside of the caisson is denoted as  $h_p$ . The unit weight of water is  $\gamma_w$  and that of soil is  $\gamma$ .

As illustrated in Figure 6(b), the total effective weight of suction caisson is presented as  $V'$ . The side frictions between soil with outside and inside of the caisson are written as  $Q_{in}$  and  $Q_{out}$ , respectively. The end bearing capacity on the tip of suction caisson is defined as  $Q_{tip}$ .

(a) Parameters definition (b) Free body diagram  
Figure 6 Cross section of suction caisson (Modified after Houlsby and Byne, 2005b)

When the caisson penetrates into the soil, a bearing capacity failure will occur around the wall tip. It is assumed that the soil plug is mainly due to these displaced soil flow into the caisson. We make the simplifying assumptions that: (a) there is a volume of clay,  $V_s$ , flows into the caisson because of the replacement of caisson walls,  $V_c$ , and  $V_s = mV_c$ ; (b) the flowed clay does not change the original unit weight of clay within the caisson; and (c) the flowed clay forms the soil plug with its height shown in Eq. (1). These assumptions were especially valid for the suction caisson installed in clay which have already been verified by model test results (Whittle et al., 1998), prototype behavior (Colliat et al., 1996), and finite element analyses (Andersen and Jostad, 2002; Andersen and Jostad, 2004). The values of  $m$  will be calculated using the model test results.

$$h_p = m(D_o^2 / D_i^2 - 1)h \quad (1)$$

For the case of suction caisson installation in clay, the calculation neglects the effect of the applied suction pressure and the side frictions along the caisson walls. Then this procedure can be treated as undrained conditions. Therefore, the side frictions are calculated by applying a factor  $\alpha$  to the value of the undrained strength ( $\alpha$ -method), i.e.  $Q_{in} = \alpha s_{u0}(\pi D_i)$  and  $Q_{out} = \alpha s_{u0}(\pi D_o)$  where  $s_{u0}$  is average undrained strength between mud line and depth  $h$ . If the undrained strength of clay increased along depth linearly, i.e.  $s_u = s_{u1} + \rho z$ , the average undrained strength of soil,  $s_{u0}$ , can be calculated as  $s_{u0} = s_{u1} + \rho h/2$  where  $\rho$  is the coefficient of undrained strength increasing. Similar calculation method can also be applied to the internal

undrained strength,  $s_{ui}$ . The bearing capacity on the tip is calculated according to the standard bearing capacity calculation, i.e.  $\sigma'_{tip} = \gamma' h N_q + s_{u2} N_c$  and  $s_{u2} = s_{u0} + \rho h$ , where  $N_c$  is the capacity factor for a deep strip footing in clay (a typical value of 9 may be adopted) and  $N_q = 1$  for undrained analysis. During the suction assisted penetrations, the driving force is the weight of suction caisson and applied suction pressure. The resistance to the caisson is calculated as the sum of the side frictions ( $Q_{in} + Q_{out}$ ) and the end bearing capacity on the tip ( $Q_{tip}$ ). The force equilibrium along the vertical direction yields the following equation:

$$V' + s \left( \frac{\pi D_o^2}{4} \right) = h \alpha_0 s_{u0} (\pi D_o) + (h + h_p) \alpha_i s_{ui} (\pi D_i) + (\gamma' h + s_{u2} N_c) (\pi D t) \quad (2)$$

The internal and external side frictions calculated by  $(h + h_p) \alpha_i s_{ui}$  and  $h \alpha_0 s_{u0}$  may be assumed to have the same magnitude. This is reasonable as the internally remold clay will have a lower undrained shear strength and a lower coefficient of side friction (Andersen and Jostad, 2004). Then Eq. (2) can be further simplified as follows:

$$V' + s \left( \frac{\pi D_o^2}{4} \right) = 2 h \alpha_0 s_{u0} \pi D + (\gamma' h + s_{u2} N_c) (\pi D t) \quad (3)$$

The penetration depth  $h$  can be derived from Eq. (3) and shown as follows:

$$h = \frac{V' + s \left( \frac{\pi D_o^2}{4} \right) - s_{u2} N_c (\pi D t)}{2 \alpha_0 s_{u0} \pi D + \gamma' (\pi D t)} \quad (4)$$

### 4 COMPARISON BETWEEN THE TWO METHODS

It should be point out that the analytical method for caisson penetration is only applicable when the caisson is penetrating into clay with a constant velocity. Then the driving forces and resistance forces can be treated as balanced during each calculation step. The results shown in Figure 4, the penetration depth versus time curve is almost in a linear relationship. The comparisons between these two sets of results were made by assuming the caisson was penetrated into the clay in a constant speed or the forces in each calculation step were balanced.

In the following calculation, the tested vacuum pressures were taken as inputs. This procedure maybe not the way for engineering designing but could be used to verify the accuracy of this theoretical method. The comparison could also give a way to evaluate the key design parameters for caisson designing. The average undrained shear strength of soil bed used for calculation was  $13 \text{ kPa}$  as discussed in section 2.1. The values of  $N_c$  and  $N_q$  for undrained analysis were adopted as 9.0 and 1.0, respectively. The average unit weight of soil bed is  $12.3 \text{ kN/m}^3$  which can easily be derived from  $w\%$  (42.7%) and  $G_s$  (2.61). The total weight of concrete caisson is  $0.272 \text{ kN}$  ( $27.2 \times 10 \text{ kN}$ ).

The model test results and the analytical results for the displacement of suction caisson are compared in Figure 7. It can be seen that when  $\alpha = 0.72$ , the two sets of results agree well with each other. The analytical results show that the penetration of suction caisson needs a minimum driving suction pressure. However, the model tests show a much smaller value. Furthermore, the penetration procedure for model No. 2 was delayed (start time of  $t = 25 \text{ s}$ ) comparing to model No. 1 (starting time of  $t = 13 \text{ s}$ ) because the applying speed of vacuum pressure for model No. 2 is lower than that for model No. 1.

The comparison between the theoretical and the model test results regarding the heave of soil plug is shown in Figure 8. The analytical model indicates that a minimum vacuum pressure is required for the soil plug to start to heave as there is no plug

movement at the beginning. This is related to the assumption that the heave of soil plug is caused by the penetration of caisson walls. A fitting of the experimental curves using a value of  $m=1.4$  was also made.  $m=1.4$  implies that the volume of the soil going into the caisson cavity was 140% of the volume of the soil replaced. This is possible as the additional 40% could come from the expansion of the remolded soil or flow of soil beneath the caisson. As discussed before, the soil plug was broken at the end of the experiments. This aspect could not be modeled by the analytical method.

Figure 7 Predicted and measured penetration depth vs. time curves

Figure 8 Predicted and measured heave vs. time curves

## 5 CONCLUSIONS

Suction caissons have been used mainly as foundations to support offshore structures in deep water. Their applications in shallow water are more challenging as the amount of suction that can be applied to install the caissons is much less. Several model tests on the use of suction caisson in clay in shallow water were carried out. The height of soil plug, displacement of the suction caisson and applied vacuum pressure were measured during the model tests. An analytical method proposed by Housby and Byrne (2005b) were adopted to simulate the model test results. The analytical results agree well with the model test results with the selection of appropriate parameters.

## 6 ACKNOWLEDGEMENT

The authors would like to thank Dr. LIU Kejin, WU Shifan and LI Mangyuan for their contribution to the research program and Prof YAN Shuwang for useful discussions with him.

# Instrumentation de la paroi moulée du bassin de Blanc-Mesnil : retro-analyse et calage des modèles de calcul

## Instrumentation of the diaphragm wall of the Blanc-Mesnil Basin : retro-analysis and calibration of calculation models

Gutjahr I., Doucerain M., Schmitt P.  
SOLETANCHE-BACHY, Paris, France

Heumez S., Maurel C.  
CETE-IF, Le Bourget, France

**RÉSUMÉ :** Le chantier du bassin du Vieux Blanc-Mesnil a fait l'objet d'une instrumentation afin de confronter le comportement réel de l'ouvrage aux calculs aux coefficients de réaction menés lors des études d'exécution, puis en complément aux calculs aux éléments finis. Une particularité de ce projet réside dans le fait que le soutènement est surmonté d'un talus de grande hauteur, le suivi du comportement du soutènement permet donc également de comparer les différentes modélisations d'un talus à la réalité. Suite aux différences constatées entre les courbes de déformée réelle et calculée lors des études d'exécution, il a été procédé à un affinage du modèle géotechnique consistant à ne tenir compte que des sondages les plus proches des sections instrumentées. Il a ainsi été possible de valider les résultats obtenus par les différentes méthodes (coefficient de réaction et éléments finis), moyennant la prise en compte d'une modélisation réaliste du talus et l'utilisation de paramètres de sols équivalents et représentatifs.

**ABSTRACT:** The diaphragm wall of the Blanc-Mesnil Basin was subject to instrumentation in order to compare the structure's actual behaviour to calculations based on the coefficient of subgrade reaction, as used in the execution studies, as well as to calculations based on the finite element model. A peculiarity of this project lies in the fact that the retaining wall is surmounted by a high slope, thus the monitoring also permits to compare different slope calculation models to reality. Following the differences observed between the measured and calculated displacement curves, the geotechnical model was refined considering the boreholes closest to the surveyed sections. Thus it has been possible to validate the results obtained by different calculation models (finite element and coefficient of subgrade reaction).

**Mots-Clés :** suivi inclinométrique, modélisation d'un talus, calcul aux coefficients de réaction, calcul aux éléments finis

**Keywords:** inclinometer survey, slope calculation model, coefficient of subgrade reaction calculation, finite elements calculation

### 1 INTRODUCTION

Le soutènement périphérique du bassin de retenue du Vieux Blanc-Mesnil est constitué d'une paroi moulée d'épaisseur 0.80m ancrée par un niveau de tirants précontraints à caractère permanent.

Deux sections distinctes ont fait l'objet d'une instrumentation et d'un suivi complets dans le cadre de l'action de recherche FONDAMS pilotée par l'IFSTTAR afin de permettre une analyse du comportement réel de l'ouvrage puis ensuite le comparer non seulement aux calculs aux coefficients de réaction utilisés pour le dimensionnement, mais encore aux calculs aux éléments finis réalisés *a posteriori*.

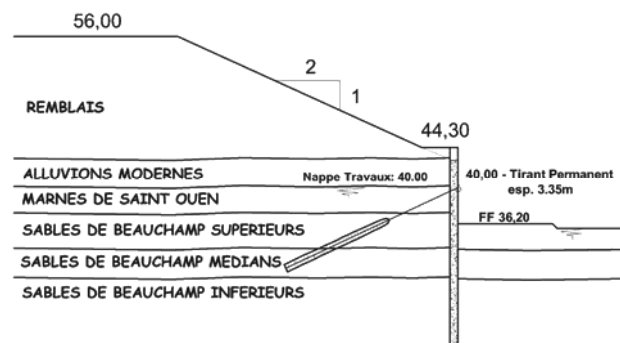

Figure 1. Profil de mesure « Coupe 1 B ».

Un intérêt particulier du projet est la présence d'un talus surmontant la paroi moulée sur une forte hauteur, variable de 7

à 12 m au droit des deux profils de mesure. La comparaison entre le comportement réel de l'ouvrage et les calculs permettra ainsi de confronter les différentes modélisations d'un talus utilisées dans la pratique courante à la réalité des mesures.

On a utilisé le logiciel PARIS (logiciel de calcul interne Solétanche-Bachy) pour les calculs aux coefficients de réaction et le logiciel PLAXIS 2D pour les calculs aux éléments finis.

Figure 2. Profil de mesure « Coupe 2 B ».

### 2 PRÉSENTATION DES MESURES

L'instrumentation de la paroi a consisté en la mise en place de deux inclinomètres scellés dans des tubes de réservation liés aux cages d'armatures de deux panneaux distincts. Plusieurs relevés inclinométriques ont donc été possibles au cours de la réalisation du bassin (un point zéro avant le début des excavations, une mesure lors de la phase en console avant la

mise en tension des tirants, et une mesure en phase fond de fouille). La précision des mesures inclinométriques est de l'ordre de 0,1 mm/m.

Afin de suivre l'évolution des efforts dans les tirants, des cales dynamométriques ont également été installées.

### 3 MODÉLISATION D'UN TALUS POUR LES CALCULS AUX COEFFICIENTS DE REACTION

Avant de procéder aux calculs de recalage, nous avons d'abord tenté d'établir quelle modélisation du talus est la mieux adaptée à la géométrie et au phasage du projet.

Pour cela nous avons mené une étude comparative portant sur la géométrie de la Coupe 1 B.

#### 3.1 Modélisations étudiées

Nous avons comparé la modélisation du talus fini par différentes méthodes :

- approches en plasticité avec hypothèse sur le schéma de rupture : méthodes de Graux (Graux, 1967) ou Houy par bandes horizontales
- approches en élasticité : méthode de Boussinesq par bandes horizontales ou verticales
- approche en plasticité avec recherche du schéma de rupture critique : module de calcul « talus-risberme » de PARIS par recherche automatique de lignes de rupture critiques (voir figure 3) (Schmitt et al, 2002)

Figure 3. Lignes de rupture – modèle « Talus-Risberme ».

Nous avons complété ces approches par le calcul des talus infinis par les coefficients de Caquot-Kérisel (1990), constituant dans le cadre de notre projet une méthode de référence car :

- l'angle du talus (27°) est inférieur à l'angle de frottement interne des remblais (30°).
- le talus peut être considéré infini par rapport à la hauteur excavée.

Afin de prendre en compte le retrait du talus par rapport à la paroi, nous avons réalisé 2 calculs de talus infini avec 2 cotes de pied de talus correspondant pour l'un à l'impact du prolongement du talus réel avec la paroi (42.90 NGF) et pour l'autre au sommet de la paroi (44.30 NGF) duquel on fait partir un talus fictif parallèle au talus réel, constituant ainsi les 2 bornes de référence pour la comparaison des différentes modélisations.

#### 3.2 Analyse des résultats et conclusion

Les calculs ont été menés avec le logiciel PARIS. Nous avons analysé l'influence des différentes modélisations sur les poussées actives et réelles ainsi que sur les déformées du soutènement par rapport aux bornes de référence données par les calculs des talus infinis.

Les conclusions sont les mêmes pour l'ensemble des paramètres comparés.

On constate notamment que les approches en élasticité donnent des poussées et déformées largement supérieures aux

autres modèles et aux bornes de référence, comme il fallait s'y attendre.

Les approches en plasticité avec hypothèse sur le schéma de rupture donnent des poussées et déformées supérieures aux bornes de référence et au modèle « talus risberme ».

Enfin la modélisation « talus risberme » donne les résultats les plus proches des bornes de référence. De plus, on constate que cette modélisation donne des courbes de poussée lissées, ne présentant pas les sauts observés dans les calculs « talus infini », ce qui devrait se rapprocher le plus des poussées réelles dans le terrain.

Figure 4. Comparaison des poussées actives selon modèle.

Notons que la modélisation « talus risberme » permet de modéliser l'aménagement d'une plateforme de circulation à l'arrière du soutènement, subtilité ne pouvant pas être prise en compte par les modèles « talus infini » ce qui explique que la poussée calculée par PARIS soit localement inférieure à la borne minimale : ceci traduit simplement le fait que la ligne d'influence du talus intercepte l'écran à une cote inférieure à 42.90, comme on le voit sur la figure 3.

Nous avons donc retenu la modélisation « talus risberme » pour les calculs aux coefficients de réaction.

### 4 COMPARAISON DES COURBES INCLINOMÉTRIQUES AVEC COURBES DE CALCUL CORRESPONDANT AUX CALCULS D'EXÉCUTION

Après avoir adapté les stratigraphies en fonction des sondages situés à proximité des inclinomètres, nous avons estimé les courbes de déformées théoriques à l'aide de calculs aux coefficients de réaction, en considérant les caractéristiques géotechniques des terrains tels que considérés lors des études d'exécution.

Tableau 1. Caractéristiques des terrains « Etudes d'exécution »

Terrain	EM / pl (MPa)	$\gamma / \gamma'$ (kN/m <sup>3</sup> )	$\phi$ (°)	c (kPa)	k (MN/m <sup>3</sup> )
Remblais	8.3 / 1.1	20 / 10	30	0	8.1
Alluvions Modernes	6.2 / 0.7	20 / 10	30	0	8.1
Marnes de St. Ouen	8.3 / 1.1	20 / 10	30	0	11.2
Beauchamp Supérieurs	23 / 2.3	22 / 12	35	0	36.5
Beauchamp médians	16 / 2.2	22 / 12	30	5	22.5
Beauchamp Inférieurs	37 / 3.8	22 / 12	35	10	67.5

EM / pl : module pressiométrique / pression limite

$\gamma / \gamma'$  : poids volumique / poids volumique déjaugé

$\phi$  : angle de frottement interne

c : cohésion

k : coefficient de réaction estimé selon la formule de Schmitt(1998)

#### 4.1 Coupe 1 B

On constate que les courbes obtenues pour la phase console divergent tandis qu'elles sont proches pour la phase fond de fouille. Nous en déduisons que pour la phase console les caractéristiques et modèles de calcul initialement retenus sont globalement réalistes, mais les propriétés mécaniques des terrains supérieurs semblent sous-évaluées.

Figure 5. Coupe 1 B : Comparaison des Courbes de Déformées.

#### 4.2 Coupe 2 B

Nous observons que les déplacements calculés sont supérieurs aux déplacements mesurés. Bien que l'influence du talus soit moindre en raison de sa plus faible hauteur, l'écart entre les déplacements calculés et mesurés est systématiquement plus important que dans la coupe 1B, ce qui tend à montrer que les caractéristiques réelles des terrains sont globalement meilleures.

Figure 6. Coupe 2 B : Comparaison des Courbes de Déformées.

L'amplitude des déformations mesurée est parfois très faible, ce qui rend illusoire toute interprétation précise de l'allure des déformées. Par ailleurs des paramètres ne pouvant pas être pris en compte dans les calculs peuvent avoir une influence : la qualité du scellement des tubes inclinométriques, la poutre de couronnement (poids important et discontinuité du bétonnage), la température...

Afin de permettre une bonne interprétation des courbes de déformées obtenues par les mesures inclinométriques, il est toujours utile de disposer de plusieurs relevés concomitants (cibles topographiques, cales des tirants, niveaux piézométriques).

## 5 CALCULS DE RECALAGE

Suite aux divergences entre les courbes de déformées réelles et théoriques, nous avons recalé le modèle géotechnique en ne tenant compte que des sondages proches des sections étudiées.

En l'absence de mesures du niveau de la nappe phréatique nous avons gardé le niveau de calcul.

#### 5.1 Calculs aux coefficients de réaction

Nous avons introduit deux couches de St.Ouen suite à l'analyse du sondage PR107 situé au droit du profil 2B et qui montre des caractéristiques pressiométriques nettement meilleures dans la partie basse de cette couche. Etant donné que l'épaisseur de la couche de St.Ouen est plus importante au droit du profil 2B (7m) qu'au droit du profil 1B (3m), nous avons considéré cette deuxième partie du St.Ouen uniquement pour les calculs de recalage du profil 2B.

Nous avons également introduit une cohésion à court-terme dans les Alluvions Modernes ainsi que dans les deux couches du St.Ouen, justifiée par la faible durée entre la mesure 0 des inclinomètres et la mesure de la phase console (1 mois).

De plus nous avons revu les valeurs des coefficients de réaction des terrains suite à l'analyse du sondage PR107 montrant des valeurs pressiométriques plus élevées que celles considérées lors des études d'exécution.

Tableau 2. Caractéristiques des terrains obtenus après recalage.

Terrain	$E_M / pl$ (MPa)	$\gamma / \gamma'$ (kN/m <sup>3</sup> )	$\phi$ (°)	$c - ct$ (kPa)	$c - lt$ (kPa)	$k$ (MN/m <sup>3</sup> )
Remblais	8.3 / 1.1	20 / 10	30	0	0	8.1
Alluvions Modernes	6.2 / 0.7	20 / 10	30	5	0	8.1
Marnes de St. Ouen 1	6.4 / 0.9	20 / 10	30	15	0	20
<b>Marnes de St. Ouen 2</b>	<b>30 / 3.0</b>	<b>20 / 10</b>	<b>30</b>	<b>40</b>	<b>15</b>	<b>75</b>
Beauchamp Supérieurs	40 / 3.2	22 / 12	35	0	0	65
Beauchamp médians	29 / 2.6	22 / 12	30	5	5	35
Beauchamp Inférieurs	55 / 3.5	22 / 12	35	10	10	80

Modifications par rapport aux paramètres initiaux en gras.

Nous obtenons les courbes suivantes :

Figure 7. Coupe 1 B : Comparaison des Courbes de Déformées après recalage.

Figure 8. Coupe 2 B : Comparaison des déformées après recalage.

Concernant les efforts dans les tirants, nous observons que les efforts trouvés par le calcul de recalage sont environ 10%

plus importants que les efforts mesurés après le terrassement au fond de fouille.

### 5.2 Calculs aux éléments finis

Parallèlement aux calculs aux coefficients de réaction, des calculs par la méthode des éléments finis ont été menés à l'aide du logiciel Plaxis2D. Afin de permettre la comparaison entre les deux méthodes de calcul, nous avons repris les mêmes caractéristiques des sols (issues du recalage).

La loi de comportement considérée est élasto-plastique avec critère de plasticité de Mohr-Coulomb. Les modules d'Young ont été fixés grâce à la relation  $E_Y=4E_M/\alpha$  (avec  $E_M$  module pressiométrique, et  $\alpha$  coefficient rhéologique des sols).

Figure 9. Vue du maillage de la coupe 1B.

La présence de la pente oblige à éloigner assez fortement la limite gauche du modèle pour minimiser l'influence des conditions limites (tout en ne l'éloignant pas trop car cela a une incidence sur la propagation des déformations). La limite droite a été choisie sur l'axe de symétrie du bassin.

Afin de prendre en compte l'inclinaison des contraintes dans la pente, la première phase de calcul a été une phase fictive d'application de la gravité.

Figure 10. Coupe 1 B : Comparaison des Courbes de Déformées mesurées et calculées par EF.

On constate qu'il existe une bonne concordance entre les déformées mesurées et calculées. Certains phénomènes ne sont cependant pas retrouvés par le calcul, comme la déformation vers 41 m NGF de la coupe 2B (cette déformation est présente dès la phase console, et pourrait être due à la réalisation de la poutre de couronnement).

On notera également qu'il existe un déplacement d'ensemble de la paroi (translation horizontale vers la fouille de 3,2 mm pour 1B et de 1,5 mm pour 2B), non représenté sur les courbes de déformées. Ce déplacement d'ensemble est peu réaliste et est certainement lié à la modélisation numérique, mais en l'absence de suivi topométrique, et avec des mesures inclinométriques ne descendant pas sous la base de la paroi, il n'est pas possible de certifier que ce mouvement d'ensemble n'existe pas.

Figure 11. Coupe 2 B : Comparaison des déformées mesurées et calculées par EF.

Quant aux efforts calculés dans les tirants, on constate qu'ils sont sous-estimés de 15% pour la coupe 1B, et surestimés de 20% pour la coupe 2B.

## 6 CONCLUSIONS

On observe que les résultats des calculs de recalage obtenus avec PARIS et PLAXIS avec les mêmes caractéristiques de terrain, sont très similaires, tant en valeur qu'en allure de déformée et relativement proches des mesures inclinométriques.

L'ensemble des calculs menés, et notamment la similarité des résultats obtenus par PARIS et PLAXIS 2D, montre la validité du modèle « talus risberme » avec recherche automatique des lignes de rupture critiques dans le cadre de cette étude, ainsi que la bonne concordance du calcul aux éléments finis en modèle Mohr-Coulomb ( $E_Y=4E_M/\alpha$ ) avec le calcul aux coefficients de réaction estimés selon Schmitt, ce qui confirme les résultats obtenus sur des chantiers antérieurs (Schmitt 2009)

## 7 REMERCIEMENTS

Remerciements à l'IFSTTAR qui a permis la mise en place de l'instrumentation et une partie de cette étude dans le cadre de l'opération de recherche FONDAMS.

# Displacement of an apartment building next to a deep excavation in Rotterdam

## Déplacements d'un bâtiment d'habitation adjacent à un chantier profond d'excavation à Rotterdam

Hannink G., Oung O.

*Engineering Consultancy Division, City of Rotterdam, The Netherlands*

**ABSTRACT:** A new underground car park is being realized near the Rotterdam Central Railway Station. The car park will contain five stories and will be about 150 m long and 35 m wide. The depth of the underground car park is about 20 m. Tall office buildings are present at both sides. A 30 m high apartment building is situated perpendicular to the car park, and the distance of this building to the car park is only 7 m. This building is founded on prefabricated concrete piles with a base level that equals the excavation depth of the car park. The underground car park is being realized inside a dry building pit surrounded by 40 m deep diaphragm walls. Predictions, based on calculations with analytical as well as 2D and 3D finite element models, showed that the expected settlements of the apartment building were acceptable. The measured displacements remained well within the limits that were predicted.

**RÉSUMÉ :** Près de la gare ferroviaire centrale de Rotterdam, un parking souterrain est encore en construction. Ce parking sera pourvu de cinq niveaux et aura les dimensions de 150 m de long en 35 m de large. La profondeur de ce parking sera de 20 m. Le long des côtés du parking en construction se trouve de hauts bâtiments. En particulier, un bâtiment d'environ 30 m de haut est situé à peine à une distance de 7 m de ce parking et se tient perpendiculairement à celui-ci. Ce bâtiment est fondé sur des pieux en béton préfabriqués dont la base est au même niveau que celui de l'excavation réalisée pour la construction du parking. Cette excavation est délimitée par des parois moulées dont la base se trouve à 40 m de profondeur. Les prédictions, basées sur des calculs pour lesquelles des modèles d'éléments finis bi- et tridimensionnels ont été montés, ont montré que les tassements de ce bâtiment prédits étaient acceptables. Les déplacements mesurés durant la réalisation de l'excavation sont restés dans les limites des calculs de prédiction.

**KEYWORDS:** deep excavation, settlement of structures, finite element models, prediction, monitoring.

### 1 INTRODUCTION

In the centre of Rotterdam, extensive reconstruction works are executed as part of the overall project Rotterdam Centraal. The reconstruction comprises of the building of a large Public Transport Terminal to facilitate passenger transfer between (inter)national trains including the high-speed train, and local public transport like trams, buses and underground trains. The project also includes a new underground metro station, a new underground parking facility for bicycles, a new traffic tunnel below a newly created square, and a new underground car park.

The car park will contain five stories and will be about 150 m long and 35 m wide. The depth of the underground car park is about 20 m. Tall office buildings are present at both sides. A 30 m high apartment building is situated perpendicular to the car park and the distance of this building to the car park is only 7 m (see Figure 1).

The apartment building is founded on prefabricated concrete piles with a base level that equals the excavation depth of the car park. The underground car park is being realized inside a dry building pit surrounded by 40 m deep diaphragm walls.

Calculations of the expected settlement of the apartment building were made in the design stage of the project, and a fall-back option was thought out in case the settlement would exceed the criteria.

The apartment building was continuously monitored during the construction of the parking facility. This paper describes the expected impact of the construction of the underground car park on the apartment building, and the results of the monitoring. The car park is presently in the final stage of construction.

Engineering of the car park Kruisplein, and supervision of the execution of the project is performed by the Engineering Consultancy Division of the City of Rotterdam.

Figure 1. The construction of the underground car park Kruisplein (February 2012). The apartment building is situated in front, at the left (perpendicular to the car park). Photograph Nick de Jonge – Skeyes fotografie.

### 1.1 Subsoil

The ground level in the area is situated at about sea level (this corresponds to the Dutch reference level NAP). The subsurface conditions at the building site are presented in Table 1. The hydraulic head in the fill is about 1.5 m below sea level, and in the Pleistocene sand layers about 2 m below sea level.

Table 1. Soil conditions

Elevation (m NAP)		Origin – Type of soil
from	to	
-0.3	-4.5	Fill - sand
-4.5	-5.5	Holocene - soft clay
-5.5	-8.0	Holocene - peat
-8.0	-17.0	Holocene - soft clay
-17.0	-35.0	Pleistocene - sand
-35.0	-37.0	Pleistocene - stiff clay
-37.0	-40.0	Pleistocene - sand

### 1.2 Challenge

The horizontal as well as the vertical equilibrium of the foundation of the apartment building may be influenced by the building activities (see Figure 2). The foundation piles of the apartment building:

- will be horizontally loaded by the soil that displaces into the direction of the diaphragm wall, because of its deflection;
- will displace vertically, because the soil that displaces into the direction of the diaphragm walls also displaces slightly into the vertical direction;
- will displace vertically, because the deflection of the diaphragm wall causes some relaxation of the sand layer, and therefore results in a decrease of the bearing capacity.

The effects of these phenomena had to be assessed, and taken into account during the design stage of the construction of the underground car park.

Figure 2. The consequences of the deflection of the diaphragm wall to the apartment building.

## 2 APARTMENT BUILDING

The length of the apartment building is 50 m, the width is 10 m. Prefabricated concrete piles 380 mm square and 450 mm square support the building. The foundation piles are connected by beams in north-south direction. The pile rows in the vicinity of the building pit support via columns bearing walls (see Figure 3). These walls distribute the load to the piles. The apartment

building can therefore be considered as stiff in the north-south direction. In the east-west direction pile rows are not able to redistribute the loads. In that direction the apartment building is considered as flexible.

Figure 3. The apartment building.

Before analyzing the expected settlement behavior of the apartment building, the building regulations of the period in which the apartment building was constructed had to be translated, and compared with the current building regulations. Therefore calculations of the vertical bearing capacity of the foundation piles were made, based on the Dutch standard NEN 6743-1. The original building documents of the apartment building mentioned the design loads on the piles. These had to be converted first into representative and design values. This resulted in a ratio of 1.9 between the average bearing capacity of the pile foundation and the representative value of the load. This fits reasonably well with the overall safety factor of 2.0 that was used for this type of piles in the period the apartment building was constructed. Because of this small difference in safety level NEN 6743-1 was used to analyze the settlement behavior of the apartment building.

## 3 ANALYSIS

### 3.1 Settlement due to the relaxation of the subsoil

The analysis was directed to the first five rows of piles of the apartment building. The first row is situated at about 7 m distance of the diaphragm wall; the fifth at about 23 m. The distance between the pile rows is 3.9 m. Load-settlement diagrams have been derived for a single prefabricated concrete pile based on general curves presented in NEN 6743-1. Both a pile 380 mm square and a pile 450 mm square were considered.

The calculations with the computer code MFoundation 5.3.1.4 were based on data of six CPT's. The maximum bearing capacity for each CPT, the representative value of the average bearing capacity and the design value of the bearing capacity were determined for both pile sizes. The magnitude of the negative skin friction was also calculated.

The subsoil, in particularly the sand layer with the top at 17 m below sea level, will relax as a result of the excavation of the

building pit. Based on CPT-measurements of the cone resistance at a comparable building pit, it was assumed that the relaxation amounts to 20% up to a distance of 12 m of the building pit, and that the relaxation from this distance decreases with 2.5% every 5 m. The decrease of the vertical bearing capacity was assumed to be proportional to the relaxation of the sand layer.

Figure 4. Graphical determination of the pile base settlement.

Load-settlement diagrams have been composed for the serviceability limit state, based on NEN 6743-1 (see Figure 4). For example, a pile base settlement of 4 mm is expected for the original situation. Due to a relaxation of the sand layer of 20% a pile base settlement of 8 mm is calculated, thus an additional settlement of 4 mm as a consequence of the relaxation.

It was concluded that the piles 380 mm square could settle 2 to 4 mm as a result of a relaxation of the sand layer of 12.5 to 20%. For piles 450 mm square these values varied between 3.5 and 5 mm.

### 3.2 Horizontal soil displacement due to the deflection of the diaphragm wall

The greenfield horizontal soil displacement at the position of the relevant foundation piles of the apartment building has been calculated by using the Hardening Soil (HS) model with the Small Strain Stiffness (HSS), of the computer code Plaxis 2D 8.5. Three cross-sections were considered (see Figure 5):

- at the middle section of the building pit where the excavation took place according to the conventional method;
- next to the apartment building, where the car park was built according to the top down method: after the construction of the diaphragm wall the roof is built, and after that the soil is excavated below the roof and the successive floors are made;
- in the transition zone between the two building methods.

Figure 5. The cross-sections of the building pit that were considered with the Plaxis 2D computer code.

The different stages of the excavation with the corresponding lowering of the groundwater pressures in the building pit, and the installation of the successive layers of struts have been

considered, and the displacements have been calculated. The stiffness of the diaphragm wall was based on cracked concrete.

The calculated deflection of the diaphragm wall was about 70 mm in the middle section of the building pit, at a depth of 18 m. Next to the apartment building, the deflection was about 40 mm, at a depth of 20 m. The expected deflection of the diaphragm wall was about 55 mm in the transition zone.

At the location of the first pile row of the apartment building, the calculated greenfield horizontal soil displacement was 20 mm. At the following pile rows this displacement was according to the calculations 10 to 15 mm.

From additional calculations with the elastoplastic spring model of the computer code MSheet 7.7, it was concluded that the expected moments and shear forces in the foundation piles would remain smaller than the acceptable values.

### 3.3 Consequences of the soil displacement to the pile foundation

The computer code Plaxis 3D Foundation 2.1 has been used to determine the combined effect of the horizontal and vertical ground displacements. With the computer code MFoundation 5.3.1.4 the vertical displacement was considered, and with the computer code Plaxis 2D 8.5 the greenfield horizontal soil displacement.

The diaphragm wall has been modeled from the southern wall up to the middle of the conventionally built section. The floors that are part of the section that was built according to the top down method form part of the model. Only the five pile rows next to the building pit, and the complete ground floor were part of the model.

The piles were modeled as embedded piles. This made it possible to determine the moments and shear forces as well as the displacement of the foundation piles directly from the calculations. The calculated settlements of the pile base may be exaggerated, because the model does not take into account the densification of the soil as a result of the installation of the piles.

The with the computer code Plaxis 2D calculated deflection of the different parts of the diaphragm wall was used to calibrate the Plaxis 3D model. For the greater part of the building pit the calculated maximum horizontal displacement of the diaphragm wall was about 70 mm, in accordance with the results of the calculations with the Plaxis 2D computer code. Near the southern part of the diaphragm wall the calculated displacement varied between 15 and 40 mm.

According to the calculations, the pile base of both the 380 mm pile, and the 450 mm piles will settle 8 to 12 mm as a consequence of the soil displacement. The calculated horizontal deflection of the foundation piles was 25 mm as a maximum. The calculated moments and shear forces are relatively small.

## 4 PREDICTION

Based on the calculations the predicted settlement of the apartment building was 2 to 5 mm due to relaxation and 8 to 12 mm due to the soil displacement. This means in total 10 to 15 mm as a consequence of the building activities for the underground car park. Damage was not expected, because of the decrease of settlement with distance from the building pit. The settlement difference of the piles was expected to be small.

Horizontal displacements of the pile foundation, varying between 10 and 25 mm, were also expected. Also no damage was expected in this case, because the displacement would manifest itself underground, with only a limited effect on the foundation piles and the superstructure.

## 5 MONITORING

### 5.1 Set-up

Measuring points at 4 m above ground level were installed on the columns that were supported by the first four rows of piles of the apartment building (see Figure 6).

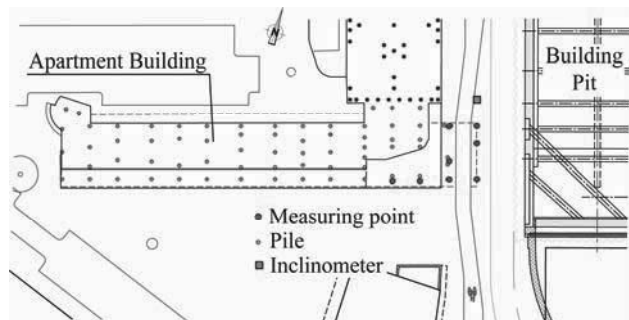

Figure 6. Measuring points on the apartment building.

Vertical and horizontal displacements were continuously monitored by a measuring device on top of a building at a distance of more than 50 m. The results of these measurements were periodically checked by measurements that were discontinuously executed as part of an extensive measuring program around the building pit.

The results of periodically executed inclinometer measurements offered another way to check the actual displacements. The inclinometers were situated next to the apartment building at a distance of 7 m from the diaphragm wall. This corresponds to the distance of the first pile row of the apartment building from the diaphragm wall.

The owner of the apartment building was fortnightly informed about the monitoring results.

### 5.2 Criteria

A relative rotation of the apartment building of 1:600 was used as the value to intervene, and a relative rotation of 1:750 served as the value to prepare mitigating measures. Because of practical reasons these values have been converted to settlement values of 15 and 12 mm respectively at any specific point.

### 5.3 Results

The continuous measurements started in January 2010. The measured displacements appear to be according to the prediction (see Figure 7). Meanwhile the apartment building is stable, and only a limited settlement has occurred.

Figure 7. Measured vertical displacements in the period from January 2010 till May 2012.

The in June 2010 measured vertical displacement of the east front of the apartment building was the reason that the fall-back option was prepared. However, the further development of the settlement did not give rise to the actual installment of additional foundation piles below the east front.

The measurement results show that the apartment building rose again some 5 mm after the execution of the water tightness test. During the excavation of the deepest part of the building pit the apartment building settled some 8 mm. The maximum settlement of the east front appeared to be 10 to 15 mm, in accordance with the prediction.

The measured horizontal displacement of the apartment building varied between +10 and -10 mm (see Figure 8).

Figure 8. Measured horizontal displacements in the period from January 2010 till May 2012.

Inclinometer measurements started in July 2010, after the execution of the water tightness test. Next to the apartment building the maximum measured deflection of the diaphragm wall was about 35 mm at 15 m depth. At a distance of 7 m from the diaphragm wall the maximum horizontal soil displacement was about 40 mm at a depth between 5 and 10 m. From additional calculations with the elastoplastic spring model, it was concluded that the moments and shear forces in the foundation piles were smaller than the acceptable values.

## 6 CONCLUSIONS

Diaphragm walls are an appropriate type of retaining wall in an urban environment, but will also deflect as a result of a deep excavation. The consequences for adjacent structures must therefore be studied in the design stage.

A risk analysis helped to find the optimal design for the building pit as to restrict the uncertainties for adjacent structures to a minimum. It also helped to create fall-back options.

The results of the test of the water tightness of the building pit showed in an early stage that the apartment building was vulnerable to deformations of the subsoil. This resulted in a great attention for monitoring results during the whole construction period by all persons concerned.

Accurate predictions about the expected vertical and horizontal displacements appeared to be possible with the help of the available computer codes.

The case of the apartment building next to a deep building pit showed for all that a systematic approach is needed to overcome the presented challenges.

**ABSTRACT:** In the article basic condition to the calculation the soil-cement massif optimum dimensions, which ensure the assigned value of deep excavation wall displacement are presented. Problem statement and it's solution with the application of a Winkler-bed model, standard procedures for analysis of massive retaining walls and theory of optimum design are described. Some results of calculations and benchmark of these results with the use of PLAXIS 2D software package are given.

**RÉSUMÉ :** Le procédé de calcul est décrit pour la détermination des dimensions d'une masse de sol-ciment en utilisant un modèle de "Winkler-bed", des procédures standard pour l'analyse des murs de soutènement poids, et la théorie de la conception optimale. Les résultats des calculs et leur évaluation à l'aide du logiciel PLAXIS 2D sont présentés.

**KEYWORDS:** diaphragm wall, optimal design, Winkler-bed model, coefficient of stiffness.

## 1 INTRODUCTION

Acceleration of work execution for underground space constructing in dense urban conditions with the minimum influence upon surrounding buildings is one of the main problems of underground structures design today. The given paper presents the design method of optimization of the raised problem design decision. The method of excavation "top-down" is used as technological scheme only with upper floor installation and as optimized (variable) parameter, the dimensions of soil-cement mass (SCM) combined with enclosure (diaphragm wall) that provides the excavation without intermediate strutting system and minimization of wall displacement (Fig. 1).

So the main task is to determine the minimum volume of the SCM with the condition that the horizontal displacements of the enclosure during excavation of the pit do not exceed the assigned value  $S^h_{max} \leq S^{pred}$ .

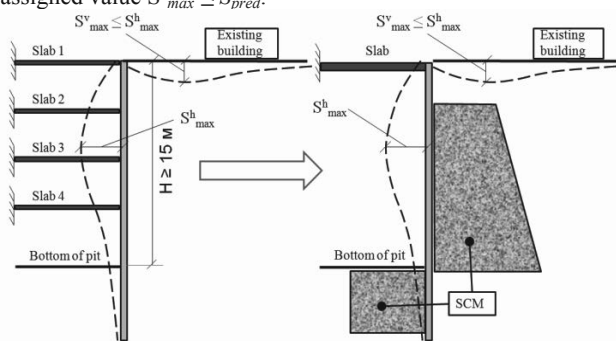

Figure 1. Problem condition

## 1 PROBLEM STATEMENT

The computational model of the optimized "wall-SCM-soil" system can be represented as a beam on an elastic Winkler bed, where the beam simulates the pit enclosure, and the SCM working in consort with the soil of the elastic bed. The stiffness coefficient of the bed, which varies over the height of the enclosure, is the only parameter of the model used to

determine the dimensions of the SCM. The stiffness coefficient of the elastic bed, and the development of a procedure to determine the SCM dimensions corresponding to the optimal solution will therefore be the subject of optimization problem.

In its initial state of rest, the enclosure is treated as a beam affixed on two sides by prestressed springs that describe the "SCM-soil" system (Fig. 2, a, b), whereupon the prestress corresponds to the lateral pressure of the soil  $q_{01}$  in a state of rest (Fig. 2, c, d). As the pit is excavated, the prestressed springs (soil) then disappears on one side together with the pressure, which they have created, and the system is taken out of equilibrium. To attain equilibrium, the enclosure is displaced within the pit (Fig. 2, e). Here, the springs below the bottom of the pit are mutually disturbed on the inside, but are undisturbed on the outside, altering the pressure of the springs against the enclosure (Fig. 2, f). During compression, this pressure is increased, and is

$$q_2 = q_{02} + kz, \quad (1)$$

but is diminished on release

$$q_1 = q_{01} - kz, \quad (2)$$

whereupon the change in pressure will depend on the coefficient of stiffness  $k$  of each spring, and the displacement  $z$  of the enclosure at the corresponding point.

During excavation, therefore, the SCM as a component part of the soil, which is simulated by the springs (Fig. 2, g) is displaced inside the pit, and the pressure against the enclosure is changed in conformity with (1) and (2), and the pressure against the SCM remains as before  $q_{02}$  and  $q_{01}$  on the side of the soil, when no Coulomb active or passive pressure is formed.

Considering that the displacement of the soil and beam below the bottom of the pit is less than that within the bounds of the pit over its height, let us simplify the computational diagram. The work of the springs on the outside of the pit below its bottom can be neglected (Fig. 2, h), and replaced by a constant pressure of the soil in a state of rest. If these springs are eliminated from the computational diagram of the beam on the outside of the pit, the pressure of the soil against the enclosure below the bottom of pit will be  $q_0 = q_{01} - q_{02}$ , and the springs on the inside beneath its bottom will be under no prestress.

Figure 2. Steps in formulation of computational diagram: 1) elastic prestressed springs; 2) and 3) compression and release of springs; 4) position of enclosure prior to excavation of pit; 5) SCM.

Considering that the displacement of the soil and beam below the bottom of the pit is less than that within the bounds of the pit over its height, let us simplify the computational diagram. The work of the springs on the outside of the pit below its bottom can be neglected (Fig. 2, h), and replaced by a constant pressure of the soil in a state of rest. If these springs are eliminated from the computational diagram of the beam on the outside of the pit, the pressure of the soil against the enclosure below the bottom of pit will be  $q_0 = q_{01} - q_{02}$ , and the springs on the inside beneath its bottom will be under no prestress.

To convert to the standard diagram of a beam on an elastic bed, let us point out that the amount  $k \cdot z$  by which the pressure of the springs is reduced against the enclosure during release in (2) is the reaction of ordinary springs with no prestress, which are positioned on the opposite side when acted upon by force  $q_{01}$ . The work of the prestressed springs is then equivalent to the work of stress-free springs under a load equal to the prestress.

Consequently, the problem reduces to one of a beam on an elastic bed (Fig. 2, i), where the beam represents the pit enclosure, the external load is the lateral pressure of the soil in a state of rest  $q_0 = q_{01} - q_{02}$ , and the coefficients of the elastic bed are the stiffness coefficients  $k$  of the "SCM-soil" system, which depend on the dimensions and shape of the SCM, as well on the strength and deformation characteristics of the soil. Considering the above, let us determine the following for further analysis:

1) the active pressure against the "enclosure-SCM-soil" system – the pressure  $q_0$  of the soil at rest;

2) the contact pressure on the enclosure, which can be transmitted through the SCM

$$q = q_0 - kz; \quad (3)$$

3) the reactive pressure of the SCM – that portion of the active pressure against the system, which can be taken up by the SCM as the system transitions to a new equilibrium position after excavation of the pit

$$r = kz. \quad (4)$$

Depending on the displacements of the enclosure, the soil mass may function in an elastic stage, which can be described by the work of elastic springs, or a plastic stage when the contact pressure against the enclosure attains the active or passive pressure of the soil. Since the basic purpose of SCM use is to ensure preservation of surrounding development, the stress-strain state (SSS) of the surrounding soil mass should not go over into a plastic state, and the displacements of the enclosure during excavation should be so small that Coulomb's limiting equilibrium will not be realized. In the analyses, therefore, only the elastic work of the system, where the SCM ensures that the soil, and, accordingly, the "SCM-soil"

system, will function elastically, is ensured. This enables us to perform the calculations in a linear statement, appreciably simplifying solution of the problem of the optimal design of the system under consideration.

In conformity with the physical essence of the problem, the contact pressure against the enclosure above the bottom of the pit cannot be less than zero (cannot act in the opposite direction due to excavation of the pit). For stiffness coefficients above the bottom of the pit should be satisfied the condition

$$q = q_0 - kz \geq 0. \quad (5)$$

Using (5) the "enclosure-SCM-soil" system, therefore, it is possible to use a finite-element formulation of a beam on an elastic bed, where the lateral pressure of the soil in a state of rest is the load.

Let us borrow terminology from (Hogg and Arora 1983) to construct the mathematical optimal-design model. Terms of the theory of matrix calculus can also be used when necessary.

In the computational model selected:

– the *equation of state* is the matrix equation of the finite-element method (FEM)

$$K(k)Z - Q = 0, \quad (6)$$

where  $K(k)$  is the global stiffness matrix of the system, the elements of which will depend on  $k$ , and  $Q$  and  $Z$  are the vectors of the nodal loads and displacements, respectively;

– the *state variables* are the displacements  $Z$  at the nodes of the finite-element diagram, which describe the behavior of the system in question under load. The transposed form of the vector

$$Z = [Z_1, Z_2, Z_3, \dots, Z_m], \quad (7)$$

where  $m$  is the number of degrees of freedom and state variables  $m = 2n + 2$ , and  $n$  is the number of finite elements. After exclusion the angle of rotation from vector  $Z$  the vector  $z$  of horizontal displacements expressed as follows

$$z = [Z_1, Z_3, \dots, Z_{m-1}] = [z_1, z_2, z_3, \dots, z_{n+1}]; \quad (7a)$$

– the *design variables* are contained in the set of coefficients  $k$ , which describes the system itself, but not its behavior.

$$k = [k_1, k_2, k_3, \dots, k_n]. \quad (8)$$

For the computational diagram under consideration, let us write in the terms of the problem statement of an optimal finite-dimensional design in state space.

It is required to determine the set of design variables  $k$ , which will minimize the efficiency function, as determined by the total stiffness coefficient with respect to all finite elements of the model

$$\psi_0 = \psi_0(k) = \sum k_i \rightarrow \min, i = 1 \dots n \quad (9)$$

$$\text{when state equations} \quad h(k, z) = K(k)Z - Q = 0 \quad (10)$$

$$\text{and constraints} \quad \psi(k, z) = [\psi_1(Z), \psi_2(k), \psi_3(k), \psi_4(k, Z)]^T \leq 0 \quad (11)$$

exist, where  $\psi(k, Z)$  is the set of its type of constraints,  $i = 1-4$ .

Let us define the types of bounded functions.

1. Bounded-function vector  $\psi_1(Z)$  is determined from the conditions of the problem for which limits should be placed on horizontal displacements  $z$  (7, a) at all  $n + 1$  nodes of the enclosure, which is broken down into  $n$  elements. The expressions  $\psi_1(Z)$  are derived proceeding from the inequalities

$$z_1 \leq S_{\max}, i = 1 \dots n + 1 \quad (12)$$

2. The vector function  $\psi_2(k)$  reflects the limits placed on the design variables  $k$ . Expressions for

$$\psi_2(k) \text{ are derived, proceeding from the inequalities} \quad k_i \leq k_{\max}, k_i \geq k_{\min}; i = 1 \dots e, \quad (13)$$

where  $e$  is the number of the last element situated above the base of the pit,  $k_{\max}$  is the value defining the upper limit of the variation of a variable, and  $k_{\min} = 0$  is the lower limit of variation in the absence of an SCM.

3. The vector function  $\psi_3(k)$  reflects the limits placed on the design variables  $k$  below the bottom of the pit. The expressions for  $\psi_3(k)$  are derived from the inequalities

$$k_i < k_{max}; k_i > k_{min}; i = e + 1 \dots n, \quad (14)$$

where  $k_{min}$  is the lower limit of variation, and  $k_{min} = k_{so}$  corresponds to the stiffness coefficient of the soil when functioning elastically.

4. The vector function  $\psi_4(k, Z)$  reflects the constraint that ensures fulfillment of (5) – a reduction in pressure on the elements residing above the base of the pit, and cannot exceed the active horizontal load of the soil at rest on the corresponding element. The expressions for  $\psi_4(k, Z)$  are derived from the inequalities

$$r_i = k_i \cdot z_i < q; i = 1 \dots e + 1 \quad (15)$$

where  $r_i$  is the reduction in pressure, or the reaction of the elastic bed at the  $i$ th node,  $k_i$  is the coefficient of the elastic bed at the  $i$ th node, and  $z_i$  is the horizontal displacement  $z$  (7, a) at the  $i$ th node.

In the problem under consideration, the limits are represented by the following type of set:

$$\psi(k, z) = [\psi_1(Z), \psi_2(k), \psi_3(k), \psi_4(k, z)] \quad (16)$$

Using (9), (10), and (16), the structure and analytical form of the components of the mathematical optimal-design model are entirely defined and ready for the solution.

## 2 PROBLEM SOLUTION

The search algorithm for optimization based on the method of gradient projection, where that variation in design variables, for which the efficiency function is decreased, and the limits are not violated, is determined in each interval, is compiled for the problem's solution, and is implemented in the software package MATLAB v.7.9.0. The gradients of the efficiency and bounded functions with respect to design variables are required for construction of the algorithm are determined from analysis of the sensitivity of the design in state space (Hogg and Arora 1983).

The search strategies consist in the plotting of a succession of  $k^p$  points calculated in accordance with the rule

$$k^{p+1} = k^p + \delta k^p, p = 0, 1, \dots, \quad (17)$$

where  $p$  is the number of iterations,  $k^p$  is a vector in the form of (8), and  $\delta k^p$  is the vector of variation in the design variables, which decreases the efficiency function as determined for each  $p$  using the gradients obtained from sensitivity analysis of the design.

Figure 3 shows a geometric interpretation of the performance of the algorithm for a two-dimensional space. The resultant vector of the variation in the design  $\delta k^p$  is obtained as a result and the iteration process of the search for the conditional extremum acquires the form shown in Fig. 3

Figure 3. Geometric interpretation of algorithm performance:

1) curve of bounded function;

After running the algorithm, the succession of points converges on the optimal value of the efficiency function, i.e., the optimal distribution of  $k^*$ . As a result of running the

algorithm, the sequence of points converges to the optimal value of the efficiency function, i.e., to the optimal distribution of the coefficient  $k^*$  of the bed's stiffness.

The dimensions of the SCM corresponding to this stiffness are required for determination of the optimal distribution of the coefficient  $k$ . The following are basic initial data for determination of the optimal dimensions of the SCM:

- the minimum height  $h$  of the SCM, as determined above and below the bottom of the pit based on the distribution curves of  $k$  and the reactive pressure  $R$ ;

- the total reactive pressure of the SCM over the height  $h$ , which should be taken up by the SCM as a component part of the soil in order that the "SCM-soil" system correspond to the elastic behavior

$$R = \sum r_i, \quad (18)$$

where  $i$  is the number of nodes over the height  $h$ , and the point of application of the force  $R$  resides at the level of the center of gravity  $r$  of the plot; and,

- the average displacement  $z_{avg}$  of the enclosure over height  $h$ , which corresponds to the displacement of the SCM under the action of  $R$

$$z_{avg} = \sum z_i / v, \quad (19)$$

where  $v$  and  $i$  are the number of nodes, and the numbers of the nodes over height  $h$ .

Use of  $R$  and  $z_{avg}$  enable us to convert to the assumption that as a component part of the soil, the SCM functions as a solid body, and is not calculated for individual elements over the height.

It is therefore required to determine the minimum dimensions of the SCM for which it will experience a horizontal displacement  $z_{avg}$  under the horizontal force  $R$ .

Let us examine the application of the above-indicated computational principles in an example of the calculation of optimal SCM dimensions for the excavation of a pit in sand with the following initial data: specific weight  $\gamma = 20 \text{ kN/m}^3$ , overall compression modulus  $E = 25,000 \text{ kPa}$ , angle of internal friction in shear  $\varphi = 30^\circ$ , cohesion  $c = 1.0 \text{ kPa}$ , pit depth of 20 m, enclosure depth of 30 m, a "diaphragm wall" enclosure with a thickness of 800 mm, and an upper thrust bracing consisting of a reinforced concrete span with a thickness of 500 mm.

Solution of the optimal-design problem (Fig. 4) includes curves of enclosure displacements (Fig. 4, a), distributions of the optimal stiffness coefficient over the height of the enclosure (Fig. 4, b), the reactive pressure (Fig. 4, c), and the contact pressure (Fig. 4, d).

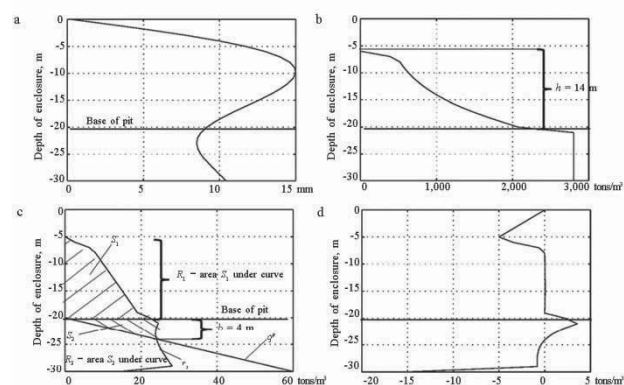

Figure 4. Results of calculation for  $S_{max} = 15 \text{ mm}$ : a) displacement; b) stiffness coefficient diagram; c) reactive pressure; d) contact pressure

To determine the optimal dimensions, let us examine the SCM above and below the bottom of the pit.

According to the plot (Fig. 4, b), the SCM above the bottom of the pit extends to the point along the height where  $k = 0$  and  $h = 14 \text{ m}$ . For the enclosure above the bottom of the pit where  $k = 0$ , no soil cement is required. Let us consider the SCM a massive retaining wall 14 m high, the upper and lower bases  $a$  and  $b$  of which should be determined from calculation of (18) for a

horizontal load  $R_1$  corresponding to area  $S_1$  under the reactive-pressure curve in Fig. 4, c and the displacements  $z_{av/2}$  (19).

Figure 5. Computational diagrams for SCM above bottom of pit: 1) initial position; 2) turning point.

The optimal dimensions of the SCM on the outside of the pit were found by solving the other optimization problem which minimize cross sectional area of the massive retaining wall (trapezoid)

$$\Psi_0(a, b) = (a+b)h/2 \rightarrow \min \quad (20)$$

for limits ensuring observance of the following conditions:

1) stability against shear (Fig. 5, a)

$$(Q(a, b) + G(a, b))\tan(\varphi) + ca \geq R_1, \quad (21)$$

where  $Q$  is the weight of the soil in the SCM benches;

2) stability against overturning about a certain point (Fig. 5, b) with consideration of the deforming bed in accordance with Klein's procedure (Klein 1964)

$$M_{re}(a, b) = N(a/2 - c) \geq M_d(a, b) = R_1y + G(a/2 - x) - Qx_c; \quad (22)$$

3) the displacement  $z_{sc}$  of the SCM under the action of  $R_1$  should not exceed the displacement

$z_{avg}$  averaged over the height  $h$  (Fig. 5, c).

$$z_{sc} = \frac{R_1}{k_{sp} a \cdot tg\varphi} \leq z_{cp};$$

Figure 6. Computational diagram for SCM below bottom of pit

If the first two stability conditions are observed, the displacement of the SCM is determined only by the horizontal deformation of the soil in the bed, which is described by the stiffness coefficient  $k_{so}$  of the soil when the rotation of the mass is disregarded.

In order for the system to function in the elastic stage, the dimensions of the SCM below the bottom of the pit are determined with consideration of the fact the soil takes up the reactive pressure, and the SCM the remaining portion. Above the point of intersection, the reactive pressure exceeds the passive pressure of the soil  $q_p$  (see Fig. 4, c), but is lower than the passive pressure below the point; the minimal height of the SCM will therefore correspond to the distance from the bottom of the pit to the point of intersection of the  $r$  and  $q_p$  curves. Here, the design load on the SCM is calculated based on area  $S_2$  (see Fig. 4, c)

The optimal dimensions of the SCM under the bottom of the pit are determined by solving the optimization problem which minimize the value of the efficiency function corresponding to the cross-sectional area of the mass

$$\Psi_0(a, b) = ab \rightarrow \min \quad (25)$$

with limits ensuring observance of the following conditions:

- the stability of the SCM against shear (Fig. 6, a)

$$R_2 \leq F_n = G \tan(\varphi) + ca; \quad (26)$$

- the displacement  $z_{sc}$  of the SCM under load  $R_2$  is no greater than the displacement  $z_{avg}$  averaged over height  $h$  (Fig. 6, b)

$$z_{sc} = \frac{R_2}{k_{so} a \cdot tg\varphi} \leq z_{avg} \quad (27)$$

Figure 7. Results of problem solution: a) optimal SCM dimensions when  $S_{max} = 15$  mm; b) results of comparison: 1) elastic bed; 2) PLAXIS 2D.

The optimal dimensions are determined for the allowable displacement of the enclosure  $S_{max} = 15$  mm as a result of solution of the problems described (Fig. 7, a).

The numerical modeling was performed in the software package PLAXIS 2D with consideration of the SCM dimensions obtained, and plots of the horizontal displacements were compared (Fig. 7, b). The discrepancy between the maximum horizontal displacements was insignificant, although the pattern of the curves differed somewhat. Similar calculations and comparison with PLAXIS were conducted for the same initial data, but with limits placed on the displacements  $S_{max} = 30$  and 60 mm. It was established that the SCM dimensions obtained with use of the proposed method yielded a high safety factor with respect to displacements with increasing tolerances. Application of the method in question is therefore restricted to the region of small enclosure displacements; this does not contradict the goals of the stated problem.

### 3 CONCLUSIONS

A computational method is developed for determination of the optimal dimensions of a soil-cement mass (SCM) that reduces the displacements of an enclosure to required values. The method includes:

- a computerized-search algorithm for optimal engineering of the coefficient of stiffness of an elastic bed; and,
- calculation of optimal SCM dimensions corresponding to the optimal stiffness using standard procedures for analysis of massive retaining walls.

The computational method makes it possible to determine optimal SCM dimensions for the excavation of deep pits in a dense urban setting, when it is necessary to shorten considerably the construction time, and ensure a minimal effect of excavation on surrounding development.

**ABSTRACT:** Various types of retaining walls, e.g. H-Pile with Timber, C.I.P (cast in place pile) and subsurface continuous walls, are domestically used for excavation sites in Korea depending on the site conditions, architectural structure and geotechnical conditions. Ground Anchor, strut and permanent slab are used as support methods. The wall displacements and axial forces of the struts are variable depending on the excavation depth, groundwater level and construction methods, etc. In this study, case studies are performed for the excavation sites, where the modified slab methods, e.g S.P.S, and S.T.D are used and the ground anchors as temporary supports. The wall displacements and the axial forces predicted at the design stage and monitored in the actual excavation stage are analyzed. The advantage of construction time using the permanent slab method is discussed.

**RÉSUMÉ :** Différents types de murs de soutènement, par exemple pieu en H avec du bois, CIP (Pieu en béton coulé en place) et des parois continues ancrées dans le sol, sont à usage domestique pour les sites d'excavation en Corée suivant les conditions du site, la structure architecturale et les conditions géotechniques. Ancrage au sol, entretoise et dalle fixe sont utilisés comme méthodes d'étalement. Les déplacements du mur et les forces axiales des entretoises sont variables en fonction de la profondeur de l'excavation, du niveau des eaux souterraines et des méthodes de construction, etc. Dans cet article, des études de cas sont réalisées pour les sites d'excavation, où les méthodes de dalle modifiées (SPS, MST) sont utilisées et aussi les ancrages au sol comme des appuis temporaires. Les déplacements du mur et les forces axiales prévus au stade de la conception sont examinés et analysés dans la phase réelle d'excavation. L'avantage de la durée de construction en utilisant la méthode de dalle permanente est discuté dans cet article.

### 1 INTRODUCTION

Recent urban building construction has trends of deep excavation and the methods of excavation are diversified. In addition, various types of structures, e.g. the subway tunnels and utility lines and pre-existing buildings are located around the excavation sites. Therefore, when the excavation is done in the metropolitan area, the excavation plans must be made considering the safety, constructability and cost effectiveness synthetically.

In this paper, the retaining wall displacements and the axial forces of the excavation sites which are constructed using the various supports, e.g. C.I.P. with ground anchor, and the permanent slab methods, i.e. S.P.S and S.T.D., are monitored and analyzed using the related case histories.

### 2 EXCAVATION METHODS

In the case studies, two new excavation methods, i.e. S.P.S and S.T.D, are used and the concepts of each methods are introduced. In the S.P.S(Strut as Permanent system) method, the subsurface steel frame and beams are designed strong enough to endure the temporary and permanent external pressures. They are used as temporary retaining walls while the excavation is going on. They can also be used as the walls of main structures without dismantling of strut after the excavation is finished. Fig. 1 shows the conceptual diagram and the field example.

S.T.D (Strut Top Down) method can use the struts which increase the resistance to horizontal pressures. It can also use various types of basement slabs such as beam & girder as well

as one or two way wide beams (Sho et al. 2004). Fig. 2 shows the conceptual view of S.T.D construction and the field example.

Figure 1. Conceptual diagram and field example of S.P.S

### 3 SITE CONDITIONS

#### 3.1 Site 1: S.P.S and ground anchor on C.I.P wall

Site 1 is the office facility of 7th floor on the ground and 3rd floor in the basement. The building is located at Chung Ju in the central region of Korea (Saegil E&C, 2011a). The excavation depth is in the range of of GL.-14.0m~GL.-20.0m. High apartments with deep parking lot are in the southern part of the site. A building with basement is located 20m apart from the site in the west. Roads of 35m and 23m are located at the north and the east part of the site.

Two types of retaining walls are used, i.e. rigid C.I.P wall and H-Pile & Timber. Ground anchor is used as the support of both walls. Considering the tall buildings with basements, S.P.S method is used at the southern part (Fig. 3).

The soil profile of the excavated site is composed of buried soil layer, alluvial layer, weathered soil and rock layers from the surface. Most of the excavated parts are composed of soils (Fig.4). Two sections, i.e. S.P.S and ground anchor, are selected as the analysis section in this paper (Fig. 5).

Figure 3. Plan view of site 1

Figure 4. Soil profile of site 1

Figure 5. Section view of Site 1

#### 3.2 Site 2: S.T.D and C.I.P

Site 2 is the office facility of 23rd floor on the ground and 7th floor in the basement. The building is located at Sang Am dong, Seoul, Korea (Saegil E&C, 2011b). The excavation depth is in the range of GL.-25.0m~GL.-31.0m. A building of 20th floor on the ground and 5th floor in the basements is located to the north of the site. In the east, the road of 30m wide and the building with 21st floor on the ground and 7th floor in the basements is located. The roads of 30m wide are located to the south and the west directions.

The retaining wall is composed of C.I.P in the soil layer and H-Pile & shotcrete in the rock layer. S.T.D method is used as the support of the excavation site (Fig. 6).

Figure 6. Plan view of site 2

Figure 7. Soil profile of site 2

The soil profile of the excavated site is composed of buried soil layer, weathered soil and rock layers, and soft rock layer from the surface. The geotechnical investigation shows that the

soft rock appears at the shallow depth of GL.-2.4m and GL.-9.2m (Fig. 7).

Figure 8. S.T.D Section A-A'

Figure 9. Schematic section for Analysis Program

The sections of retaining walls, i.e. C.I.P in the soil layer and H-Pile & shotcrete in the rock layer are selected for analysis. S.T.D method is used as the supports of the excavated site (Fig. 8).

### 4 ANALYSIS PROGRAM FOR DESIGN

The program used in the design stage is SUNEX(Step Under ground EXcavation), which is a stress-strain analysis program commonly used for the design of the deep excavation site in Korea (Geogroup Eng., 2010). This program calculates earth pressure on the braced earth retaining system, horizontal displacement, shear force and bending moment of vertical wall and axial force of supports and tieback anchors for step by step excavation.

The program adopts elasto-plastic behavior of soil to calculate earth pressure on the retaining wall. Calculation model includes elastic beam for vertical wall (elastic-plastic beam optional), elastic spring for strut and tieback anchor, elasto-plastic spring for active and passive soil (Fig. 9).

### 5 COMPARISON OF DESIGN AND MONITORED VALUES

Both the wall displacement and the axial stress of the struts obtained either from the design stage using the SUNEX or from the field monitoring using the field installed instruments. In this section, The two values are compared by separating to the mid and the final stage of the excavation.

#### 5.1 Wall displacements

##### 5.1.1 Site 1 : S.P.S and ground anchor on C.I.P wall

The displacements of wall in which S.P.S method is applied are shown in Fig. 10 for the mid and final stages of excavation, i.e. GL.-7.9m and GL.-16.5 m.

In the mid stage of excavation, the predicted design displacement was 26.7mm and was greater about 20mm than the monitored displacement of 7.0 mm. This discrepancy seemed to come from the fact that the influence factors, e.g. the loads behind the wall, the excavation height for installation of supports, and weak soil profiles near the ground surface, were selected conservatively compared with the real field conditions.

However, in the final stage the two values were come out quite close. The reasons for this consistency are: (1) The construction conditions was very similar to the one adopted in the design stage, according to the construction process identified at the site; (2) In S.P.S method, it is able to install the steel supports immediately after the excavation. This gives an advantage of reducing the time delayed displacement of the wall, which developed the quite consistent displacements between the design stage and the actual excavation.

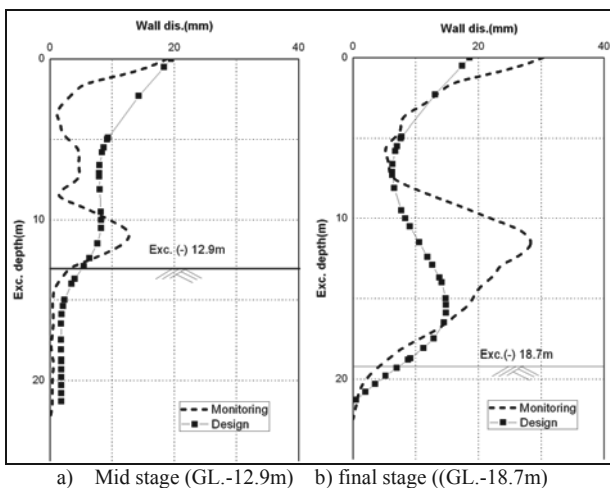

a) Mid stage (GL.-7.9m) b) final stage (GL.-16.5m)  
Figure 10. Wall displacements for S.P.S applied section

The displacements of the wall where the ground anchors are applied are shown in Fig. 11. As can be recognized in the figure, the predicted displacement in the mid stage was larger than the monitored value. In the final stage, the two displacements are consistent partly but larger displacements of 10mm are monitored at the upper and central positions of the wall.

This large displacement seems to come from the initial over-excavation length of more than 5m due to the sewage culvert box near the ground surface in Fig. 5b. As the excavation went on the final stage, the spacing of the ground anchors was about 3m and the over-excavation which was greater than the designed strut spacing was made in the field.

Therefore, it is judged that a particular sites like this one which has large sewage culvert box near the ground surface and the over excavation is made near the final stage needs the detailed design and construction considering all the factors related to spacing of the ground anchor and strut, initial displacement of the wall near the ground surface and the geotechnical conditions included.

a) Mid stage (GL.-12.9m) b) final stage (GL.-18.7m)  
Figure 11. Wall displacements for ground anchor applied section

5.1.2 Site 2: S.T.D and C.I.P

Fig. 12 shows the wall displacements for mid and final stages of excavation in the site 2 where S.T.D method is applied. The excavation depths of mid and final excavation stages were GL.-13.0m and GL.-26.0m, respectively. In the mid stage, the predicted and monitored displacements came out very similar. In the final stage, large discrepancy was recognized for the

predicted and the monitored displacements, i.e. 13mm and 93.1mm, respectively.

Proper construction process and the favorable soil conditions near ground surface seemed to create the consistent wall displacements in the mid stage. Large monitored wall displacements may come from the fact that (1) The design condition would not include the time effect of concrete curing in the slab; (2) over excavation was made since the weathered and soft rocks appeared in the initial stages of excavation. The large discrepancy of the wall displacement about 80mm was the accumulated displacement of the 26m deep excavation.

a) Mid stage (GL.-13m) b) final stage (GL.-26m)  
Figure 12. Wall displacements in S.T.D method applied

6 AXIAL FORCES OF RESISTANT BODIES

6.1 Site 1 : S.P.S and ground anchor on C.I.P wall

Fig. 13a shows the predicted and monitored axial forces acting the struts of S.P.S. The two axial forces in the initial stage showed large difference, because the construction conditions, e.g. ambient temperature and impacts, etc, create large changes in the strain gages measuring the axial forces. However, this discrepancy was reduced as the predicted and monitored displacements became similar (see Fig. 10b).

It is necessary to identify the wall displacements together when the axial forces in the supports of S.P.S are analyzed.

Figure 13 Axial forces for site 1

Fig 13b shows the axial forces of ground anchors in the locations where the ground anchors were applied. In general, the pre-stress considered in the design stage is sufficiently reflected on the ground anchors constructed in the field. However, the monitored axial forces tend to be larger than the predicted values in the design stage in site 1, although the pre-stresses are fully reflected at the excavation.

According to Fig. 11b, the axial forces were large at the locations in which the large wall displacements are detected. At the location of 5th floor in which the design and monitored

displacements are closer to each other, the two axial forces were also close to the values of 35tons.

High correlation is recognized between the wall displacements and the axial forces in the struts. In addition, the changes of axial forces were negligible as the time elapses at the locations where the large wall displacements are detected. This means that the ground anchors are working quite well at such locations (Jang et al., 2012).

6.2 Site 2: S.T.D and C.I.P

Fig. 14 shows the axial forces which act on the slab of S.T.D method by comparing design and monitored values. The monitored axial forces are mostly larger than the predicted values set in the design stage. This result came from the increased wall displacement due to over-excavation and the characteristics of S.T.D. method.

Contrary to the direction of the soil pressures, tensile forces are developed on the 1st anchor from the top. This may come from the large displacement in the central part of the wall, i.e. B2F and B3F, which gave reverse stresses on the upper part of the wall.

Figure 14. Section A-A' Slab axial forces

7 COMPARISON OF CONSTRUCTION TIME

The current retaining wall design, which uses slab as the support of the wall, applies S.P.S and S.T.D methods. These methods can save the construction time because they can support the retaining walls as well as can use the slabs as the permanent basement structure of the building. The two sites have different excavation area and depth. Hence a direct comparison of the construction period was difficult. In this study, construction period was calculated and relative comparison was made based on the Site 1, which was quantified by area (15,000 m<sup>2</sup>) and the excavation depth (GL.-19m).

Table 1 shows the comparison of the construction time of the basement for different support methods. In Site 1 where the ground anchors are partly used, the construction time was 9 months. However, in Site 2 where the slab support S.T.D is used, the slabs are installed simultaneously with the excavation and the time taken to finish the basement structure was 7 months.

Table 1. Comparison of construction time for two sites

Construction Method		Site 1: Chung Ju	Site 2 : Sang Am
		S.P.S & Anchor	S.T.D
Excavation Depth		GL.-19m	GL.-26m
Excavation And Sub- structure	Start	2010.10	2012.04
	End	2011.06	2012.11
	Period	9 month	7 month

8 CONCLUSIONS

In this study the displacement on the C.I.P. walls and the axial forces on the slabs are monitored in the two excavation sites. In the sites, two new top down methods, S.P.S & S.T.D, are applied with the traditional support method, i.e. ground anchor. The monitored values are analyzed and compared with those predicted at the design stage. The conclusions obtained are the following:

- 1) The monitored displacements of C.I.P rigid walls with S.P.S support were similar to the predicted values. The displacement of the S.P.S support wall came from the characteristics of the support which does not applies the pre-stresses to the wall. The displacement of the wall is allowed by the slab without restriction.
- 2) Even though the rock layer is appeared in the shallow depth, large displacements and axial forces are monitored compared to the values predicted at the design stage in the site where S.T.D. method is applied. This is because the excavation depth is deep and the over-excavation was made at the final stage of construction to reduce the construction time.
- 3) It is necessary to reflect the characteristics of the excavation method and the soil conditions when the retaining walls are planned for excavation site. At the site of excavation, the monitored value in each stage should be reviewed and compared with the designed values. Feedback analysis is sometimes needed when some field problems are anticipated.
- 4) Quantitative inspection of the construction time of the selected sites identifies the significant reduction of the construction time when the slab support methods are applied compared with the traditional ground anchor supports.

# Passive Pressure on Skewed Bridge Abutments

## Pression passive sur des culées de pont asymétriques

Jessee S.

*Terracon Consultants, Oklahoma City, Oklahoma, USA*

Rollins K.

*Brigham Young University, Provo, Utah, USA*

**ABSTRACT:** The passive force-deflection relationship for abutment walls is important for bridges subjected to thermal expansion and seismic forces. Although a number of tests have been performed to investigate these relationships for non-skewed abutments, no tests have been performed for skewed abutments. To determine the influence of skew angle on the development of passive force, lab tests were performed on a wall with skew angles of 0°, 15°, 30°, and 45°. The wall was 1.26 m wide and 0.61 m high and the backfill consisted of dense compacted sand. As the skew angle increased, the passive force decreased substantially with a reduction of 50% at a skew of 30°. An adjustment factor was developed to account for the reduced capacity as a function of skew angle. The horizontal displacement necessary to develop the peak passive force was typically about 2.5 to 3.5% of the wall height, H, and the residual passive force typically dropped by 40% at a deflection of 4 to 6% of H. For the no-skew case, the shape of the failure plane closely resembled that predicted by the Rankine theory but was much shorter than that predicted by the log-spiral approach. Nevertheless, the log-spiral method accurately predicted the measured force while the Rankine method grossly under predicted the force.

**RÉSUMÉ:** La relation force- déformation passive des murs en retour est importante pour les ponts soumis à la dilatation thermique et des forces sismiques. Bien qu'un certain nombre de tests aient été réalisés afin d'étudier ces relations pour les murs non-biais, aucun test n'a été effectué pour les murs biais. Pour déterminer l'influence de l'angle du biais sur le développement de la force passive, des tests de laboratoire ont été effectués sur un mur ayant des angles de 0°, 15°, 30° et 45°. Le mur a une largeur de 1.26 m et 0.61 m de hauteur, le remblai se compose de sable compacté. Lorsque l'angle du biais augmente, la force passive diminue considérablement avec une réduction de 50% pour un biais de 30°. Un facteur d'ajustement a été mis au point pour tenir compte de la réduction de capacité en fonction de l'angle du biais. Le déplacement horizontal nécessaire pour développer la force maximale passive est généralement d'environ de 2.5 à 3.5% de la hauteur du mur H, et la force résiduelle passive chute généralement de 40% pour un biais de 4 à 6% de H. Pour les cas non-biais, la forme du plan de rupture est proche de celle prévue par la théorie de Rankine, mais beaucoup plus courte que celle prédite par la méthode de la spirale logarithmique. Néanmoins, la méthode de la spirale logarithmique prédit avec précision la force mesurée alors que la méthode de Rankine sous-évalue largement la force.

**KEYWORDS:** Passive force, Passive Pressure, Skewed abutments, Earth pressure, Dense sand, Plane Strain, Log-Spiral.

## 1 INTRODUCTION

The passive force-deflection relationship for abutment walls is important for bridges subjected to thermal expansion and seismic forces. Although a number of tests have been performed to investigate these relationships for non-skewed abutments (Maroney 1995, Duncan and Mokwa 2001, Rollins and Cole 2006, Rollins and Sparks 2002, Lemnitzer et al 2009), no tests have been performed to investigate these relationships for skewed abutments. Performance of skewed bridges during the 2010 M8.8 Chilean earthquake suggests that this may be an issue of concern as several such bridges were observed to have rotated about a vertical axis, becoming unseated in their acute corners (EERI, 2010).

While current design codes (AASHTO 2011) consider that the ultimate passive force will be the same for a skewed abutment as for a non-skewed abutment, numerical analyses performed by Shamsabadi et al. (2006) indicate that the passive force will decrease substantially as the skew angle increases. Reduced passive force on skewed abutments would be particularly important for bridges subject to seismic forces or integral abutments subject to thermal expansion. To better determine the influence of skew angle on the development of passive force, a series of large size laboratory tests were performed on a wall that was 1.26 m (4.1 ft) wide and 0.61 m (2 ft) high. A dense sand was compacted behind the wall to simulate a bridge approach fill. Passive force-deflection curves were measured for skew angles of 0°, 15°, 30°, and 45°. Vertical

columns of red soil were embedded into the backfill sand so that the failure surface could be located at the completion of the testing. This paper describes the test program, the test results, and the implications for design practice based on analysis of the test results.

## 1 BACKGROUND

The distribution of forces at the interface between a skewed bridge and the adjacent backfill soil is illustrated in Fig. 1 as originally outlined by Burke (1994). The longitudinal force ( $P_L$ ) can be induced by thermal expansion or seismic forces. For static or simplified pseudo-static analyses, the components of the longitudinal force normal and transverse to the abutment must be resisted by the passive force ( $P_p$ ) normal to the abutment backwall and the shear resistance ( $P_R$ ) on the backwall. Summing forces normal to the abutment produces the equation

$$P_p = P_L \cos \theta \quad (1)$$

where  $\theta$  is the skew angle of the backwall.

Figure 1. Illustration of forces acting on a skewed bridge at the soil-abutment interface

The transverse applied shear force ( $P_T$ ) can be computed using the equation

$$P_T = P_L \sin \theta \quad (2)$$

while the transverse shear resistance ( $P_R$ ) can be given by the equation

$$P_R = cA + P_p \tan \delta \quad (3)$$

Summing forces transverse to the backwall produces the equation

$$(cA + P_p \tan \delta) / F_s \geq P_L \sin \theta \quad (4)$$

where  $c$  is the soil cohesion,  $A$  is the area of the backwall,  $\delta$  is the angle of wall friction between the backfill soil and the concrete abutment backwall, and  $F_s$  is a factor of safety. If the applied transverse shear resistance exceeds the ultimate shear resistance, the abutment could slide against the soil leading to an unstable condition.

In addition, the offset in passive force on the abutments produce a force couple which must be resisted by the force couple produced by the shear resistances on each abutment. Summing moments about a vertical axis leads to the equation

$$(cA + P_p \tan \delta) L \cos \theta / F_s \geq P_p L \sin \theta \quad (5)$$

Again, if the shear resistance is insufficient, the bridge will tend to rotate, which would likely change the distribution of passive force on the abutments. Based on Eq 5, Burke (1994) suggested that rotation would be expected for skew angles greater than  $15^\circ$  with smooth abutment-soil interfaces and no cohesion as the factor of safety dropped from 1.5 to 1.0. If cohesion is ignored, the potential for rotation is independent of both  $P_p$  and the length of the bridge,  $L$ .

## 2 TEST LAYOUT

The test layout is illustrated in Fig. 2. A concrete wall 1.26 m (4.13 ft) wide and 0.61 m (2 ft) high was used to model the backwall of an abutment. Passive force-deflection tests were performed with skew angles ( $\theta$ ) of  $0^\circ$ ,  $15^\circ$ ,  $30^\circ$ , and  $45^\circ$ . Two tests were performed for each skew angle to evaluate repeatability. A dense sand was compacted behind the wall to simulate the backfill in a typical approach fill. The sand backfill was 0.9 m (3 ft) thick and extended 0.3 m (1 ft) below the base of the wall. The backfill was 3 to 4 m (10 to 13 ft) long to completely contain the failure surface and was slightly wider than the wall 1.28 m (4.21 ft) to allow the backwall to move into the sand backfill without any friction on the concrete sidewall. To support the sand backfill during compaction, two

1.5 m concrete blocks were bolted to the structural floor of the laboratory on either side of the fill near the wall. Beyond the concrete blocks, plywood walls were braced into a vertical position. Two plastic sheets were placed along the sidewalls to create a low friction surface and produce a 2D or approximately plane strain geometry. A base was constructed below the concrete backwall and rollers were placed at the interface between the backwall and the base to provide a normal force but minimize base friction.

Figure 2. Plan and elevation views of the test layout.

Tests were performed by pushing the backwall longitudinally into the backfill sand using a 490 kN (110 kip) hydraulic actuator which was bolted to the backwall. Load was applied at a rate of 0.25 mm/min (0.1 inch/min); but sand is not very rate sensitive. Vertical and horizontal load cells were mounted between the reaction frame and the actuator so that the loads necessary to hold the wall in place could be measured.

### 2.1 Instrumentation

Load was measured by pressure transducers in the actuator. To measure the movement of the backwall, four longitudinal string potentiometers were positioned at the corners of the wall and two transverse string pots were positioned at the top and bottom of one side. In addition, a final string pot was used to monitor the vertical movement.

The position of the failure surface was monitored by marking 0.3 m (1 ft) square grids at the backfill surface. The subsurface failure plane position was located by placing vertical

columns of red sand spaced along the longitudinal axis behind the wall.

## 2.2 Backfill soil properties

The sand backfill is clean poorly-graded sand classifying as SP according to the Unified Soil Classification System and A-1-b according to the AASHTO system. The particle size distribution curve falls within the gradation limits for washed concrete sand (ASTM C33) with  $C_u$  of 3.7 and  $C_c$  of 0.7. A modified Proctor test was performed on the sand and indicated a maximum dry unit weight of 17.8 kN/m<sup>3</sup> (113.5 lbs/ft<sup>3</sup>). The sand was placed in 150 mm (6 in) lifts and the average relative compaction achieved was typically about 98%.

Load testing was generally performed two days after compaction and moisture content measurements at various depths were made immediately after testing. These measurements indicated good consistency between tests, with the moisture content typically falling within 7 to 9%.

Based on a direct shear test the drained friction angle ( $\phi'$ ) was found to be 46° with a cohesion of 7 kPa (140 psf). Interface friction tests were also performed between the sand and the concrete and a wall friction angle ( $\phi$ ) of 33° was measured.

Because the compacted sand in a partially saturated state could be excavated with a vertical face and remained stable for long periods, the potential for apparent cohesion owing to matric suction was also investigated. Suction measurements indicated that the sand at the moisture content during testing had a matric suction ( $\psi$ ) (negative pressure relative to atmospheric pressure) of approximately 4 to 5 kPa (80 to 100 psf). Based on recommendations of Likos et al (2010), this magnitude of suction produces an apparent cohesion ( $c_a$ ) of approximately 4 to 5 kPa (80 to 100 psf).

## 3 TEST RESULTS

### 3.1 Passive force-deflection curves

The passive force versus longitudinal deflection curves for the tests at each of the skew angles are plotted in Fig. 3. Although the initial stiffness for each curve is remarkably similar, the peak passive force clearly decreases as the skew angle increases. In addition, there appear to be some differences in the shape of the passive force displacement curves as skew angle increases.

The passive force-deflection curve appears to exhibit a typical hyperbolic curve shape for the no skew case however, it transitions to a different shape as the skew angle increases. As the skew angle increases, the passive force exhibits a longer plateau where the force remains relatively constant or increases gradually with deflection before reaching a peak and abruptly decreasing to a residual value. The peak passive force typically developed at a normalized deflection of 2.5% to 3.5% of the wall height (H), and did not change consistently with skew angle. The tests typically showed a reduction in the passive force to a residual value at a normalized displacement of 0.04H to 0.06H. The post-peak residual strength ranged from 53 to 72% of the peak value with an average of 60%. This decrease in post peak resistance is consistent with results from the direct shear tests.

The peak passive force for each test at a given skew angle has been divided by the peak passive force at zero skew and the results are plotted as a function of skew angle in Fig. 4. Normalized data from numerical analyses of skew abutments reported by Shamsabadi et al (2006) are also shown in Fig. 4 and the results follow the same trend line. The curve has been extrapolated to zero at a skew angle of 90°. The no skew case involves pure passive resistance and zero shear force. A skewed wall is subject to a combination of both passive resistance and side shear force. At the largest possible skew angle, 90°, the

forces acting on the wall transition to pure side shear force with zero passive resistance.

Figure 3. Passive force versus longitudinal backwall displacement for the tests at each skew angle.

Figure 4. Normalized peak passive force versus skew angle from lab tests and numerical model results.

As indicated previously, vertical and horizontal displacements of the wall during the tests were minimal. Wall displacement was less than 4.4 mm for vertical movement and less than 2.3 mm for transverse movement for the skew angles tested.

### 3.2 Failure surface geometry

The failure surface for the no skew case was approximately the same length across the width of the sand box; however, when a skew angle was involved, the failure surface also exhibited a skew across the width of the sand box. The failure surface did not manifest itself at the ground surface until after the peak force had been reached.

The failure surface within the sand was clearly identifiable from the offset in the red sand columns. The failure surface geometry is shown as a function of distance behind the middle of the wall for the various skew angles in Fig. 5. In addition, the ground surface heave is also plotted for each test. The average length of the failure surface behind the middle of the wall was 2.1 m (7.0 ft) with a standard deviation of 0.3 m (1.0 ft). The length of the failure surface ranged from 1.8 to 2.6 m (5.9 to 8.6 ft). The failure surface typically extended 75 mm to 300 mm horizontally from the bottom of the wall then exhibited a relatively linear trend line upward to the surface. The angle of inclination of the trend line was between 19° and 21.5° with an average of 20°. Assuming that the angle of inclination ( $\alpha$ ) of the straight line segment of the log-spiral failure wedge is given by the equation:

$$\alpha = 45 - \phi'/2 \quad (8)$$

as suggested by Terzaghi and Peck (1948), then the interpreted drained friction angle would be between 47° and 52° with an average of 50°. The inferred friction angle value is higher than the measured friction angle from the direct shear test, but is close to the value that would be expected for the plane strain friction angle. The conditions and geometry of the sand box simulated a plane strain condition as well. Based on a number of studies, Kulhawy and Mayne (1990) determined that the plane strain friction angle for dense sand was 11% higher than the triaxial value on average. Thus, the plane strain friction angle for the sand used in the tests would be about 51°, which is approximately the same value as that of the inferred friction angle from the inclination of the failure wedge.

Figure 5. Measured failure surface depth versus distance from the backwall for each test.

#### 4 ANALYSIS OF RESULTS

Test results were analyzed using the Rankine (1857) and log-spiral (Terzaghi, 1948) passive pressure theories. Table 1 shows comparisons of the test results with computed passive force and failure surface orientation for the no-skew case. The measured and theoretical failure surface geometries for the no-skew case relative to the top of the wall are shown in Fig. 6. For the analysis, the soil friction angle was taken as 50°, consistent with the plane strain value, with a cohesion of 4.5 kPa (90 psf), and the wall friction angle was taken as 33° based on interface tests. While the failure plane according to the log-spiral method generally exceeded the length of the failure surface by 45 to 50%, this method was most effective in computing passive force. In contrast, the Rankine method grossly underestimated the measured force, but gave a reasonable approximation of the failure surface geometry. Although the Coulomb theory is widely used, it is limited to cases where  $\delta/\phi$  is less than about 0.5. For these tests,  $\delta/\phi$  is equal to 0.66. Thus, analyses using the Coulomb method predict an unreasonably high value for the passive force, and the failure surface extent is likewise unreasonably over-predicted (see Table 1).

#### 5 CONCLUSIONS

1. Large scale laboratory tests and numerical analyses indicate that the peak passive force for a skewed abutment significantly decreases as the skew angle increases. Based on available results, this reduction can be accounted for by using a simple reduction factor. This reduction may be dependent on abutment geometry and other unknown factors and should thus be used with caution until further research is performed.
2. For the dense sand typical of approach fills, the peak passive force for all tests typically developed at longitudinal deflections between 0.025H and 0.035H. However, the shape of the passive force-deflection curve up to the peak value transitioned from a typical hyperbolic shape for the no skew case to a bilinear shape for the skewed walls.
3. At wall displacements beyond the peak (0.04 to 0.06H) the passive force decreased substantially and the residual force was typically about 40% below the peak force, which is in agreement with the behavior in the direct shear tests.
4. Based on the measured soil parameters the log spiral method provided the best agreement with the measured passive force,

while the Rankine method grossly underestimated the force. However, the failure surface geometry was closer to that predicted by the Rankine method than the log spiral shape.

Table 1. Summary of measured tests results in comparison with computed values using different passive pressure theories.

	Passive Force		Failure Surface Geometry	
	(kN)	% of measured	Orientation (degrees)	Extent (m)

# Deformation behaviour of clay due to unloading and the consequences on construction projects in inner cities

## Étude du comportement en déformations de l'argile suite à un retrait de charge et conséquences lors de projets de constructions en zone urbaine

Katzenbach R., Leppla S.

Technische Universität Darmstadt, Institute and Laboratory of Geotechnics, Germany

**ABSTRACT:** In the course of construction projects in many cases the soil is unloaded. For example at the construction of excavations or the deconstruction of existing buildings the soil relaxes due to the reduced stress level. Cohesive soil materials like clay react strongly time dependent. At all construction projects in the city of Frankfurt am Main, Germany, which belong to the Geotechnical Category 3 regarding Eurocode EC 7 the deformation of the soil was measured during and after the construction works. It has to be determined that the settlement relevant soil layer, the tertiary Frankfurt Clay, relaxes time-delayed due to the unloading in the dimension of centimetres. The new acknowledgement of the deformation behaviour of the Frankfurt Clay due to unloading the subsoil is presented in detail by typical projects for the development of the city.

**RÉSUMÉ :** Il arrive régulièrement dans le cadre de projets de construction en zone urbaine que le sol subisse un déchargement. Dans le cas d'excavations par exemple, le sol se détend suite à une baisse des contraintes appliquées. Le comportement des sols cohésifs tels que l'argile dépend fortement du temps. Pour l'ensemble des projets de construction à Francfort en Allemagne, ces projets étant classés en Catégorie Géotechnique 3 selon l'Eurocode 7, les déformations du sol ont été mesurées pendant et après les travaux. Il est à mettre en avant que le sol de la couche pertinente en terme de tassements, l'argile tertiaire de Francfort (Frankfurt Clay), subit un relâchement différé dans le temps suite au retrait de charge de l'ordre du centimètre. Les nouvelles reconnaissances sur le comportement de l'argile de Francfort suite à un déchargement du sol sont présentées ici en détail pour des projets typiques dans le cadre du développement de la ville.

**KEYWORDS:** Soil-structure-interaction, Frankfurt Clay, time dependent deformation behaviour, observational method.

### 1 INTRODUCTION

Since the beginning of the large infrastructure and high-rise building constructions in Frankfurt am Main the bearing and deformation behaviour of the Frankfurt Clay has been scientifically researched intensely (Chambosse 1972, Breth and Stroh 1974, Amman et al. 1975, Sommer et al. 1990, König 1994, Katzenbach and Moormann 1999, Breth and Katzenbach 2000, Katzenbach et al. 2001, Moormann 2002, Katzenbach et al. 2002, Dürrwang et al. 2007, Janke et al. 2010, Vogler 2010, Katzenbach et al. 2011). The first research and experiences made with the Frankfurt Clay result from new constructions, i.e. from high-rise buildings and tunnel constructions.

Due to the development of the city a lot of deconstruction activities occur in advance of new construction projects. In the course of these projects new knowledge about the time dependent bearing and deformation behaviour of the Frankfurt Clay is obtained, especially if there is a larger timeframe between the deconstruction (unloading) and the new construction activity (reloading). In such cases the uplifting is not overlapped or compensated by an early reloading. For example a deep excavation base usually heaves up to several centimetres as shown in Figure 1 (Amman et al. 1974).

The time dependent deformation behaviour of the over-consolidated tertiary Frankfurt Clay is presented in detail by 2 large deconstruction projects. The first project is the deconstruction of the building complex of the Zürich Insurance consisting of 2 high-rise buildings (Zürichhochhaus I and II) and the construction of the new high-rise building Opernturm at the same location. The project is located very close to a tunnel of the metro system. The second project is the deconstruction of an up to 14 storeys high-rise building in the historic centre of Frankfurt am Main. The project is located directly over 2 tunnels and an underground station of the metro system.

Figure 1. Measured uplift of the surface of the excavation pit at BfG high-rise building (now: European Central Bank ECB).

### 2 DECONSTRUCTION OF THE ZÜRICH INSURANCE HIGH-RISE BUILDINGS

The Zürich Insurance building complex was built between 1959 and 1963. It consisted of 2 high-rise buildings (Zürichhochhaus I and II) with heights of 70 m and 63 m and annexe to the high-rise buildings with up to 8 storeys. The complex was founded on a raft in a depth of 7 m below the surface. In the years 2001 and 2002 the complex was deconstructed down to the ground

level. The sublevels remained. A cross section through the project area is shown in Figure 2.

Figure 2. Soil, groundwater and foundation conditions.

5 years after the deconstruction the 177 m high-rise building Opernturm was built. The annexe of the high-rise building is up to 7 storeys high (Fig. 3) and was founded on the existing raft foundation. Under the Opernturm the existing raft was deconstructed and a new sublevel was built.

Figure 3. New high-rise building Opernturm.

The Opernturm is founded on a Combined Pile-Raft-Foundation (CPRF) consisting of a 3 m thick raft and 57 piles with a diameter of 1.5 m and a length of 40 m. For design of the CPRF a whole characteristic load of 1,500 MN was calculated. The bearing behaviour of the CPRF is described by the CPRF-coefficient  $\alpha_{CPRF}$ , explained in Equation (1) (Viggiane 1998, Hanisch et al. 2002). The Opernturm has a  $\alpha_{CPRF} = 0.9$ .

$$\alpha_{CPRF} = \frac{\sum_{j=1}^n R_{pile,k,j}}{R_{tot,k}} \quad (1)$$

The soil and groundwater conditions are typical for the inner city of Frankfurt am Main:

- 0 m to 7 m: quaternary sands and gravel
- 7 m to 67 m: Frankfurt Clay
- below 67 m: Frankfurt Limestone
- groundwater level in a depth of 5.5 m

The measured settlements during the construction of the Zürichhochhaus I and II as well as the uplift during their deconstruction are depicted in Figure 4. The measured settlements increase continuously up to 60 % of the final settlement during the construction time of the superstructure. Due to the consolidation process the deformation rate decreases continuously. About 5 years after the construction the settlement stopped at 9.5 cm at Zürichhochhaus I and 8.5 cm at Zürichhochhaus II. The deconstruction started in the middle of 2001. In March 2002 the deconstruction was completed. Only

the sublevels were kept. After 5 years the measured uplift is in the same magnitude as the settlements before.

Figure 4. Measured settlements and uplifts of the soil in the area of the high-rise buildings.

The measured time dependent settlement and uplift evolution with reference to the maximum value can be approximately mathematically described by Equation 2. Figure 5 shows the application of Equation 2 to the presented project.

Figure 5. Measured settlement and uplift and correlation to Equation 2.

$$\frac{s(t)}{s_{max}} = k \cdot (1 - e^{-(n \cdot t)}) \quad (2)$$

where:  $k$  = Consolidation factor  
 here:  $k = 0,104 [-]$   
 $n$  = Time factor  
 here:  $n = 0,7 [-]$   
 $t$  = Time in years ( $t \leq 5$  years)

(3)

$$\frac{s(t)}{s_{\max}} = k \cdot (1 - e^{-(n \cdot t)})$$

where:  $k$  = Consolidation factor  
 here:  $k = 0,104 [-]$   
 $n$  = Time factor  
 here:  $n = 0,7 [-]$   
 $t$  = Time in years ( $t \leq 5$  years)

To verify Equation 2 the measured time dependent settlement behaviour during the construction of the high-rise building Mainzer Landstraße in Frankfurt am Main is used (Fig. 6). The construction of the 155 m high-rise building began in 1973 and the settlements were measured for 5 years. After this time a settlement of 25.4 cm was measured in the core area of the high-rise building. At the completion of the superstructure after 1.5 years the measured settlement was about 70% of the total settlement. The estimation of the time dependent deformation behaviour can also be described by Equation 2.

Figure 6. Measured settlement of the high-rise building Mainzer Landstraße.

### 3 DECONSTRUCTION OF A HIGH-RISE BUILDING FOUNDED ON AN UNDERGROUND STATION

In the context of the urban development the city of Frankfurt am Main plans to redesign the historic centre. Historic façades and buildings will be reconstructed. To create the necessary space on the surface an up to 14 storeys high-rise building was deconstructed. According to the present state of planning the deconstruction was carried out down to the sublevels.

The high-rise building and its underground parking overlay 2 tunnels and an underground station of the urban metro system. The loads of the superstructures are directly transferred onto the tunnels and underground station. Figures 7 and 8 give an overview on the primary situation prior to the deconstruction. The sealing of the structures was made of outside layers of bitumen-based materials. It must be guaranteed that during the deconstruction of the existing high-rise building and the construction of the new buildings the sealing of the underground structures and the sublevels remained intact. For this purpose especially the uplifts due to the deconstruction and the deformations of the underground structures and the sublevels had to be monitored during the execution of the project according to the observational method.

Figure 7. Overview of the project area.

Figure 8. Cross section of Figure 6.

The soil and groundwater conditions are as follows:

- 0 m to 7 m: quaternary sands and gravel
- 7 m to 30 m: Frankfurt Clay
- below 30 m: Frankfurt Limestone
- groundwater level in a depth of 6 m

The groundwater level is influenced by the river Main which is 180 m far away. In the course of the geotechnical survey two aquifers have been encountered. The top aquifer is located in the non-cohesive soil. The lower confined groundwater layer is located in the Frankfurt Clay and in the Frankfurt Limestone.

According to the classification of the project into the Geotechnical Category 3, that is the Category for very difficult projects in EC 7, an extensive geodetic monitoring program with 580 measuring points was installed. 220 measuring points are located around the deconstructed building, 110 are located in the underground parking and in the sublevels of the deconstructed building, 30 are in the underground station and the remaining 220 are located in the tunnels.

The existing buildings were deconstructed down to the 2 sublevels. The uplift that occurred due to the unloaded of the soil is shown on selected points (Figures 9 and 10).

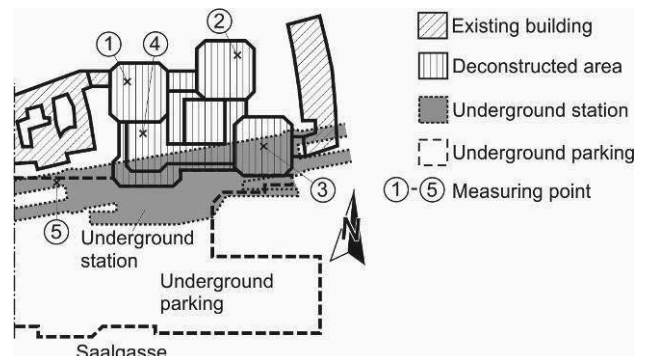

Figure 9. Selected measuring points.

The selected measuring points 1 to 4 are in the sublevel of the former high-rise building. Measuring point 5 is at the transition of the underground station to the tunnel. At the

measuring points 1 to 4 uplift between 1 cm and 5 cm was detected in the deconstruction time (March to December 2010). The measured uplift of measuring point 5 is less than 0.5 cm.

Figure 10. Measured uplift at selected measuring points.

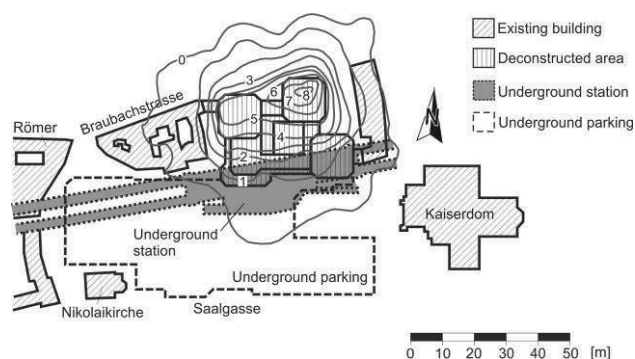

Figure 11. Measured uplift of the whole project area [cm].

After the deconstruction down to the sublevels in December 2010, the modification of the sublevels began. In that phase the loads only were changed insignificantly. The uplift of the whole project area and the neighbourhood in October 2012 is drawn in Figure 11. The uplift due to the reduced stress level of the stress and time related deformation behaviour of the Frankfurt Clay is continuously raising due to the consolidation processes. A maximum uplift of 8.5 cm was measured in the area where the most storeys were deconstructed. The uplifts fade down related to the distance very quickly. So no dangerous deformations of the neighbourhood were measured.

#### 4 CONCLUSIONS

At the construction of excavations or the deconstruction of existing buildings the soil is unloaded and relaxes due to the reduced stress level. Cohesive soil materials like clay react strongly time dependent. For example the tertiary Frankfurt Clay relaxes time-delayed due to the unloading in the dimension of centimetres. Regarding the guarantee of the stability and the serviceability of structures in the neighbourhood the influence of the arising deformation of the soil has to be taken into

account during an early planning stage and has to be considered during analyses and design.

For verification of the analyses and to proof the design all projects with large soil deformations have to be monitored by means of the observational method. Only high-level analyses compared with the observational method are the guarantee for a safe construction phase for the project itself and the influenced structures.

**ABSTRACT:** In the context of potassium fertilizer production the residua, mostly consisting of granular rock salt, is stored on large tailings heaps. The salt residue has a strongly visco-plastic material behaviour with a rate-dependant strength. The heaps have a base area up to a square kilometre and heights up to 120 m. Using the Finite-Element-Method (FEM) and a numerical constitutive law for the salt residue, developed at the Technische Universität Darmstadt (TU Darmstadt), the influence of the heaps on infrastructures like buildings, streets, railway tracks and pipelines can be estimated. In the context of the approval procedures of the extension of existing heaps comprehensive numerical investigations regarding stresses and deformations are necessary to guarantee the stability and the serviceability of the heaps and influenced infrastructures. For verification of the numerical investigations according to the observational method monitoring programs have to be installed.

**RÉSUMÉ :** Dans le contexte actuel de production d'engrais riches en potassium, les résidus, principalement constitués de sel gemme granulaire, sont stockés sous forme de larges terrils. Les résidus salins présentent un important comportement visco-plastique, et une résistance à la rupture fortement dépendante du temps. La surface occupée par ces terrils peut atteindre un kilomètre carré et une hauteur de 120m. L'influence de ces terrils sur les infrastructures du type bâtiments, routes, rails et pipelines peut être estimée en combinant la Méthode des Eléments Finis (MEF) et l'utilisation d'une loi constitutive numérique pour le matériau salin, développée à la Technische Universität Darmstadt (TU Darmstadt). Dans le contexte actuel qui encourage l'extension des terrils existants, il devient nécessaire de mener des études numériques poussées évaluant les contraintes et déformations, afin de garantir la stabilité et le bon fonctionnement des terrils et des infrastructures avoisinantes. Des programmes de contrôle doivent être mis en place afin d'effectuer la vérification des études numériques, obtenues grâce aux méthodes observationnelles.

**KEYWORDS:** Tailings heap, visco-plastic material behaviour, observational method.

## 1 INTRODUCTION

During the production of potash and the converting into fertilizer for agriculture and into specialty products for the chemical industry a large amount of residua, mostly consisting of granular rock salt, is deposited on large heaps. The resulting tailings heaps with a ground view up to 1 km<sup>2</sup> and a height up to 120 m cause normal stresses of 2,200 kN/m<sup>2</sup> and shear stresses of 550 kN/m<sup>2</sup> on the contact surface. An impression of the dimensions of such tailings heaps is given in Figure 1.

Figure 1. Rock salt heaps.

For analyses of the load and deformation behaviour of the heaps the Finite-Element-Method (FEM) in combination with elastoplastic constitutive laws for the soil and a viscoplastic constitutive law for the granular rock salt, developed at the Institute and Laboratory of Geotechnics of the TU Darmstadt, are used.

The verification of the developed constitutive law for the granular rock salt was done by back-analyses of laboratory tests and the monitoring data of specific projects. The paper focuses on the challenges of an extension of a tailings heap and the influence on a railway track as only 1 example from engineering practice (Katzenbach et al. 2004, Katzenbach et al. 2006).

## 2 PROJECT DESCRIPTION

In order to ensure the further production an existing 120 m high tailings heap needs to be extended (Figure 2).

The planned extension of the tailings heap approaches the railway track to the south. The existing heap was stored in blocks with a lower and an upper layer (Figures 3 and 4). The slope ratio is up to 40°. Since 2008 the extension is stored with layers on the slope (Figure 5).

Figure 2. Site plan of the project.

Figure 3. Spreader on a heap.

Figure 4. Schematic procedure of the block storing method.

Figure 5. Schematic storing with layers on the slope.

The project area is situated in a glacial plain with a rather flat ground surface. The soil is horizontally stratified. At the surface a 5 m to 10 m thick layer of sand and marl glacial deposits was investigated. Below the sand and marl deposits a 50 m thick layer of quaternary sand with loose density was found, followed by a 130 m to 150 m thick layer of Rupel Clay and dense sand with varying layers of silt. At a depth of approximately 200 m

below the surface the new red sandstone begins. The groundwater level is about 5 m below the surface.

### 3 MATERIAL BEHAVIOUR OF GRANULAR ROCK SALT

The material behaviour of granular rock salt is characterized by a distinctive time and stress dependence. Initially fresh granular rock salt has a non-cohesive texture. After a short period the loose, granular rock salt converts into a cohesive texture with a high strength (Ankes 1972). The salt material attains a shear strength with a friction angle of  $\phi' = 50^\circ$  and a cohesion of  $c' = 850 \text{ kN/m}^2$ , as well as a stiffness of  $E_s = 2,500 \text{ MN/m}^2$ . The material behaviour of the granular rock salt is strongly dependent to the deformation rate. High, overcritical deformation rates lead to high strength and stiffness of the rock salt and to brittle fracture. Small, undercritical deformation rates lead to minor strength and stiffness and to a plastic creep without fracture.

Directly after storing the granular stockpiled material has a density of  $\rho = 1.4 \text{ to } 1.5 \text{ t/m}^3$ . Due to the atmosphere, chemical processes and the pressure because of the increasing covering the granular stockpiled material in the core of the heap transforms nearly into solid body.

Under constant deviatoric stress the stockpiled material presents a constant creep behaviour despite a huge strength. The material behaviour of stockpiled material is strongly dependent on the state of stress and of the deformation rate. Figure 6 shows the results of two strain controlled triaxial tests on specimen of stockpiled material, obtained from core drillings from the top of a heap. For both tests a cell pressure of  $\sigma_3 = 0.5 \text{ MN/m}^2$  was specified. Both deformation rates vary by the factor 1,000.

Figure 6. Typical results of strain controlled triaxial tests on stockpiled material samples.

The sample with the higher, overcritical deformation rate of  $d\epsilon/dt = 10^{-5} \text{ 1/s}$  presents the usual material behaviour on high deformation rates. After the peak stress  $q_{fr}$  follows a deep drop of the deviatoric stress (brittle fracture). The sample with the lower (undercritical) deformation rate of  $d\epsilon/dt = 10^{-8} \text{ 1/s}$  does not collapse. The sample creeps under a constant deviatoric stress  $q_{stat}$ .

On the left in Figure 7 is shown the specimen after the test with undercritical deformation rate. On the right is shown the specimen after the test with overcritical deformation rate.

Figure 7. Specimens of triaxial tests with undercritical (left) and overcritical (right) deformation rates.

Due to deviatoric stress levels the stockpiled material creeps with high deformation rates at the beginning. The deformation rate decreases under constant deviatoric stress dependent on the time and approaches asymptotic the stationary creep rate (Figure 8).

Figure 8. Typical creep curve of granular stockpiled material.

For further information of the material behaviour of granular rock salt see *Fordham 1988, Munsan and Wawersik 1991, Chumbe et al. 1996 and Boley 1999.*

Figure 9. Deformation rate dependent system behaviour.

Although the heaps have a slow creep deformation and the soil has a continuously, slow changing load the heaps do not collapse due to the viscoplastic material behaviour of the granular rock salt as long as the deformation rate is undercritical. The collapse of the slope of a heap only results from a progressive failure (Figure 9) due to an increasing overcritical deformation rate. The system behaviour of a heap consisting of granular rock salt normally is like type 2 in Figure 9, if there is no weakening in the contact area.

On the basis of more than 150 triaxial tests a constitutive law for the material behaviour of granular stockpiled material was developed at the Institute and Laboratory of Geotechnics of TU Darmstadt (Boley 1999, Wachter 2009, Wachter and Katzenbach 2009). This constitutive law was implemented in a Finite-Element-Software for analyses of the ultimate limit state (ULS) and serviceability limit state (SLS) of granular rock salt heaps and infrastructures and buildings in the influenced area around the heaps.

#### 4 ANALYSES OF THE EXTENSION OF THE HEAP

For analyses of the extension of a tailings heap and the influence on the railway track numerical simulations using the FEM were carried out. The model has a length of 1,800 m. The heap is 120 m high. Regarding the analyses of an extreme situation the groundwater level was set to the surface. The soil is modelled with an elastoplastic constitutive law based on a modified Drucker-Prager-Modell, the new red sandstone was modelled with an elastic constitutive law. The FE-Model is shown in Figure 10.

Figure 10. FE-Model of the soil and the heap before and after the extension.

The interaction between the tailings heap and the soil is modelled by a contact surface. The shear strength is defined by the friction law of *Coulomb*. The shear stress is proportional to the vertical stress. The time dependent material behaviour and the changing geometry of the heap are considered by a step-by-step analysis.

Figure 11 shows the analysed cross sections. The horizontal distance  $s_t$  of the toe of the slope to the railway track is varying along the track.

The relative deformations and the deformation rates have been calculated. The deformation rates increase when the extension approaches the railway track and decrease to a low rate when the extension area is totally filled up.

Due to the complexity of the project and the interaction between soil, heap and the infrastructure an extensive monitoring program according to the observational method was installed. The main part of the monitoring program consists of geodetic and geotechnical measurements (Figure 12).

For example the measured, absolute, horizontal displacements orthogonal to the toe of the slope of 2 measurement points are presented. The measurement point MR 54 is at the toe of the slope before the extension started. The measurement point MR 51 had a distance of 150 m to the toe of the slope before the extension started.

Figure 11. Cross sections for the analyses of the deformation of the railway track.

The measurement point MR 54 had a horizontal displacement of 0.30 m before it was covered with salt. After the covering no further measurement data for this point existed. The measurement point MR 51 had a horizontal displacement of 0.45 m before it was covered with salt.

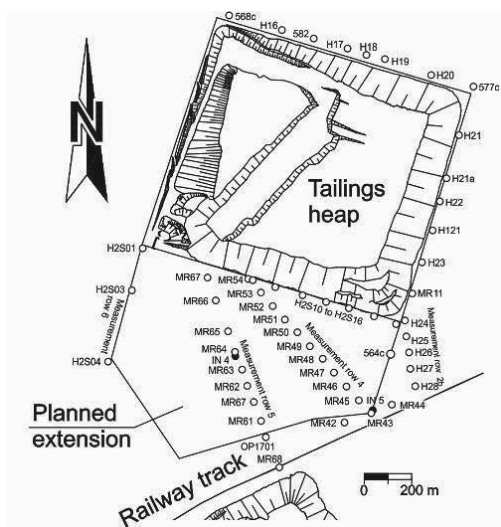

Figure 12. Geodetic and geotechnical monitoring program.

For calibration of the numerical simulations the calculated displacements are compared to the measurement data. In result numerical simulations supply horizontal displacements in a comparable range.

## 5 CONCLUSIONS

Due to the storing of granular residues of potash production on large tailings heaps enormous loads are transferred into the soil. In this context vertical and horizontal deformation occur even in a distance of hundreds of metres. For analyses of the ultimate limit state and the serviceability limit state of the heaps and infrastructures and buildings in the area of influence realistic simulations are necessary.

Using a complex constitutive law for the viscoplastic stockpiled material, developed at the Institute and the Laboratory of Geotechnics of TU Darmstadt, the numerical simulations of an extension of a heap and the influence on a railway track were investigated. The comparison of the results of the numerical simulations and the monitoring program shows a good accordance.

The developed constitutive law can be judged as a robust, efficient and purposeful material routine which offers an instrument for the simulation and investigation of complicated, time variant systems using numerical simulations.

# In-situ tests of permanent prestressed ground anchors with alternative designs of anchor bond length

## Essais in situ des tirants d'ancrage précontraints permanents avec des conceptions alternatives de la longueur de scellement

Klemenc I.  
Slovenian National Building and Civil Engineering Institute

Logar J.  
University of Ljubljana, Faculty of Civil and Geodetic Engineering

**ABSTRACT:** Some concepts of cost efficient ground anchors with enhanced pull-out resistance from single borehole already exist: single bore multiple anchors (Barley, 1990) and prestressed ground anchors of variable stiffness (Škrabl, 2004). A third alternative with anchor bond length of increased stiffness has been proposed. All three concepts have been combined with the concept of comprehensive corrosion protection. Five anchors of all three design alternatives as well as ten investigation tests on standard permanent prestressed ground anchors were tested in-situ on a large retaining wall in N-E Slovenia. The paper presents the design of each type of anchor bond length, test procedure and test results. The test results of our in-situ research on the specific location show that the highest anchor pull-out resistance was obtained for the anchor bond length of increased stiffness.

**RÉSUMÉ:** En plus des conceptions existantes d'augmentation de la résistance des tirants d'ancrage dans un même forage avec un bon rapport coûts-efficacité, tels les tirants à torons multiples (technologie SBMA – Barley, 1990) et les tirants précontraints de rigidité variable (Škrabl, 2004), nous proposons une troisième alternative: les tirants d'ancrage à rigidité renforcée. Les trois types étudiés ont été combinés parallèlement avec une conception de protection anti-corrosion. Nous avons testé in situ des ensembles de cinq groupes de chacun des trois types proposés et de dix tirants d'ancrage standard, sur une construction de soutènement importante réalisée dans la partie nord-est de la Slovénie. Dans cet article nous présentons le dimensionnement de la longueur de scellement de tous les types de tirants d'ancrage ainsi que le déroulement et les résultats des essais effectués. Les résultats des essais in situ démontrent que la résistance maximale est obtenue avec la longueur de scellement du tirant à rigidité renforcée.

**KEYWORDS:** ground anchor, design of bond length, pull-out resistance, in-situ test, comprehensive corrosion protection.

## 1 INTRODUCTION

In 1934 the first prestressed ground anchors were built during the raising of the Cheurfas Dam (Algeria). Such anchors have been increasingly used since then, in cases, where the execution of other geotechnical measures is significantly more difficult, more expensive or even impossible. The most widespread is the use of the friction tensile type of ground anchors (Limelette, 2008), with which the technological design and implementation of the corrosion protection has reached a level that promises a long-term operation (provided that adequate maintenance is ensured). This especially applies to anchors with a comprehensive corrosion protection, which was two decades ago developed in Switzerland: the steel parts of these anchors are encapsulated by a waterproof polyethylene (PE) cover, which also provides electrical isolation of steel parts against the environment. In parallel with technological improvements, the price of anchors has also grown. Therefore, increasing tendencies to rationalize anchors have appeared.

Three different simple modifications of a permanent prestressed anchor bond length were designed and investigated in order to achieve higher values of pull-out resistances and better efficiencies of anchors. The prototypes of such alternative anchors were installed and tested in a testing field. The obtained results were compared with those of reference anchors.

## 2 ALTERNATIVE DESIGNS OF BOND LENGTHS

The starting-point in the task of searching for the most effective concept of permanent prestressed ground anchors with the tendon contained within joint PE cover were reference (standard) anchors **RCP/D**. These anchors were used in a retaining wall that served as a test site. The total length of each

individual anchor is  $l = 35$  m with the tendon bond length of  $l_v = 7$  m, consisting of six low-relaxation strands  $\varnothing 15.2$  mm ( $f_{p0.1k}/f_{pk} = 1670/1860$  MPa).

Figure 1. Conceptual designs of bond lengths of permanent prestressed strand anchors with joint PE encapsulation: reference anchor RCP/D, alternative types of anchors RCP/D-K (increased stiffness of bond length), RCP/D-Z (multiple anchor) and RCP/D-I (anchor of variable stiffness).

Three different conceptual designs of anchor bond lengths (Fig. 1) were conceived and implemented with the intention to improve stress distribution along the tendon bond length and to consequently increase the pull-out capacity of anchors:

- anchors with increased stiffness of bond length, with which six additional steel wires  $\varnothing 5$  mm were placed in empty spaces among bond lengths of strands (type **RCP/D-K** with strand free lengths of 28 m and strand bond lengths of 7 m),
- multiple anchors with staggered anchor units based on the idea of Barley's anchors SBMA, only that three anchor units

(two strands each) of 2.2 m bond length were not installed into a borehole as independent elements but were placed into the joint corrugated PE duct (type **RCP/D-Z** with strand free lengths of 28 m, 30.4 m and 32.8 m),

- *anchors with variable stiffness of bond length* after the patent of Škrabl, 2004, with the tendon combined of three anchor units (2 strands each), with strand free lengths of 28.0 m, 30.4 m and 32.8 m, and with strand bond lengths of 7.0 m, 4.6 m and 2.2 m (type **RCP/D-I**).

### 3 IN-SITU TESTING

The test field has been located at the level of the middle berm of a larger retaining wall, where load-bearing stratum consists of marl and silty marls with thin lenses of siltstone and sandstone. A total of 18 anchors were installed: three reference RCP/D anchors and five anchors of each alternative type (RCP/D-K, RCP/D-Z and RCP/D-I). Boreholes, deflected 15° downwards, were drilled with a chisel (Ø 140 mm) using air-flushing for the removal of drill spoil. The ratio of 6-strand anchor steel cross-sectional area to cross-sectional area of the borehole equaled 5.5% of the theoretical cross-sectional area of the borehole. The appearance of moist in the ground was repeatedly detected in the region of the anchor bond lengths. Cement grout with w/c ratio of 0.42 was used for grouting within the PE encapsulation as well as for the collar of the borehole with an average grout consumption of about 17 dm<sup>3</sup>/m<sup>1</sup>.

At in-situ testing individual strands were tensioned with monostrand jacks, connected to a joint hydraulically synchronized system (Fig. 2). An electrical load cell was used for the precise adjustment of stressing forces. Extensions and creep behavior of strands were measured with digital displacement transducers, attached on the monostrand jacks.

Figure 2. Test setup for simultaneous stressing of all strands of prestressed ground anchors using monostrand jacks.

As a measure for the assessment of load-bearing characteristics of anchor bond lengths creep displacement rate  $k$  was used (Ostermayer, 1975):

$$k = \frac{s_2 - s_1}{\log t_2 / t_1} \quad (1)$$

where  $s_1$  and  $s_2$  are head displacements at times  $t_1$  and  $t_2$ , respectively. For the failure of anchor bond length the critical creep displacement rate  $k_{crit} = 2$  mm was used.

All reference anchors and one anchor of each alternative type were tested up to the maximum test load  $P_{pv} = 1254$  kN (80 % steel tensile strength  $R_m$ ) or until failure of anchor bond length was reached (*investigation test* - IT). Other alternative anchors were tested using the same procedure, except that the

test was stopped at the first sign of anchor bond length failure, i.e. as soon as  $k_{crit}$  appeared (*comprehensive suitability test* - CST). All test field anchors were tested according to the loading procedure and methodology for IT as described in Swiss standard SIA 267/1, which is very similar to test Method 1 of standard EN 1537: each anchor was loaded in eight incremental cycles from a datum load  $P_a = 150$  kN (10 %  $R_m$ ) to the maximum test load  $P_{pv}$ . The increments of strand extensions were measured at the end of specified time intervals, which were used for the evaluation of  $k$  values. Individual strand extensions as well as average extensions for all strands of the RCP/D-I anchor SBZ-33 at load level  $P_6 = 978$  kN of CST are presented on the left diagram of Fig. 3. The right diagram shows the development of apparent free lengths  $l_f$  of individual strands during the same CST, which is based on the measured elastic displacement  $\Delta s_{el}$  at load decreasing from current level  $P_i$  to the initial level  $P_a$ , knowing the characteristics of the tendon (cross-section area  $A_p$  and modulus of elasticity  $E_p$ ):

$$l_f(P_i) = \frac{\Delta s_{el}}{P_i - P_a} A_p E_p \quad (2)$$

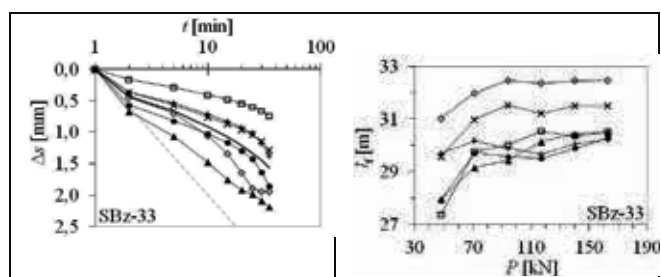

Figure 3. Measured increments of displacements of the anchor SBZ-33 (type RCP/D-I) at load level  $P_6$  of CST (left), apparent free lengths of individual strands  $l_f$  during CST (right).

The behaviour characteristics of anchor bond length could be recognized only on the basis of strand extensions, measured on displacement transducers, fixed on the monostrand jacks. The problem is that due to the limited amount of data and the inability of physical insight into the bond lengths deep in the load bearing stratum, we cannot always directly link measured extensions with creep displacement rate  $k$  of the bond length (i.e. it is not necessary that each measured strand extension actually originates from the bond length deterioration). Therefore, in the analysis of the in-situ test results it is recommendable to compare the  $k$  values of individual strand with the  $k$  values of other individual strands of the same tendon, with  $k$  values of anchor units (average of two strands, only at types RCP/D-Z and RCP/D-I), with the average  $k$  values of all strands, as well as with the permanent displacements  $\Delta s_{bl}$  and apparent free lengths  $l_f$ , obtained after each loading stage. In order to prevent sudden failures of bond lengths at CST, an appropriate software tool was prepared to enable simultaneous recording and evaluation of the most important behaviour parameters of an anchor during in-situ test.

### 4 ANALYSIS OF RESULTS OF THE IN-SITU TESTING

There are several possible failure mechanisms at the anchor bond length, which occur at the IT of prestressed ground anchor with a comprehensive corrosion protection: inside or outside the PE corrugated duct, under some circumstances it may also come to the rupture of PE duct. The types and incidences of individual mechanisms depend on the design of bond length and packing connections at the transition between strand free and bond lengths, possible surface contamination of the bare strand bond length, the design, dimensions and distribution of the constituent components of anchors, local conditions in the ground, configuration of strands in the bond length, drilling and flushing techniques as well as specifics of grouting. According to the

principle of the weakest link in the chain, there starts a mechanism that occurs at the lowest load level, although in the following load steps some additional mechanisms may also occur.

The bond lengths (2.2 m) of the shortest anchor units (RCP/D-Z and RCP/D-I anchors) were determined according to the available anchor bond length 7 m and previous experience (Barley and Windsor, 2000, Bruce et al., 2007). The bare strands of the bond length of RCP/D and RCP/D-K anchors were spirally rotated along the longitudinal axis, while the strands of the short bond length of RCP/D-Z and RCP/D-I anchors were straight. The bare strands of the bond length of RCP/D anchors (and to a certain extent of RCP/D-K anchors) were additionally arranged in a pattern of alternating spatial extension and compression of strands. Although the lengths of strand bond lengths were selected in accordance with the aforementioned recommendations, the analysis of the in-situ test results of RCP/D-Z and RCP/D-I anchors showed predominant mechanism of pull-out of strands bond length from cement grout inside the corrugated PE duct. Such behavior can be associated with the greasing technology of strand free length, in which some strands in bond lengths can be locally stained with vaseline, although most of the stains were later on removed. Contrary to expectations, only in individual cases of RCP/D and RCP/D-K anchors, there appeared the pull-out mechanism of the whole tendon from the cement grout inside corrugated PE duct. Such behaviour can be partly ascribed to the local contamination of bare strands with vaseline stains, and partly to the direct contact of strand bond lengths with the bottom part of the corrugated PE duct (no minimum grout cover was provided).

The behaviour of anchor bond length is reflected in the most important outcome of the IT: pull-out resistance  $R_a$ , which is determined as the intersection of experimentally obtained curve of interval creep displacement rate  $k_{int}$  to the assumed margin that denotes the failure of an anchor  $k_{crit} = 2$  mm. In cases where such intersection does not exist, the failure of anchor bond length is not reached – in these cases the standard SIA 267/1 allows for an extrapolation of  $R_a$  as a proof load extrapolated up to 10%. The problem with this assessment remains when the anchor bond length can be assessed as failed, or in other words, in those cases when it is a reasonable to expect that the anchor bond length would be able to sustain a load of 1.10  $P_{pv}$ . The analysis of in-situ obtained test results for the considered type of anchors showed: if the following criteria are satisfied, this could be a suitable basis for 10 % extrapolation of  $P_{pv}$ , provided that the estimate is made by an experienced specialist:

- linear trend approximation of the creep displacement rates at the proof load  $P_{pv}$  (considering all strands and the anchor as a whole) should not exhibit any noticeable increase in creep rate,
- maximum creep displacement rate in each time interval after the second minute of observation (for each strand and the anchor as a whole) must not exceed the criterion of failure  $k_{crit}$ ,
- the interval creep displacement rate  $k_{int}(P_{pv})$ , of each strand and the anchor as a whole should not be greater than 1.35.

Results of all performed in-situ tests are presented as values of pull-out resistances  $R_a$  [kN] (Table 1) as well as in the diagrams of interval creep displacement rates  $k_{int}$  obtained at all stages of IT and CST (Fig. 4).

The general impression in the ratio of pull-out resistances among various types of tested anchors can already be obtained on the basis of visual assessment of the curves in the diagrams: the highest values of anchor bond length resistance (i.e. high loads  $P$  reached at low values of  $k_{int}$ ) were achieved at RCP/D-K anchors with increased stiffness of bond length, which slightly exceeded the bond length resistance of reference RCP/D anchors. An unexpectedly rapid failure of two reference RCP/D anchors was a result of problems at grouting (anchor SBz-23) and distinctive slip of two strands, probably due to bare strand contamination with vaseline (anchor SBz-59). On the other hand, multiple anchors with staggered bond lengths (RCP/D-Z

type) demonstrated the poorest performance of all tested anchors due to early failure of bond lengths at low load stages of IT or CST (deterioration of bond between strands and cement grout resulted in the pull-out of the strands). The behaviour of RCP/D-Z and RCP/D-I anchors was probably influenced by the surface contamination with vaseline as well as configuration of strands in the bond length. Additional impairment of the conditions within the corrugated PE duct was caused by the use of soft and relatively spacious packing connections in the transition between anchor unit bond and free length.

Table 1. Results of in-situ tests: pull-out resistances  $R_a$  [kN] of all tested anchors of reference and alternative types.

RCP/D	RCP-D/K	RCP-D/Z	RCP-D/I
Anchor $R_a$ [kN]	Anchor $R_a$ [kN]	Anchor $R_a$ [kN]	Anchor $R_a$ [kN]

SBz-56* 1211			
SBz-59* 642			

Figure 4. Interval creep displacement rates  $k_{int}$  for reference testing anchors as well as for all types of alternative anchors.

To confirm the relationships among pull-out resistances  $R_a$  (Table 1) a one-sided Student's T-test with unequal variance was used to check whether the average values of different types of anchors differ significantly from each other.

Results of testing the hypothesis of the equality of the means of two normal populations at the 5 % significance level showed that the mean value of RCP/D-Z anchor pull-out resistance was statistically typically lower than the mean values of pull-out resistance of reference RCP/D and alternative RCP/D-K anchors (Table 2). Somewhat unexpectedly, using statistical methods we could not confirm that the mean value of RCP/D-Z anchor pull-out resistance was statistically typically lower than the mean value of pull-out resistance of RCP/D-I anchors, as it could be inferred only on the basis of visual comparison of the curves in the graphs in Fig. 4.

Table 2. Results of one-sided Student's T-test with unequal variance of mean pull-out resistances  $R_a$  for reference and alternative anchors.

	RCP/D	RCP/D-K	RCP/D-Z	RCP/D-I

## 5 CONCLUSIONS

Based on the theoretical background of bond length behaviour of a prestressed ground anchor and the patents of Barley and Škrabl, three types of anchors with alternative concepts of bond lengths inside PE encapsulation (RCP/D-K, RCP/D-Z and RCP/D-I types) were designed, installed and tested at a test field. The behaviour of alternative types of anchors was compared with the behaviour of the reference RCP/D anchors. Different aspects of design (especially limited anchor bond length of 7 m, the diameter of available type of corrugated PE duct), formation, manufacturing details and installation of testing field anchors resulted in different pull-out resistances  $R_a$  and they indicate the relations among bond length capacities of different anchor types.

Test results of 25 anchors showed that the maximum values of pull-out resistance  $R_a$  were reached at the modified RCP/D-K anchors with increased stiffness of bond length - the mean values of  $R_a$  of RCP/D-K anchors exceeded the mean values of  $R_a$  of RCP/D anchors by 16 %. Although the free space within the corrugated PE duct of bond length of the RCP/D-K anchors was very restricted, allowing only  $\varnothing$  5 mm additional steel wires to be installed (instead of originally planned  $\varnothing$  12.5 mm steel strands), high values of pull-out resistances of RCP/D-K anchors were obtained. The behaviour of RCP/D-Z and RCP/D-I anchors was probably influenced by the surface contamination with vaseline as well as the configuration of strands in the bond length. Additional impairment of the conditions within the corrugated PE duct was caused by the use of soft and relatively spacious packing connections in the transition between anchor units bond and free length. The RCP/D-Z anchors demonstrated the poorest performance of all tested anchors (the bond length of RCP/D-Z anchors failed at low force levels of IT and CST). In all cases local debonding at the strand/grout interface resulted in the pull-out of strands. With improvement of particular technological details of alternative anchors, higher values of pull-out resistances can be expected. According to the experiences of Barley with multiple anchors, the pull-out resistances of RCP/D-Z anchors should attain (and probably exceed) the pull-out resistances of reference RCP/D anchors, provided that the pull-out of strands from cement grout, placed within the corrugated PE duct, is prevented. At least it is necessary to provide the immaculate condition of bare strands in the bond length within the PE encapsulation. Moreover, it is also possible that instead of RCP/D-K anchors the highest values of pull-out resistance could be achieved at one of the other alternative types (RCP/D-I or RCP/D-Z).

With the intention to increase the efficiency of alternative types of permanent prestressed anchors (RCP/D-K, RCP/D-Z and RCP/D-I) the following improvements are suggested:

- Results of field testing confirm the already known fact (Littlejohn, 1993, Hanna, 1982) that for effective performance

of bond length the bare strands should be covered with sufficiently thick layer of cement grout, irrespective of the anchor bond length design.

- The efficiency of anchor bond length could be improved with the increase of corrugated PE duct diameter. In that case the region around bare strands within corrugated PE duct could be reinforced (spiral micro reinforcement, cement grout with admixed fibres, etc.). Simultaneously, extra space would be gained for nodding or local deforming of strands.
- The efficiency of RCP/D-Z and RCP/D-I anchors could also be improved by upgrading the technological detail of anchor unit packing connections at the transition between strand bond and free lengths. Performance of RCP/D-z and RCP/D-I anchors could also be improved if the greased and sheathed strands in the free length would possibly be replaced with some other solution that offers higher stiffness in radial direction.
- For specific design of RCP/D-Z and RCP/D-I anchors the combination of strand and anchor unit nodding is suggested, whereat the minimal anchor unit strands bond length should be 2.5 m (in case of the increased diameter of corrugated PE duct) and 3.0 m (in case of the unchanged diameter of corrugated PE duct).

## 6 ACKNOWLEDGEMENTS

The authors are grateful to the Slovenian motorway agency DARS, for their financing of the research project. We are also much obliged to the manufacturer CA.TI. Carnica Tiranti, Srl, Italy for their donation of the anchors, and to the contractor GEOT for successful installation and in-situ testing of anchors.

# Response of piled buildings to deep excavations in soft soils

## Déformations des bâtiments liés aux excavations profondes situés dans les sols mous

Korff M.  
Delft and Cambridge University

Mair R.J.  
Cambridge University

**ABSTRACT:** This paper explores the building displacements related to deep excavations for a case study from the Netherlands: the construction of the North South Metro Line in Amsterdam. The overall goal of the analysis of the displacement is to study the interaction of deep excavations with piled buildings. The response of buildings is governed by the soil displacements resulting from the excavation. These displacements are described in a second, related paper in this conference. In this paper, the response of the piled buildings is described.

**RÉSUMÉ :** Les auteurs ont analysé déformations des bâtiments liés aux excavations profondes à Amsterdam pour la Ligne nord/sud. L'objectif général de l'analyse des déformations est d'étudier l'interaction des excavations profondes avec des bâtiments sur pieux. La réponse des bâtiments est régie par les déformations du sol résultant de l'excavation. Ces déformations, du niveau de la surface et de niveaux plus profonds, sont décrites dans un article connexe à cette conférence. Dans le document présent, la réponse des bâtiments sur pieux est décrite.

**KEYWORDS:** deep excavation, ground displacement, piles.

### 1 INTRODUCTION

The North-South Line in Amsterdam passes under the historical centre of the city in twin tunnels. Five underground stations are currently under construction. Rokin, Vijzelgracht and Ceintuurbaan Station are three of the deep stations in the historic city centre. They are built using the top down method, see Figure 1. In a related paper for this conference by the same authors, the construction method and ground displacements related to the deep excavations have been described. The settlement measurements for the Amsterdam deep excavations have been compared to several, mostly empirical, relationships to determine the green field surface displacements and displacements at depth. In summary, the surface displacement behind the wall is 0.3 – 1.0% of the excavation depth, if all construction works are included. Surface displacements behind the wall can be much larger than the wall deflections and become negligible at 2-3 times the excavated depth away from the wall. The shape of the displacement fits the proposed profile by (Hsieh and Ou 1998) best. In all three of the Amsterdam cases, the largest effect on the ground surface displacement can be attributed to the preliminary activities, which include amongst others the diaphragm wall construction, jet grout strut installation and construction of the roof, and took in total about 4 years. See Table 1 for details.

Table 1 Construction activities and dates for Ceintuurbaan

Construction activity	End date
Base monitoring start 2001	2003-11-01
Preliminary activities	2007-04-01
Excavation to NAP -6.2m	2007-09-13
Excavation to NAP -15.3 m	2007-12-10
Excavation to NAP -19.4 m	2008-03-01
Excavation to NAP -24 m	2008-08-01
Excavation to NAP -25.6 m	2009-06-24
Floor construction, pumping test	

The actual excavation stage caused only about 25-45% of the surface displacements, with 55-75% attributed to the

preliminary activities. At larger excavation depths the influence zone is significantly smaller than 2 times the excavation depth.

This paper describes the building displacements related to the excavation works in more detail.

Figure 1 Cross section of Ceintuurbaan Station with soil profile and extensometer locations.

## 2 SOIL-STRUCTURE INTERACTION

The excavation-induced displacements described in the related paper can be considered as green field displacements. To assess the potential impact of these ground displacements on buildings, these displacements are usually directly projected onto the building, leading to bending and shear strains in the structure. It is however known that the presence of the building and the interface between building and soil also influences the settlement trough and transfer of deformations to the building. (Potts and Addenbrooke 1996, Franzius et al. 2006 and Farrell 2010) have shown this for displacements related to tunnels and (Goh and Mair 2011) for buildings influenced by deep excavations. (Goh and Mair 2011) modified the relative stiffness proposed by Potts and Addenbrooke for tunnelling to the following for deep excavations:

$$\rho_{exc}^* = \frac{EI}{E_s L^3} \quad (1)$$

$$\alpha_{exc}^* = \frac{EA}{E_s B} \quad (2)$$

where EI is the building stiffness, Es a representative soil stiffness and L the length of the building in either hogging or sagging. EA is the axial stiffness of the building and B is the total length of the building.

Furthermore (Jacobsz et al. 2005) described the soil-structure interaction in more detail for piled buildings related to tunnelling. In Amsterdam the piled buildings were influenced by deep excavations, which requires a combined approach influenced by the presence of pile foundations: the initial stresses in the foundation and the ground, and possible load transfer within the building. If these effects are not considered, the current assessment methods may be too conservative or too optimistic, leading to costly measures either being taken unnecessarily or having to be applied at a late stage in the project.

## 3 BUILDING AND FOUNDATION CHARACTERISTICS

Most buildings in the historic centre of Amsterdam are built with masonry walls, wooden floors and timber pile foundations, the piles being founded in the First Sand Layer at about 12m below the surface level (see Figure 1). More recent buildings with 1-4 storeys are built with concrete walls and floors and prefabricated concrete or steel piles. Foundations for some recent buildings are in deeper layers such as the second sand layer. The buildings considered in this paper are from the older type, see Figure 2.

Figure 2 Historic buildings at Vijzelgracht (left) and Ceintuurbaan Station (right), dated 1880-1920

The wooden piles are installed in pairs, see Figure 3, with 0.8m between the pairs. Pile diameters for the timber piles vary from

160 - 300 mm (typical 180-200 mm) at the head and usually diminish by 8 mm/m to about 70-200 mm (typical 120-140 mm) at the toe. Based on several pile load tests in the historic centre it is known that the wooden pile foundations have low factors of safety. Up to 15% of the buildings of this age in Amsterdam are not up to current standards, according to (van Tol 1994). A large number of timber piles deteriorate due to decay of the wood, which may lead to a different kind of building response; this effect is not described here.

Figure 3 Typical cross section of base of the wall in masonry buildings (Zantkuyl 1993)

Two typical load-displacement curves are shown in Figure 4. The timber piles in failure generally find 60% of their capacity at the toe, 10% as friction in the sand layer and 30% as friction in the Holocene clay the maximum shaft friction develops at a relative displacement of about 25 mm and in the base sand layer at about 15 mm. The maximum base capacity for piles with average diameter at the base of 130 mm is reached at about 10% of the diameter, which is consistent with common design methods. The high horizontal flexibility assures that the piles can move rather easily with the soil in horizontal direction, compared to concrete piles.

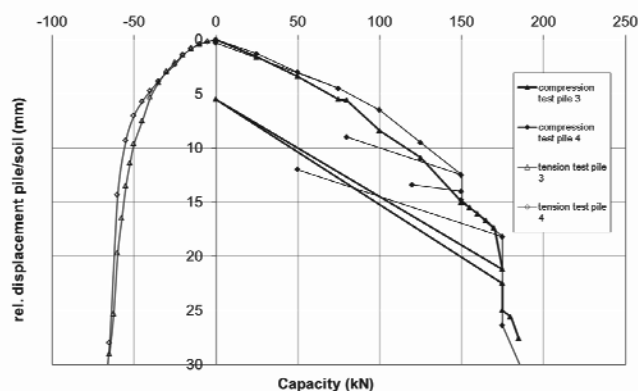

Figure 4 Representative load-settlement curves for timber piles in Amsterdam (Hoekstra 1974)

To determine the response of piled buildings to excavations knowledge of the current state of the piles is essential. Most piles in the historic centre of Amsterdam will already have experienced the maximum negative skin friction possible over time. The presence of soft soil layers combined with earlier city developments which included raising of the ground level causes on-going subsidence due to consolidation and creep. Negative skin friction develops as a result along the shaft of a pile when the soil surrounding the pile settles more than the pile itself. Positive skin friction occurs in opposite circumstances when the pile settles more than the surrounding soil. Both forces are likely to act on the timber piles in Amsterdam, see Figure 5.

#### 4 RESPONSE OF PILED BUILDINGS

For end bearing piles with sufficient factor of safety the neutral level is found close to the location of the bearing layer. For the most historic Amsterdam foundations, the reserve capacity is smaller, and positive skin friction is also found in the soft or settling layers. The maximum force in the pile is found at the neutral level (the level at which the soil and pile settlements are the same and the shear stresses acting on the pile change direction). Usually in Amsterdam, it is considered that the negative skin friction is already fully mobilized before the excavation takes place.

Figure 5 Development of negative and positive skin friction along a pile with low factor of safety

Buildings in the influence zone of the excavation may experience several phenomena:

1. reduction of pile capacity due to lower stress levels ( $s_1$ )
2. settlement of soil below the pile base ( $s_2$ )
3. development of negative (or positive) skin friction due to relative movements of the soil and the pile shaft ( $s_3$ )
4. redistribution of pile load between the piles ( $s_4$ )
5. horizontal deformations of the piles.

The settlement of the pile head is determined by the combination of the first four effects described above:

$$s = s_1 + s_2 + s_3 + s_4 \quad (3)$$

Settlement  $s_1$  for end bearing piles is significant if the pile tips are very close to the excavation and stress relief takes place around the pile tip. Settlement  $s_2$  does not involve interaction with the piles, whereas  $s_3$  is a true interaction component. For end bearing piles complying with current standards negative skin friction, if already fully developed, will not cause additional settlements, which means  $s_3 = 0$ . For all other piles  $s_3$  depends on the amount of negative skin friction mobilized in the initial state. If the shaft friction is already fully mobilized, the neutral level will remain at about the same level and the pile follows the settlement of the soil at this level. If the shaft friction initially is not developed completely, the neutral level will change if soil displacements take place. For piles close to failure, the neutral level is found close to the surface and  $s_3$  is about equal to the surface settlement.

An important issue is to determine the initial neutral level. This could be done theoretically based on CPT data or from historic data of relative building settlements to surface settlements. Based on the average pile capacity, the neutral level for an old pile in Amsterdam is found to be between NAP -7 and NAP -12 m, depending on the load on the pile, see (Korff 2012). Assuming a linear relationship between the ground settlement at surface and pile tip level, the pile-soil interaction

can be determined from the relative position of the neutral level to the surface and the tip level, see Figure 6.

If the negative skin friction is not fully mobilized at the initial state or if the tip resistance reduces, the skin friction will further mobilize, which will raise the neutral level. Settlement  $s_3$  might also include an elastic component of the shortening of the pile if the total stress in the pile increases with increasing negative skin friction. If the pile redistributes its load,  $s_4$  needs to be determined together with  $s_3$ . This could occur if the piles closest to the excavation settle more than the piles further away. The building stiffness will prevent the building from following the different pile movements and the pile load will redistribute accordingly. If this happens, the external load on the pile changes, leading to a new equilibrium. This effect should be determined by a coupled analysis for a pile group, such as with a boundary element method as described by (Xu and Poulos 2000).

Figure 6 Settlement profile and neutral level, assuming linear relationship

#### 5 BUILDING DISPLACEMENTS

The effects that cause the piles and hence the buildings to settle have been evaluated by analysing substantial amounts of monitoring data available from the Amsterdam cases. The settlement of the building is compared to the greenfield soil deformations at surface and pile tip level. It is not possible to distinguish between the contributions of  $s_1$ ,  $s_3$  and  $s_4$ . Settlement  $s_2$  however can be directly evaluated against the results of the extensometer measurements at pile tip level. Figure 7 shows the building displacements (LevelingS) compared to the soil displacements at surface (GroundSurface) and pile tip level (ExtensioNAP-12m) for a series of buildings with old timber piles. The settlement of these buildings is equal to the soil settlement at approximately 0.3 to 0.5 times the pile length if a linear soil settlement profile between the surface settlement and the settlement at the first sand layer is assumed.

Figure 7 Ground and building displacements for CS13044 (at Ceintuurbaan).

In most cases in practice, no detailed information is present about the foundation and the soil-pile interaction has to be estimated or measured during construction.

For a second series of buildings with more modern foundations (old timber piles combined with renovation steel piles), the depth at which the pile and soil settlement are equal is found at approximately 0.8 – 1.0 times the pile length, see Figure 8.

Figure 8 Ground and building displacements for CS13110 (at Ceintuurbaan) in the period 2001-2009

Based on the soil and building displacements as presented in more detail in (Korff 2012), the average interaction between pile and soil is found at 0.3 – 0.8 times the pile length for most original timber pile foundations and 0.8-1.0 times the pile length for most renewed foundations in the first sand layer. Some modern buildings settle very little and the pile settles the same as the pile tip level (1.0).

The settlement of the piles is shown to be between the settlement of the surface and the foundation layer. The deflection of the building is smaller than the deflection of either of the surface or base level soil deflections due to the stiffness of the building. The (Goh and Mair 2011) method to compare building settlement with greenfield settlement was used to determine the modification factors. In this case this was done comparing with greenfield surface settlement and with greenfield settlement of the foundation layer (first sand). For the deflection of buildings next to excavations, deforming in hogging shape, the modification factor is based on (Potts and Addenbrooke 1996):

$$M_{hog}^{DR} = \frac{\Delta/L \text{ hog, building}}{\Delta/L \text{ hog, greenfield}} \quad (4)$$

Figure 9 Modification factors from Amsterdam deep excavation for surface level and foundation level, compared with the design envelope presented by (Mair 2011)

The deflection of the buildings is clearly less than the deflected shape of the surface (70% reduction). A reduction of the deflection of 45% is found compared to the foundation level. The variation in these factors can to a certain degree be explained by the relative stiffness of the buildings compared to the soil as shown in Figure 9.

## 6 CONCLUSIONS

Piled buildings adjacent to deep excavations have to be assessed differently from buildings with shallow foundations. Piled buildings settle an amount between the surface settlement (for friction piles in failure) and tip level settlement (for end bearing piles with sufficient capacity to take full negative skin friction). The precise soil-pile interaction can be estimated based on the pile load, the pile capacity and the shaft friction development based on a method described in (Korff 2012). Based on measurements of Amsterdam timber pile foundations, the pile settlement is equal to the soil settlement at a depth of 0.3 – 0.8 times the pile length for most original timber pile foundations and 0.8-1.0 times the pile length for most renewed foundations in the first sand layer. Most of the modern buildings settle not more than the pile tip level.

The method proposed by (Goh and Mair 2011) provides a realistic, although rather large, range of possible modification factors to estimate the building deflection compared to the deflected shape of the soil surface and foundation level.

## ACKNOWLEDGEMENTS

This research was performed in cooperation with the Dutch Centre for Underground Construction (COB). The authors wish to thank the city of Amsterdam for permission to use the data.

# Deep excavation in Irish glacial deposits

## Excavation profonde des dépôts glaciaires Irlandais

Long M., O'Leary F.

*Department of Civil, Structural and Environmental Engineering, University College Dublin (UCD), Ireland*

Ryan M., Looby M.

*Byrne Looby Partners, Dublin, Ireland*

**ABSTRACT:** A good number of deep excavations have been recently completed in Irish glacial deposits. These have included propped walls up to 12 m deep. Experience elsewhere in the world was used to design and construct these walls. However case history data has shown that the behaviour of these walls is very rigid and much stiffer than comparable systems worldwide. It appears this behaviour is due to the inherent natural strength and stiffness of the soil and the slow dissipation of excavation induced depressed pore pressures or suctions. There appears to be scope for developing more efficient designs and in particular for greater use of cantilever walls and less stiff systems with smaller piles and reducing propping requirements. For temporary works, the use of undrained parameters in serviceability limit state calculations together with implementation of the observational approach on site could be considered for future schemes.

**RÉSUMÉ :** Un bon nombre d'excavations profondes ont été récemment réalisées dans les dépôts glaciaires Irlandais. Elles ont inclus des murs de soutènement jusqu'à 12 mètre de profondeur. La conception de ces murs a été réalisée grâce aux méthodes utilisées dans les autres pays du monde. Toutefois, les analyses a posteriori ont montré que les caractéristiques de ces murs étaient extrêmement rigides et bien plus rigide que d'autres systèmes comparables dans le monde. Il semble que ces caractéristiques sont dues à la résistance naturelle et à la rigidité du sol ainsi qu'à la lente dissipation des pressions interstitielles déprimées ou aux suctions induites par la réalisation des excavations. Il semble y avoir des possibilités de développer des méthodes de conceptions plus réalistes et moins conservatives permettant en particulier une utilisation accrue des murs cantilevers et des systèmes moins rigides avec de petits pieux de fondation et en réduisant les besoins de butonnage ou d'ancrage. Pour les travaux temporaires, l'utilisation de paramètres non drainés dans les calculs des états limite de service ainsi que la mise en œuvre de l'approche observationnelle sur le chantier, pourraient être envisagées pour de futurs projets.

**KEYWORDS:** deep excavations; retaining walls; glacial deposits; ground movements

### 1 INTRODUCTION.

Over the previous 15 years, economic growth in Ireland has led to an increase in the use of underground space, with some development now including four underground levels. Valuable full scale data has been obtained from a good number of these projects. The purpose of this paper is to provide an overview of aspects relating to the design, construction and behaviour of retaining walls in Irish glacial deposits.

This paper will exclude projects located in the two main cities of Dublin and Cork. Case histories from these two locations have already been well documented (Long et al., 2012a; Long et al., 2012b; Long et al., 2012c; Long et al., 2013).

Specifically the paper will:

- Briefly review the background geology and ground conditions,
- Outline the presently used design approach,
- Review in detail the general behavior of walls in Irish glacial deposits by reference to two case histories namely:
  - lightly supported "regular" wall for 6 m excavation in Limerick,
  - 6 m excavation in Middleton, Co. Cork where a cantilever solution was used,
- Present an overall summary of the behavior of retaining walls in Irish glacial deposits compared to similar support systems worldwide,
- Provide some overall conclusions and recommendations for the design and construction of future similar schemes.

### 2 BACKGROUND GEOLOGY

Broadly speaking the coastline of Ireland is formed of strong older igneous and metamorphic rocks such as sandstones, granites and quartzite. The central basin of Ireland is formed of Carboniferous limestone. However the engineering geology of Ireland is dominated by the mantle of 10,000 to 15,000 year old glacial tills and glacial sands and gravels which cover much of the country. These deposits generally have a high gravel, cobble and boulder content and are usually medium dense to dense or stiff to very stiff in consistency. They form a thin layer (but usually greater than 3 m in thickness) draped over and conforming to the underlying bedrock topography. Later alluvial activity has covered the glacial deposits with soft clays, silts and peats in some low lying areas, in estuaries and along river flood plains (Edwards and Warren, 1985).

### 3 THE SITES

The location of the study sites is shown on Figure 1 and some details of the projects under consideration are given on Table 1. The sites are located throughout Ireland but mostly in the most populated areas to the east and south-east.

At each of the chosen sites inclinometers had been used to measure the lateral pile retaining wall movements. Details given on Table 1 include the depth of excavation (H), the support details including the spacing of the structural piles and the maximum measured pile deflection ( $\delta_h$  max).

#### 4 DESIGN

Current geotechnical design procedures for retaining walls in Irish glacial deposits often involves the following steps:

- Following the general guidelines of Gaba et al. (2003) or BS8002 (BSI, 1994), for ultimate limit state, determine the required retaining wall toe penetration. Calculations use effective stresses and are often performed by hand, using conventional Rankine active and passive earth pressure theory, or with a relatively simple piece of software,
- Check that this toe penetration is adequate to support any vertical loads and also to prevent significant water seepage,
- Determine wall bending moments, shears, prop / waler forces and lateral wall movements (serviceability limit state) by means of a beam – spring computer program such as OASYS – FREW<sup>®</sup>,
- Determine the associated ground movements using empirical based methods, such as those developed by Clough and O'Rourke (1990). Possible adjacent building damage is then assessed by comparing parameters such as differential settlement with empirically based tolerable limits, e.g. those of Burland et al. (1977)

#### 5 OVERVIEW ALL SITES

Data for the 12 available case histories are presented in Table 1. A plot of maximum measured lateral movement ( $\delta_h$ ) versus retained height (H) is shown on Figure 2. Except for the Main St. Cavan, Portlaoise Phase 1 and the Midleton cantilever excavations,  $\delta_h$  values are less than 7 mm. There does appear to be some weak tendency for an increase in  $\delta_h$  with H.

Also shown on Figure 2 are lines representing normalised movement ( $\delta_h/H$ ) of 0.08% and 0.4%. The former relationship was obtained by Long et al. (2012a) for projects in Dublin boulder clay – a very stiff glacial lodgement till. The behaviour of the projects presented here is similar if not better than the Dublin sites. The 0.4% line represents a typical design value as recommended by Gaba et al. (2003) in CIRIA Report C580 and clearly this relationship is very conservative for most of the cases presented but is consistent with the data from the Cavan and Midleton cantilever sites.

The data shown on Figure 2 takes no account of the retaining wall type, its stiffness or the prop / anchor configuration. In order to attempt to include these factors, the data are replotted on Figure 3 in the normalised form of  $\delta_h/H$  against Clough et al. (1989) system stiffness. This is defined on Figure 3 where  $EI$  = wall stiffness,  $\gamma_w$  = unit weight of water (so as to make expression unitless) and  $s$  = support spacing.

Figure 2. Maximum lateral wall movement versus excavation depth

Figure 3. Normalised maximum lateral wall movement versus Clough et al. (1989) system stiffness

The two relationships included in Figure 2 are also shown here. In addition the relationship  $\delta_h/H = 0.18$ , which was obtained by Long (2001) for an average of 169 case histories worldwide where there was stiff soil at dredge level, is also shown. Lateral movement is clearly a function of system stiffness with the two walls with low system stiffness showing relatively high movements. The Cavan wall had very slender piles and the Midleton wall had no props or anchors. However the remaining data plot well below the worldwide trend suggesting that a more flexible (and hence a more economic) wall may perform adequately in many cases.

Some of the trends shown on Figure 2 and 3 are explored further by examining two detailed case histories as follows

### 6 CASE HISTORY OF A LIGHTLY SUPPORTED “REGULAR” WALL – SAVOY, LIMERICK

Details of this site are shown on Figure 4. The approach and techniques used at the Savoy Site are typical of those used at many sites in Ireland. The site is underlain by about 2 m of made ground over about 5 m of glacial deposits over limestone bedrock. The glacial deposits have standard penetration test (SPT) N values increasing from about 20 blows / 300 mm near the top of the stratum to an average of 60 blows / 300 mm with depth.

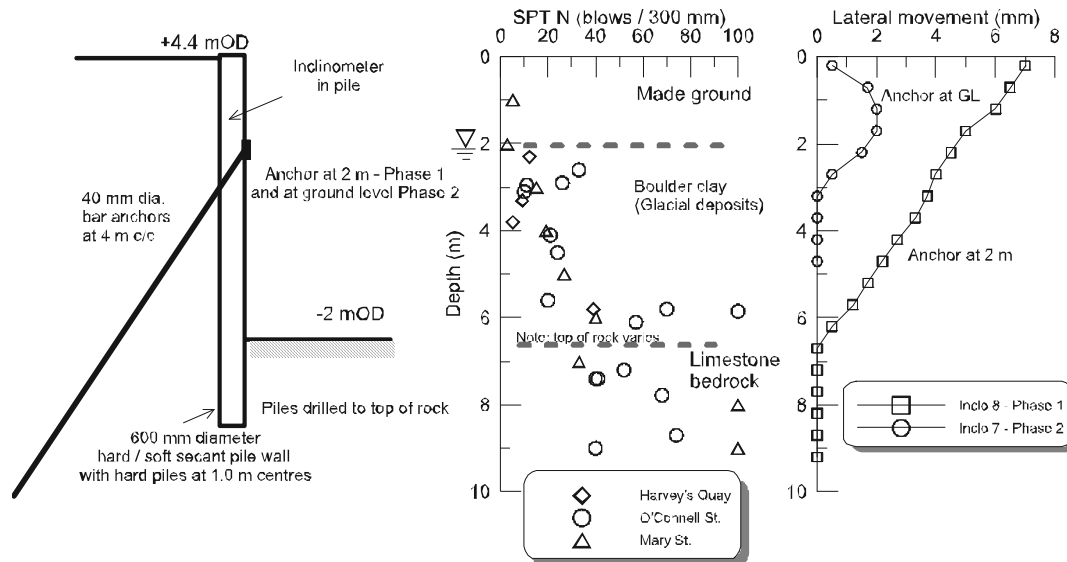

Figure 4. Savoy, Limerick

The retaining wall was required for temporary works purposes only and comprised a 600 mm diameter “hard / soft” secant wall with a single anchor. For the Phase 1 excavation the anchor was located at about 2 m depth. Much of the 7 mm or so movement recorded occurred while the wall was acting in a cantilever mode during the installation of the anchors. This is consistent with the findings of Long (2001) for a good number of world wide projects. Thus for Phase 2 the anchor was relocated to ground level and the measured movements were much smaller.

It would seem that a less stiff system, e.g. smaller diameter / more widely spaced piles or a cantilever wall would have performed perfectly adequately in this case.

### 7 CASE HISTORY OF CANTILEVER WALL

Details for the Midleton site are shown on Figure 5. This project was carried out in 2012 and thus many of the lessons learned over the previous 10 to 15 years could be used. Again the wall was required for temporary works purposes. It comprised a “hard / firm” secant pile wall with 640 mm diameter structural “male” piles and 900 mm diameter “female”. A single anchor was used at locations where sensitive adjacent buildings were present. However for non sensitive areas of the site and based on the experiences listed above a cantilever solution was used.

Ground conditions are more complex than those at Limerick and comprised a variable sequence of glacial clays, silts, sands and gravels. SPT N values increase from about 10 blows / 300 mm at the surface to an average of 25 blows / 300 mm at 7 m depth and thereafter remain approximately constant.

As would have been expected from previous experience measured movements for anchored section were very small. For the cantilever sections the wall also behaved very well and maximum lateral movements were of the order of 20 mm

Predicted wall deflections, using *FREW*<sup>®</sup> for the anchored wall are also shown on Figure 5. The key input parameters are the effective friction angle ( $\phi'$ ), the undrained shear strength ( $s_u$ ) and the Young's modulus ( $E_u$  or  $E'$ ). These were determined from correlations with SPT N. For the clay layers it was assumed  $s_u = 5N$  and  $E_u = 750N$  (Gaba et al., 2003; Stroud, 1988). For the granular soils  $E'$  was assumed = 2500N and  $\phi'$  was found from the relationships of Peck et al. (1974).

It can be seen that the predicted values considerably overestimate the measured ones. A similar finding was made for the cantilever wall at Midleton.

Figure 5. Midleton

## 8 DISCUSSION

The reasons for the very stiff behaviour of the retaining walls in Irish glacial deposits are complex but are due to a combination of the following factors:

- Excavation induced depressed pore pressures (or even suctions) in the material. These result in increased effective stress and hence stability (Long et al., 2012a).
- The low permeability of the clay fraction of the material ( $10^{-10}$  m/s or less) meaning that the dissipation of the depressed pore pressures takes a long time.
- The material has extremely high strength and stiffness.

A possible approach for the design of temporary retaining structures in the clay fraction of the material may be in the use of undrained parameters in conjunction with the observational approach. This approach should only be considered where the predicted deflections using an effective stress approach would be within defect limits to prevent the possibility of damage, economic loss or unsafe situations. The risk associated with the decision should be clearly assessed in terms of understanding of the site geology, type and condition of structures to the rear of the pile wall and the quality of monitoring procedures and contingency measures put in place.

It seems there is scope for the greater use of cantilever walls, less stiff walls (e.g. smaller diameter piles) and also greater retained heights at least for temporary works purposes. It must also be emphasised that an effective stress design approach is always needed for the ultimate limit state analysis in permanent works as the suctions will eventually dissipate.

## 9 CONCLUSIONS

Case history data confirms that retaining wall behaviour in Irish glacial deposits is extremely stiff.

The reasons for this stiff behaviour lie in the low permeability and high strength and stiffness of the material and the resulting very slow dissipation of depressed excavation induced pore pressures.

It appears that the current approach, for serviceability limit state calculations, which usually involves beam – spring type computer programs is clearly conservative.

For temporary works, the use of undrained parameters in conjunction with the observational approach may be considered for reducing predicted deflections to simplify the construction sequence and reduce costs.

There is scope for greater use of cantilever walls and walls and systems with lower stiffness.

## 10 ACKNOWLEDGEMENTS

Some of the data used in this paper was kindly provided by Mr. Tony O'Dowd of PJ Edwards & Co., Mr. Pat Fox of Murphy International Ltd., Mr. Patrick Casey of Arup Consulting Engineers and Mr. Eddie Meade of NVM Ltd. and their co-operation is gratefully acknowledged.

# Active earth thrust on walls supporting granular soils: effect of wall movement

Pression active des terres sur des murs soutenant des sols granulaires: l'effet du mouvement du mur

Loukidis D.  
University of Cyprus, Cyprus

Salgado R.  
Purdue University, USA

**ABSTRACT:** The methods currently used in the design practice of retaining walls supporting granular soils (sand, gravel, silt, and their mixtures) assume that the soil friction angle and, consequently, the active earth pressure coefficient  $K_A$  are independent of wall movement. However, the mobilized friction angle inside the retained soil in reality first reaches a peak value and then decreases towards the critical state value as shear strain increases with wall movement. This study aims to investigate the development and evolution of the active earth pressure by modeling the soil mechanical behavior in a realistic way in a series of finite element analyses. Based on the numerical results, an equation is proposed for the estimation of  $K_A$  as a function of the initial relative density and the wall crest displacement.

**RÉSUMÉ :** Les méthodes actuellement utilisées dans la pratique de la conception des murs de soutènement supportant des sols granulaires (sable, gravier, limon et leurs mélanges) supposent que l'angle de frottement du sol et, par conséquent, le coefficient de pression active des terres  $K_A$  sont indépendantes du mouvement du mur. Toutefois, l'angle de frottement mobilisé à l'intérieur du sol retenu atteint en réalité d'abord une valeur de pic, puis diminue vers la valeur d'état critique à mesure que la déformation en cisaillement augmente avec le mouvement du mur. Cette étude vise à étudier le développement et l'évolution de la pression active des terres par la modélisation du comportement mécanique des sols de manière réaliste dans une série d'analyses par éléments finis. Sur la base des résultats numériques, une équation est proposée pour l'estimation de  $K_A$  en fonction de la densité relative initiale et le déplacement en crête du mur.

**KEYWORDS:** retaining wall, active earth pressure, sands, finite element analysis.

## 1 INTRODUCTION

The active earth pressure is expressed as the product of the vertical effective stress  $\sigma'_v$ , in the retained soil mass or backfill and the active earth pressure coefficient  $K_A$ . The earliest and simplest methods for the calculation of the active earth pressure for purely frictional soils are those based on the Coulomb and Rankine theories. For a retained soil with horizontal free surface and a vertical wall backface, Coulomb's solution yields

$$K_A = \frac{\cos^2 \phi}{\cos \delta \left[ 1 + \sqrt{\frac{\sin(\phi + \delta) \sin \phi}{\cos \delta}} \right]^2} \quad (1)$$

The Coulomb solution can be proven to be equivalent to a rigorous limit analysis upper bound solution. It is also in good agreement with other upper bound solutions (Chen 1975, Soubra and Macuh 2002), as well as the lower bound solution by Lancellotta (2002), with the differences not exceeding 7%.

Furthermore, these methods, which are currently used in design practice, assume that  $\phi$  and, consequently, the active earth pressure coefficient  $K_A$  are constant, i.e. their values do not change as the wall moves. However, the value of the mobilized friction angle in reality depends on a number of factors, such as the current mean effective stress, and, most importantly, the shear strain. Granular soils, unless in a very loose state, are strain-softening materials, meaning that the mobilized friction angle first reaches a peak value  $\phi_p$  and then decreases towards the critical state value  $\phi_c$ . Hence, the active state developing inside the mass of the supported soil is a function of the wall movement.

The goal of this study is to investigate the development and evolution of the active earth pressure as the wall moves away from the retained soil using finite element (FE) analysis. The study focuses on retaining wall that are free to translate and rotate, such as gravity walls, cantilever walls and self-supported (cantilevered) sheet pile, secant pile or slurry walls. The mechanical behavior of the soil is captured realistically using a two-surface constitutive model based on critical state soil mechanics.

## 2 FINITE ELEMENT METHODOLOGY

The FE analyses were performed using the code SNAC (Abbo and Sloan 2000). A typical finite element mesh is shown in Fig. 1. The mesh consists of 8-noded, plane-strain quadrilateral elements and includes the wall, the supported soil and the foundation soil. The free surface of the supported soil is horizontal and without surcharge. The wall has a rectangular cross-section with width  $B$  and height  $H$ , and is modeled as a linear elastic material with very large Young's modulus so that it can be considered rigid. The retaining wall is also embedded a small distance  $D$  into the foundation soil. The analyses start with the supported soil at rest ( $K_0$  state). No interface elements are placed between the soil and the wall. As a consequence, slippage between the wall and retained soil occurs due to the formation inside the soil mass of a shear band parallel to the wall backface. This roughness condition is realistic for walls made out of concrete; however, this may not be the case for sheet pile walls.

Figure 1. Typical mesh and boundary conditions used in the FE analyses.

The constitutive model used in this study is the two-surface plasticity model based on critical state soil mechanics developed originally by Manzari and Dafalias (1997) and subsequently modified by Dafalias et al. (2004) and Loukidis and Salgado (2009). The model parameters were determined by Loukidis and Salgado (2009) for two sands: air-pluviated/dry-deposited Toyoura sand and Ottawa sand. The model takes into account inherent and stress-induced anisotropy, and predicts accurately the soil response at both small and large strain regimes.

Because the problem under investigation involves material softening, the numerical simulations were inherently unstable. For this reason, the analyses were performed under displacement control. In the beginning of the analysis, the wall is fully supported at two points, namely the crest (node C) and the toe (node T), shown in Fig. 1, where the corresponding horizontal reactions are  $R_{C,0}$  and  $R_{T,0}$ , respectively. Equivalently, the wall is initially prevented to move horizontally or rotate because of the external application of a horizontal force  $F_{ext,0} = R_{C,0} + R_{T,0}$  and a moment  $M_{ext,0} = R_{C,0}/H$ . The analysis proceeds by the application of horizontal displacement increments  $\Delta u_C$  and  $\Delta u_T$  pointing away from the retained soil. As a result, the reactions  $F_{ext}$  ( $=R_C + R_T$ ) and  $M_{ext} = R_C/H$  begin to decrease. These displacement increments are applied in such way that the ratio  $F_{ext}/F_{ext,0}$  is maintained equal to the ratio  $M_{ext}/M_{ext,0}$ . As a consequence, the prescribed displacements  $u_C$  and  $u_T$  are not equal to each other, leading to an overall wall motion that includes both translation and rotation. The wall is allowed to move vertically as no restraints are imposed on its nodes in the vertical direction.

### 3 SIMULATION RESULTS

Finite element analyses were performed for  $B$  ranging from 1.5m to 2.5m and  $H$  ranging from 6m to 8m. The sand unit weight  $\gamma$  was set equal to  $18\text{kN/m}^3$ , while the coefficient  $K_0$  was set equal to 0.5. For the sake of simplicity, the foundation soil is assumed to be of the same type and density as the retained soil.

#### 3.1 Failure mechanism

Fig. 2 shows contours of the incremental maximum shear strain  $\gamma_{max}$  at the final stages of the simulations. The failure mechanism inside the supported soil consists of a wedge shaped sliding mass delimited by the wall backface and an oblique shear band originating from the heel of the wall. It can be seen also that families of secondary shear bands develop inside the sliding wedge. This is consistent with experimental observations by Leśniewska and Mróz (2001), as well as with FE analysis results by Gudehus and Nubel (2004). As shown in Fig. 2, the inclination angle of the shear bands in the retained

soil mass with respect to the horizontal is larger in the case of dense than loose sand. A shear band running parallel to the wall back face also forms in all analyses, representing sliding between the sliding soil mass (wedge) and the wall.

Figure 2. Contours of incremental  $\gamma_{max}$  from analyses with dense and loose Ottawa sand.

Below the wall base, a bearing capacity mechanism forms, the shape of which resembles that of mechanisms presented by Loukidis et al. (2008) for the case of strip footings on purely frictional material and subjected to eccentric and inclined loading.

#### 3.2 Active earth pressure evolution

Fig. 3 illustrates how the normal (horizontal) stress distribution along the back of the wall changes during an analysis. At the beginning, there is the triangular stress distribution corresponding to geostatic stress conditions ( $K=K_0$ ). With increasing wall displacement, the horizontal stress decreases progressively until a minimum active pressure state (MPS) is reached. From that point on, the average horizontal stress increases, but at a much lower rate than the rate at which it decreased earlier. Although before the MPS the stress distribution is smooth, afterwards, local peaks and valleys develop as consequence of bifurcation and the shear banding inside the sliding mass.

The evolution of the lateral earth pressure coefficient  $K$  with crest displacement  $u_C$  is shown in Fig. 4 for analyses with Toyoura sand with 60% relative density but different values of  $H$ ,  $B$ , and  $D$ . It can be seen that  $K$  drops sharply towards a minimum value ( $K_{A,min}$ ) corresponding to MPS at  $u_C$  approximately equal to  $0.003H$  and, subsequently, rises smoothly, approaching a residual value ( $K_{A,cr}$ ) related to the full development of critical state inside the sliding wedge. The results in Fig. 4 suggest that  $K_{A,min}$  and  $K_{A,cr}$  are practically independent of the wall dimensions and the embedment.

Fig. 5 shows the  $K/K_0$  evolution for Toyoura and Ottawa sands with different values of relative density. The figure also

shows the  $K_A$  value resulting from finite element analyses for an elastic-perfectly plastic soil following the Mohr-Coulomb failure criterion (M-C analyses) with friction angle  $\phi$  equal to the critical state friction angle value  $\phi_c$  of each sand for plane strain conditions and dilatancy angle  $\psi$  equal to zero (consistent with the constant volume response at critical state).

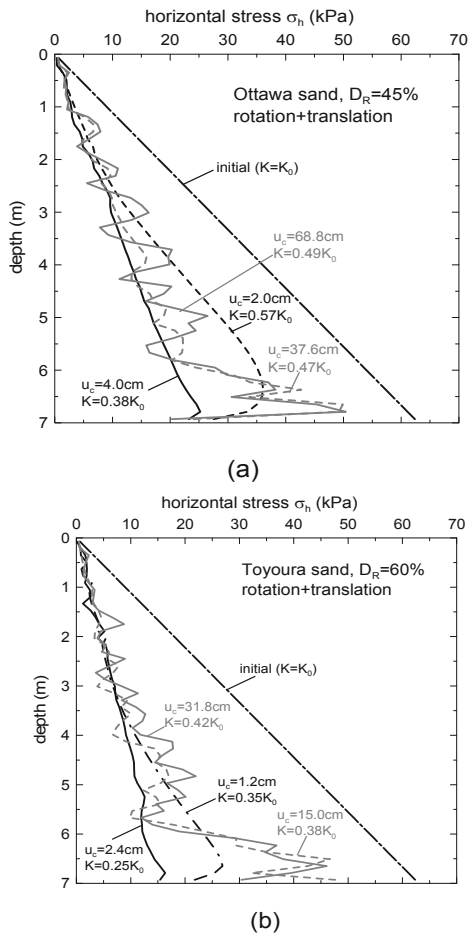

Figure 3. Examples of horizontal stress distribution acting on the wall backface at different stages during the analysis.

As expected,  $K_{A,min}$  decreases with increasing relative density and, consequently, peak friction angle. The crest displacement required for reaching the MPS is in the  $0.003H$  to  $0.006H$  range, regardless the  $D_R$  value. On the other hand, attainment of  $K_{A,cr}$  requires  $u_c$  larger than  $0.10H$ .

Interestingly,  $K_{A,cr}$  seems also to depend on the relative density despite the fact that  $\phi_c$  is independent of  $D_R$ . Only the curves for loose sand appear to attain  $K_{A,cr}$  values that are in agreement with the  $K_A$  from the analyses with a perfectly plastic soil with material parameters consistent with critical state. This is because the inclination of the sliding plane delimiting the wedge depends on the dilatancy that the soil exhibits during the early stages of the wall movement, since the theoretical value of the shear band inclination with respect to the minor stress (i.e. horizontal) axis is equal to  $45^\circ + (\phi + \psi)/4$  (Vardoulakis 1980). The sliding wedge forms at MPS, when the soil mass close to the wall is strongly dilative for all except very loose sand. Once the main inclined shear band forms, it tends to stay more or less at that location because of strain localization.

In most of the analyses, the  $u_c$  values required to cause bearing capacity failure of the wall foundation is in the  $0.01H$  to  $0.09H$  range, corresponding to toe displacement of  $0.01B$  to  $0.065B$ . Hence, the foundation is expected to fail before full development of the residual active earth pressure state.

Figure 4. Variation of normalized lateral earth pressure coefficient with wall crest displacement from analyses with medium dense Toyoura sand ( $D_R=60\%$ ).

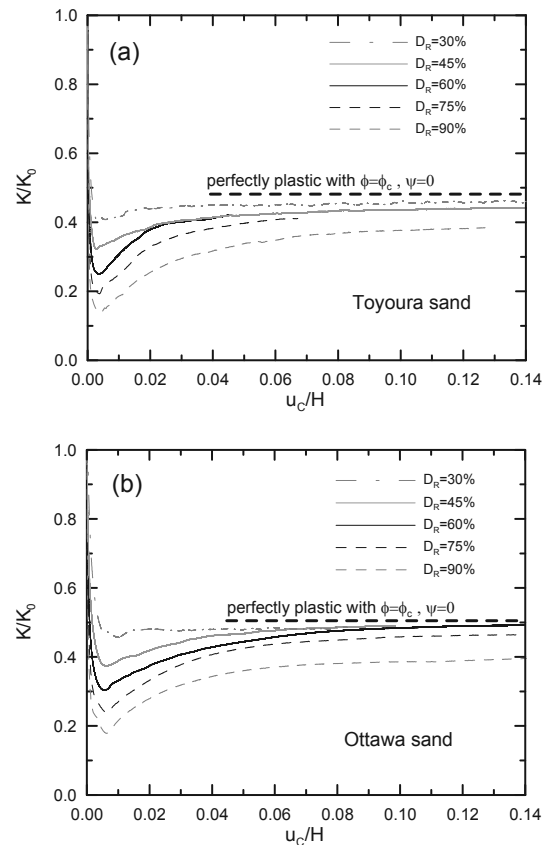

Figure 5. Variation of normalized lateral earth pressure coefficient with wall crest displacement from analyses of a wall with  $H=7m$ ,  $B=1.5m$  and  $D=0.5m$ .

### 3.3 Mobilized resistance along the wall-soil interface

The mobilized friction coefficient  $\mu$  ( $=\tan\delta$ ) on the wall backface reaches a peak value at very early stages of the analyses, before the attainment of the MPS. After the peak,  $\delta$  decreases quickly towards a residual value  $\delta_c$  that is consistent with development of critical state inside the thin shear band that runs parallel to the wall backface. Despite this, it can be seen that the mobilized friction angle  $\delta_{mob}$  at MPS ranges from 1.0 to 1.25 times the  $\delta_c$  (Fig. 6). The  $\delta_c$  values are  $30.8^\circ$  and  $29.6^\circ$  for Toyoura sand and Ottawa sand, respectively. These are consistent with the theoretical  $\delta_c$  values calculated as  $\arctan(\sin\phi_{c,ps})$ , where  $\phi_{c,ps}$  is the critical state friction angle for plane strain conditions. For Toyoura and Ottawa sands, this takes the values of  $36.6^\circ$  and  $34.6^\circ$ , respectively, which are

roughly 4° to 5° larger than the values corresponding to triaxial compression conditions  $\phi_{c, TX}$  (=31.6° and 30.2°, respectively).

Figure 6. Ratio of the  $\delta$  mobilized along the wall-soil interface at MPS to the  $\delta$  corresponding to critical state conditions.

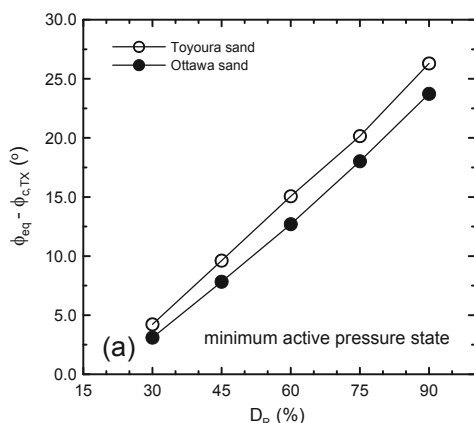

Figure 7. Equivalent value of the friction angle to be used in the calculation of  $K_{A,min}$ .

### 3.4 Expression for the estimation of $K_A$

The variation of the earth pressure coefficient  $K$  with crest displacement  $u_C$  observed in Figs. 4 and 5 can be described mathematically by the following equation:

$$K = \left[ \frac{\frac{(K_0 - K_{A,cr})}{(K_0 - K_{A,min})} u_{Cp} - 2u_C}{\frac{u_{Cp}}{(K_0 - K_{A,min})} + \frac{u_C^2}{(K_{A,cr} - K_{A,min}) u_{Cp}}} \right] + K_{A,cr} \quad (2)$$

where  $u_{Cp}$  is the crest displacement needed to reach MPS. Based on the previous discussion,  $u_{Cp}$  can be taken equal to  $0.005H$ .

The characteristic values of the active earth pressure coefficient,  $K_{A,min}$  and  $K_{A,cr}$ , can be calculated using the Coulomb's equation (Eq. 1) with suitable (equivalent) values  $\phi_{eq}$  for the mobilized friction angle inside the sliding wedge. In Fig. 7, we see that there is a linear dependence between  $\phi_{eq}$  for MPS and  $\phi_{c, TX}$ , which can be expressed by

$$\phi_{eq}^{(MPS)} = \phi_{c, TX} + \left( 35 \frac{D_R}{100\%} - 7^\circ \right) \quad (3)$$

We consider  $\phi_{c, TX}$  instead the more physically suitable  $\phi_{c, PS}$  because it is easier to estimate through empirical relationships, measurements of the angle of repose on a conical soil heap, or a few triaxial compression tests. On the other hand, to calculate  $K_{A,cr}$ , the friction angle can be estimated using

$$\phi_{eq}^{(cr)} = \phi_{c, TX} + \left( 9 \frac{D_R}{100\%} - 2^\circ \right) \quad (4)$$

For the calculation of both  $K_{A,min}$  and  $K_{A,cr}$  using Eq. (1), the wall-soil interface friction angle  $\delta$  can be conservatively set equal to  $\delta_c$  estimated as  $\arctan[\sin(\phi_{c, TX} + 4^\circ)]$ . Finally, it should be pointed out that, according to the numerical results, the point of application of the active earth thrust at MPS is at a distance roughly  $H/3$  from the wall base, while for the residual state is slightly smaller (roughly  $0.3H$ ).

## 4 CONCLUSIONS

This paper presented the results of a set of finite element analyses of a retaining wall supporting sand. Based on numerical results, the active earth pressure coefficient attains a minimum value  $K_{A,min}$  at wall crest displacements of the order of  $0.005H$ . Hence, from a practical standpoint, this state is of limited relevance to ultimate limit state (ULS) design; it is possibly representative of a serviceability limit state (SLS) design. A residual (maximum) value  $K_{A,cr}$  associated to full mobilization of critical state inside the soil mass is practically reached at crest displacements of the order of  $0.1H$ .

The  $K_A$  to be used in ULS calculations can be estimated using the proposed Eq. (2), provided that the designer knows *a priori* the wall crest displacement  $u_C$  corresponding to ULS. In case there is a structure founded on the supported soil, the  $u_C$  can be set equal to the allowable foundation displacement value compatible with the ULS for the structure, established according to design code provisions. In the opposite case, the  $u_C$  could be set equal to 7 times the horizontal base displacement required for wall foundation failure. In the case of granular foundation soils, this base displacement can be conservatively taken as 0.05 times the base width.

# Innovative solutions for supporting excavations in slopes

## Solutions innovantes pour le soutien d'excavations situées dans des terrains en pente

Lüftenegger R.

**ABSTRACT:** The design of support measures for deep excavations is one of the key tasks in geotechnical engineering. The choice of the most appropriate support system depends on various obvious factors such as ground conditions and excavation depth but sometimes also on less obvious boundary conditions, for example when construction of ground anchors is not possible because permission of placing them in neighbouring property is not given. In these cases other options have to be pursued, resulting sometimes in non-conventional solutions. Examples for such innovative support systems are presented in this paper. In the first case the arching effect of the retaining structure was used to design an excavation pit without any anchors reaching on the neighbouring ground, because there was no permission for construction elements there. The 6 meter spanned arches consist of mixed in place columns (MIP), which rest on supporting walls (also mixed in place columns) oriented in the direction of the slope. In the second example the behaviour of a serrated sheet pile has been investigated. Comprehensive 3D finite element analyses have been performed in order to prove that the suggested retaining structures are feasible solutions.

**RÉSUMÉ :** La conception des mesures de soutènement pour les excavations profondes est une des tâches fondamentales dans la géotechnique. Le choix du système le plus approprié dépend de plusieurs facteurs évidents comme les conditions de sol ou la profondeur de l'excavation, mais parfois aussi de contraintes moins évidentes comme par exemple le cas où des ancrages ne sont pas possibles parce qu'il n'y a pas d'autorisation pour l'installation dans la propriété voisine. Dans ces cas, d'autres options doivent être envisagées, qui résultent parfois dans des solutions non-conventionnelles. Quelques exemples de telles solutions sont présentés. Dans le premier cas, l'effet de voûte de la structure de soutènement a été utilisé pour la conception d'une excavation qui bordait une propriété pour laquelle il n'y avait pas d'autorisation pour l'installation des éléments d'ancrage. Les voûtes avec une portée de 6 mètres ont été réalisées avec des colonnes « Mixed in Place » (MIP) qui prenaient appui sur des parois orientées dans la direction de la pente. Dans le deuxième exemple, le comportement d'une palplanche dentelée a été examiné. Des analyses par la méthode des éléments finis 3D complètes ont été effectuées afin de prouver que la structure de soutien proposée était une solution réalisable.

**KEYWORDS:** deep excavation, finite element method, three-dimensional analysis.

## 1 INTRODUCTION

The design of support measures for deep excavations is one of the key tasks in geotechnical engineering and, depending on soil conditions and adjacent infrastructure, many different options exist. One of the most difficult situations to overcome is when space for support measures is limited and due to legal reasons support elements such as ground anchors cannot be built on neighbouring ground. The obvious solution in these cases, namely putting struts, is often not very convenient for the excavation process and sometimes even not possible, e.g. if the excavation is situated in a slope. These cases require special attention and two case histories where innovative solutions have been found are presented in this paper.

## 2 NUMERICAL ANALYSIS

In order to demonstrate the feasibility of the proposed design and to assess expected deformations a number of three-dimensional finite element analyses have been carried out. These analyses also served as basis for the design of the structural elements. The finite element code Plaxis 3D Foundation has been used for all analyses presented in this paper (Brinkgreve and Swolfs 2007).

It is well established that for this type of analysis simple linear elastic-perfectly plastic constitutive models are not very well suited and therefore a more advanced model, namely the

Hardening Soil model, has been employed. This model is a so-called double hardening model and allows for plastic compaction (cap hardening) as well as plastic shearing due to deviatoric loading (friction hardening). The main features of this model, as implemented in Plaxis, can be summarized as following.

- Stress dependent stiffness according to a power law.
- Plastic straining due to primary deviatoric loading.
- Plastic straining due to primary compression.
- Elastic unloading / reloading.
- Failure according to the Mohr-Coulomb criterion.

A more detailed description of the Hardening Soil model can be found e.g. in Schanz et al. 1999.

## 3 CASE HISTORY 1 – MIXED IN PLACE COLUMNS

The first example is concerned with an excavation situated in a slope, just below existing buildings. The owner of one of the buildings was particularly alerted because he experienced significant damage to his building in the past due to nearby construction activities. He did not allow ground anchors to reach his property. Thus the task was to stabilize the excavation without ground anchors and at the same time provide sufficient support to keep deformations, which could lead to damage of the building located above the excavation, to an absolute minimum. This could be achieved by arches of 6 meter span

constructed by mixed in place columns (MIP), which rest on supporting walls (also mixed in place columns) oriented in the direction of the slope. The earth pressure exerted from the slope was transferred to 5 meter deep mixed in place walls underneath the planned building at the base of the slope. Figure 1 shows the slope with the supporting structure and Figure 2 a detail of the MIP columns.

Figure 1. Overview of slope and support structure including critical building.

Figure 2. Layout of support structure (MIP columns).

Based on the results from site investigations a representative underground model consisting of three layers was established for the 3D finite element analysis, namely soft sandy silt (0-4 m below surface), stiff laminated sand-silt (4-8 m below surface) and semi-solid sand-silt (below 8 m from surface). The most important parameters for these layers are summarized in Table 1.  $E_{oed}^{ref}$  is the stiffness from an oedometer test for the reference vertical effective stress of 100 kPa,  $E_{50}^{ref}$  is a secant stiffness at 50% of maximum deviatoric stress in a triaxial compression test at a reference cell pressure  $\sigma_3' = 100$  kPa,  $E_{ur}^{ref}$  is the unloading/reloading stiffness, again at a reference cell pressure of 100 kPa from a triaxial test, and  $m$  is a parameter determining the stress dependency of above stiffness parameters.  $\phi'$ ,  $c'$  and  $\psi$  are the conventional Mohr-Coulomb strength parameters which define ultimate strength in the Hardening Soil model.

The MIP-method improves the mechanical properties of a soil by mechanically mixing and adding binder slurry. The result is a "soil-concrete-mixture" in which the soil is used as aggregate. For the MIP-columns a constitutive model based on the Mohr-Coulomb failure criterion was applied. Based on an unconfined compressive strength of 5 MN/m<sup>2</sup>, whereas this value includes a partial factor of safety on material strength, the material parameters listed in Table 2 have been adopted.

Table 1. Material parameters for Hardening Soil model for soil layers.

Parameter	Layer 1	Layer 2	Layer 3
Friction angle, $\phi'$ (°)	25	27.5	30
Cohesion, $c'$ (kPa)	0	1	5
Dilatancy angle, $\psi$ (°)	0	0	0
Unit weight, $\gamma$ (kN/m <sup>3</sup> )	20	20.5	21
$E_{oed}^{ref} = E_{50}^{ref}$ (kPa)	10000	25000	45000
$E_{ur}^{ref}$ (kPa)	30000	75000	135000
$m$ (-)	0.5	0.5	0.5

Table 2. Material parameters for MIP-columns.

Parameter	MIP

Cohesion, $c'$ (kPa)	250
Unit weight, $\gamma$ (kN/m <sup>3</sup> )	22
Elasticity modulus (kPa)	300000
Tension cut off* $\sigma_t$ (kPa)	125

\* based on reinforcement by steel rods and nails

The results of the calculation show the expected stiff behaviour of the chosen support system. The maximum calculated horizontal deformation of about 15 mm occurs at the front upper corner of the lower excavation step (Figure 3). At the back of the wall (near the border of the neighbouring property) deformations are in the order of millimetres and thus the expected settlements in this area can be considered to be not significant and will not cause any damage to the building (Figure 4). However, the finite element analysis could not model the construction process of the MIP-columns, i.e. the columns were assumed "wished-in-place" before excavation starts and therefore displacements due to the construction process have to be added to these values.

The 3D-model was also used to check the tension zones in the MIP-body. The main tension stresses were located at the connections of the arches and the wall elements. In this area the MIP-wall was reinforced with steel beams (HE-B profiles).

Figure 3. Calculated horizontal displacements, cross section

The measurements during construction on one hand confirmed the results for the numerical analysis but on the other hand showed that significant deformations occurred during construction of the MIP-columns itself (Figure 5). After construction of the columns (panels) deformation measured were less than 15 mm, comparing well with the finite element

predictions. Figure 5 shows the deformations of different points on the top of the MIP-wall. At the neighbouring buildings no movements were recorded. Figure 6 presents a view of excavated MIP-walls.

Figure 4. Calculated horizontal displacements with critical building

Figure 5. Measured horizontal displacements at several points at the top of the MIP-wall

Figure 6. View of excavated MIP-walls

The large deformations during the production of the columns had two main reasons. In the first part of the production too many MIP columns were produced within a small area. The MIP columns, which take some time to gain strength, weakened the slope during construction, which was already close to critical state. Furthermore, to reduce the length of the MIP columns (in order to save money), deeper working planes than planned were excavated.

This presented case study clearly shows that it is possible to support the earth pressure exerted from a slope by arches constructed by means of soil improvement techniques without

any anchors reaching on neighbouring ground. The numerical analysis was able to prove that the design concept is feasible, however, it is important to observe the deformation during the construction stages because not all aspects of the construction process, in this case of the MIP-columns, can be taken into account in the numerical model.

#### 4 EXAMPLE 2 - SERRATED SHEET PILE WALL

The second example is concerned with the same problem, namely limited space for support measures, but this time it is in an urban environment, namely in the city of Salzburg, Austria. Again the excavation was very close to the adjacent property and it was not allowed to put any construction elements, such as ground anchors, there. In this case the solution chosen was a serrated sheet pile wall. Generally, the subsoil conditions in Salzburg consist of a top layer with backfill and gravel, and soft silty sand and clayey silt layers underneath. The layout of the sheet pile wall follows from Figure 7 (3D finite element model). Every 6 to 8 m there is a 3 m deep indentation in the sheet pile wall. The construction of diagonal compression and tension bars at the top transfers the earth pressure to the right-angled parts of the sheet pile walls. A steel construction, similar to a whaler beam, on top prevents non-homogeneous deformations of the wall. After excavation a drainage layer and a concrete slab is installed to prevent long term movements of the wall and to reduce the influence of the soft layers below excavation level.

Figure 7. 3D finite element model

The key material parameters for the soil layers considered in the analysis are listed in Table 3. Again the Hardening Soil model has been employed.

Table 3. Material parameters for Hardening Soil model for soil layers.

Parameter	<i>backfill</i>	<i>silty sand</i>	<i>clayey silt</i>
Friction angle, $\varphi'$ (°)	35	27.5	25
Cohesion, $c'$ (kPa)	0,1	3	5
Dilatancy angle, $\psi$ (°)	0	0	0
Unit weight, (kN/m <sup>3</sup> )	19/21	20/21	18/20
$E_{oed}^{ref} = E_{50}^{ref}$ (kPa)	52000	30000	15000
$E_{ur}^{ref}$ (kPa)	208000	120000	60000
$m$ (-)	0	0.5	0.5

The 3D model showed that deformations can be kept to a minimum with maximum values below 10 mm (Figure 8), which was also confirmed by observations during construction. Deformations due to driving and removing of the sheet pile wall are not considered in the analysis. Experience has shown that in this type of soils settlements can reach 20 to 30 mm, and in this particular case observed values were within the lower range.

Figure 8. Calculated horizontal displacements

The bending moments of a sheet pile wall with this particular shape and the strengthening construction on top of the wall is not the same as for a cantilever wall, which one would obtain from a 2D analysis and therefore the 3D analysis was essential and helped to estimate the influence of the special support measures. However, 3D finite element analyses are quite time consuming if many different scenarios have to be investigated.

Figure 9. Comparison of 2D and 3D analysis of wall deformation and bending moments

An attempt was therefore made to develop an equivalent 2D analysis for performing parametric studies for a preliminary design. For that reason a 2D model of the sheet pile wall with a supporting force on top of the wall was created. It turned out that for the case of a 8 m deep sheet pile wall and a 4 m deep excavation (groundwater is also at 4 m depth) a supporting force between 15 kN/m und 20 kN/m lead to similar wall deformations und bending moments (Figure 9). This supporting force has to be carried from the additional wall elements spanning across the edges of the two lines of the serrated sheet pile wall (see also Figure 8). The calculations revealed that the earth pressure distribution of the rectangular part of the serrated sheet pile wall is between the active and the at-rest earth pressure (see Figure 10).

Figure 10. Earth pressure distribution on active and passive side

For the given geometry (distance of 8 m between the rectangular walls) this earth pressure distribution leads to a maximum resistance by wall friction of about 20 kN/m. This shows a good correlation with the presented calculations.

## 5 CONCLUSIONS

3D finite element modelling allows complex geotechnical structures to be analysed. In the two presented case histories the calculations helped to estimate the arching effect of a curved retaining structure in order to design an excavation pit without any anchors reaching on the neighbouring ground. In the second example the behaviour of a serrated sheet pile has been investigated. In both case the numerical analyses proved the feasibility of the chosen design and improved the understanding how these complex structures behave.

However, even with 3D models it is usually not possible to include all excavation stages in great detail and, more importantly, installation effects are beyond the capabilities of standard numerical tools and this has to be kept in mind when assessing numerical results. Therefore it is essential to monitor the behaviour of the structure during construction and have appropriate counter measures in mind when deformations due to installation effects or unforeseen ground conditions reach critical limits.

# Design and Construction of Inclined-Braceless Excavation Support Applicable to Deep Excavation

## Dimensionnement et Construction du Support d'Excavation Incliné Sans Butons Applicable à une Excavation Profonde

Maeda T., Shimada Y., Takahashi S., Sakahira Y.  
*Obayashi Corporation*

**ABSTRACT:** The inclined-braceless excavation support (IBES) construction method is characterized by allowing the reduction of retaining wall rigidity and omission of shoring because it reduces the earth pressure acting on the wall, compared with construction using vertical retaining walls. Thus, there are cases where inclined retaining walls are more beneficial in terms of workability and economy than vertical retaining walls, depending on the excavation depth or ground conditions. For the inclined-braceless excavation support construction method applied at open-cut (excavation depth of 9.6m) construction site, this paper presents results of centrifugal model experiments that reflected the actual excavation cross section, the design of the retaining walls in consideration of the inclination of the wall, applied construction method, and measurement results at the site.

**RÉSUMÉ:** On peut s'attendre à ce qu'une paroi de soutènement inclinée subisse une pression du sol moindre qu'une paroi verticale classique. Le Support d'Excavation Incliné Sans Butons (SEISB) pourrait donc offrir des avantages: un besoin de rigidité réduit et la disparation des étrépillons ou des ancrages. Selon la profondeur d'excavation et les conditions de sol, il peut aussi être plus efficace qu'un système vertical en termes de coût et de durée des travaux. Le présent document rapporte le cas d'un chantier où la méthode SEISB a été utilisée pour une excavation de 9,6m de profondeur: test en centrifugeuse sur un modèle de la coupe d'excavation du chantier, dimensionnement prenant en compte la pression du sol sur un support incliné, méthode de construction adaptée et réalisation des travaux.

**KEYWORDS:** Inclined-braceless excavation support, steel sheet pile, centrifuge model experiment, earth pressure

### 1 INTRODUCTION

According to earth pressure theory, the earth pressure acting on temporary earth retaining walls set up during excavation work is reduced when the earth retaining wall is reclined. However, earth retaining walls are generally installed vertically in consideration of workability and construction site limitations, and no earth retaining walls which utilized effect of reduced earth pressure for inclined retaining wall were implemented. Furthermore, deep excavation work requires shoring such as bracing or ground anchors for vertical earth retaining walls with high rigidity (Figure 1).

The inclined-braceless excavation support (IBES) construction method is characterized by allowing the reduction of wall rigidity and omission of shoring because it reduces the earth pressure acting on the wall, compared with construction using vertical retaining walls (Figure 2). Thus, there are cases where inclined retaining walls are more beneficial in terms of workability and economy than vertical retaining walls, depending on the excavation depth or ground conditions.

The authors have previously conducted centrifugal model experiments on inclined-braceless retaining walls using sand ground to examine earth pressure distributions and deformation behavior (Shimada et al. 2010, 2011) and quantitatively confirmed that the earth pressure acting on the retaining walls and deformation arising from excavation can be reduced by inclining the retaining walls.

This paper reports on centrifugal model experiments that reflected the excavation cross section at an actual scale construction site for the inclined-braceless retaining wall construction method to determine its suitability, the design of inclined-braceless retaining walls using reduced earth pressure by inclination of the wall, applied construction method, and measurement results at the site.

Figure 2. Inclined-braceless retaining wall

### 2 SUMMARY AND ISSUES OF CONSTRUCTION METHOD FOR INCLINED-BRACELESS RETAINING WALL

Cantilever retaining walls have been widely adopted to retain earth at relatively shallow excavation depths (3–4 m). Inclined-braceless retaining walls are an attempt to switch from the conventional concept of vertical retaining walls in order to reduce earth pressure and make it possible to apply cantilever retaining walls even at deeper excavation depths.

There are no application examples of temporary inclined retaining walls; design issues for the inclined-braceless retaining wall construction method include calculation of the earth pressure while considering the inclination of the retaining wall, and consideration of rollover not only to the excavation side but also to the back side in calculation of embedding of walls. Construction issues include the accuracy of the inclination angle set during retaining wall installation and the construction work cycle time. Centrifuge model experiments conducted to examine these design issues, the applied design

methods, and actual performance at construction sites where the design methods were implemented are described below.

### 3 CENTRIFUGE MODEL EXPERIMENT OF INCLINED-BRACELESS RETAINING WALL

#### 3.1 Experiment method

A 1/33-scale model ground was prepared to develop excavation cross sections of applicable construction sites (Figure 3) for this experiment. A maximum centrifugal acceleration of 33g was loaded to examine deformation of the retaining wall and distribution of the earth pressure. Figure 4 shows an outline of the model ground. The dimensions of the soil container were 80 cm width × 50 cm height × 20 cm depth. The front side of the container was fabricated from an acrylic plate so that ground displacements could be measured. A Teflon sheet was attached between the soil container, including the acrylic plate, and the model ground to reduce friction. The depth of the model ground was developed with berm to a maximum of 29 cm, and the height of the retaining wall was 36 cm. The model ground is shown in Photo 1. The retaining wall was created assuming that the retaining walls would be made of steel sheet piles. A compact earth pressure gauge (6 mm dia., capacity of 1 MN/m<sup>2</sup>) was embedded at seven locations on the active side and at four locations on the passive side to measure the earth pressure acting on the wall surface. The retaining wall model was installed and then filled with dry Toyoura standard sand by the airdrop method to prepare the model ground. Excavation steps were simulated during the experiment by repeating the method of loading centrifugal acceleration after the prescribed excavation work was performed at a 1g site. Table 1 shows the experimental cases.

Figure 3. Cross-section of inclined-braceless retaining wall applied at site

Figure 4. Outline of model ground.

Photo 1. Model ground

Table 1: Experiment Cases

No.	Case 1	Case 2
Retaining wall conditions	Vertical	Inclined (inclination of 10 degree)

Ground	Material: Toyoura standard sand (dry) Density: $\rho_d = 1.55 \text{ g/cm}^3$ Preparation method: Airdrop method	
Excavation steps	Step 0: Before excavation Step 1: Excavation depth of 3.3 m Step 2: Excavation depth of 5.3 m Step 3: Excavation depth of 9.6 m	

#### 3.2 Experiment results

Figures 5 and 6 show the deformation behavior of the retaining wall due to excavation work. The displacements shown below were converted to actual-scale displacements by multiplying the experimental measurement results by 33. Figure 5 shows the displacement distribution of the retaining wall for each excavation stage. The horizontal displacement was larger at higher sections of the wall, and deformation occurred in the frontal incline with the lower section of the wall as the axis. Regardless of the excavation depth, the amount of horizontal displacement of the inclined walls was smaller than that of the vertically installed walls. Figure 6 shows the relationship between the excavation depth and horizontal displacement at top of the wall. The deformation increased in correlation to the depth; the displacement of the vertically installed wall was measured at the maximum excavation depth as 20 cm, whereas that of the inclined wall was about 14 cm. Thus, the experimental results confirmed that the amount of deformation was about 30% smaller with inclined walls.

Strain gauges were attached to the front and back surfaces of the wall in the direction of the depth at three locations in order to obtain the bending status of the wall. Figure 7 shows the depth distribution of the bending strain: the maximum value was obtained in the vicinity of the center of the wall regardless of whether the wall was inclined. The maximum bending strain was smaller with inclined walls than with vertically installed walls regardless of the excavation depth. The gap between the two was larger when the excavation depth was 9.6 m than when it was 3.3 m; the effects of inclining the wall were significant and evident.

Figure 5. Horizontal displacement distribution of retaining walls

Figure 6. Relationship between excavation depth and horizontal displacement of retaining walls

Figure 7. Bending strain distribution of retaining

Figure 8. Earth pressure acting on wall surfaces - vertical retaining walls

Figure 9. Earth pressure acting on wall surfaces - inclined retaining walls

Figures 8 and 9 show the depth distribution of the active earth pressure that acted on the wall. Although the measurement results for the vertically installed wall showed dispersions prior to excavation, the validity of the earth pressure measurements taken by this equipment were confirmed because they were approximately equal to the earth pressure at rest assuming  $K_0 = 0.5$ , as noted in the figure. The earth pressure decreased in the excavated sections and increased more than the earth pressure at rest in the embedded sections. The figure shows the Coulomb's earth pressure, where the friction angle of the retaining wall was considered to be  $\phi/3$ . The active earth pressure measured at the excavated sections was slightly smaller in distribution than the Coulomb's earth pressure. The earth pressure acting on the inclined wall decreased more than the earth pressure at rest regardless of depth. Thus, the acting pressure was smaller than that of the vertically installed wall, which confirmed that inclination of the wall contributed to the stability of the wall in terms of earth pressure as well.

## 4 DESIGN OF INCLINED-BRACELESS RETAINING WALL

### 4.1 Calculation method for earth pressure

Ground of the site (Figure 3) was a landfill comprised primarily of loose fine sand (layer thickness: 12 m, N-value: 3–5, and  $\phi$ :  $33^\circ$ ). The inclination of the retaining wall could not be considered in the conventional design of the temporary retaining walls, because the Rankine–Resal formula is generally applied to the active earth pressure used. The earth pressure calculation method with Coulomb's formula (Figure 10) used in the design of permanent retaining walls, which considers the inclination of the wall, was therefore applied. Its use was determined safe for design purposes because the earth pressure reduction effect was confirmed in the centrifugal model

experiments with inclined walls. Similarly, the Coulomb's earth pressure was adopted for the passive earth pressure.

Figure 10. Active earth pressure calculation

### 4.2 Calculation method for embedding lengths

The embedding length was calculated using not only the “method for determining embedding length to maintain balance based on earth pressure” but also the “overall slippage including the retaining wall.” The circular slipping calculation (Figure 11) was performed to determine the embedding length so that both of the above methods were satisfied. The safety factor for the arc slipping calculation was set to 1.2.

### 4.3 Calculation of retaining wall displacements and stresses

The displacements and stresses that occurred with the retaining wall were calculated based on elasto-plasticity analysis, which evaluated the earth pressure and wall embedding length given in subsections 4.1 and 4.2 above, by considering the retaining wall as a finite length elastic beam and ground as an elasto-plastic spring (figure 12).

Figure 11. Verification on slipping stability

Figure 12. Elasto-plastic analysis

## 5 CONSTRUCTION WORK IMPLEMENTATION RECORD FOR INCLINED-BRACELESS RETAINING WALLS

### 5.1 Summary of applied construction sites

The construction sites where the inclined-braceless retaining walls were applied were located within premises used by existing electric power plant and new plant construction. Excavation work had to be performed to install two sets of water intake and water discharge steel pipes (each pipe with a diameter of 2800 mm) in a restricted construction work zone with a width of 30 m (Figures 3 and 13). The period of construction work, which included piping work, needed to be less than six months owing to adjustments that had to be made to accommodate the progress of the main unit construction work being performed at new electric power plant.

In order to satisfy the above conditions, the inclined-braceless excavation retaining wall construction method which reduces earth pressure by inclining the wall, was adopted as it requires no shoring, even when the excavation depth is deep. The retaining wall was fabricated from steel sheet pile type SP-IV, and the inclination of the retaining wall was set to 10 degree owing to restrictions imposed within the construction work zone and the excavation cross section necessary for piping work.

Figure 13. Construction work zone plan

5.2 Inclined-braceless retaining wall construction method

The steel sheet piles driven in at an inclination angle were installed in a manner similar to ordinary vertical installation: a silent piler was used combined with a water jet to reduce the insertion resistance. Because the piler was tilted according to the inclination of the piles being installed, an auxiliary cylinder was installed on the piler main unit to control the angle (Photo 2 and 3). The initial insertion until the piler was set on the piles used a blocking base (110 kN), similar to ordinary vertical installation. The top plate of the blocking base was inclined by 10 degree to accommodate the inclined installation of the piles (Photo 4). The inclination angle was monitored by infrared laser units installed at two locations aside from inclined finishing stake.

5.3 Comparison of onsite measurement results and design values

5.3.1 Earth pressure

The distribution of actual measurements for the earth pressure, which was taken by wall-surface-mounted earth pressure gauges at the time of the final excavation, indicated 20%–50% of the design values on the back side (active side) and 5% of the ultimate value on the excavation side (passive side) (figure 14). The setting method for coefficient of earth pressure (applying the Coulomb’s formula) was considered to be valid because the gradient (equivalent to the earth pressure coefficient) up to GL-3m was roughly equal for the active earth pressure distribution. With regard to the passive earth pressure, the displacement of the retaining wall was small and the ground had a sufficient margin for resistance on the passive side.

5.3.2 Displacements and stresses of steel sheet piles

The maximum displacement during final excavation was 24.1mm, which was about 20% of the design value of 119.2mm (Figure 15). The maximum stress level of the steel sheet piles according to strain gauges was a tensile stress of 8.4N/mm<sup>2</sup>, which is extremely small and about 8% of the design value of 103N/mm<sup>2</sup>. Furthermore, the bending moment distribution obtained by converting the measurement data from the inclinometers was roughly the same as the bending moment distribution obtained from strain gauges.

6 CONCLUSIONS

For the inclined-braceless retaining walls (inclination of 10 degree) with an excavation depth of 9.6 m in sand ground, the effects of earth pressure reduction and stability of retaining wall were verified by a centrifugal model experiment. A design method was developed that considers inclination of the wall by using the Coulomb’s formula in elasto-plastic analysis so that inclined-braceless retaining walls can be adopted at actual construction sites. The actual measurement values taken onsite for the earth pressure acting on the retaining wall and the displacement and stress of the retaining wall both agreed with the design values. Thus, the safety of the retaining wall can be secured using the proposed design method. The inclined retaining wall construction method was used to realize a cantilever retaining wall without shoring despite a deep excavation depth of 9.6 m. Thus, excavation, piping, and building work can be completed in a short term and safely.

We will collect design and construction work track records for the inclined retaining walls under a variety of ground conditions for verification of evaluation methods for analysis models, soil parameters, and earth pressure, and cycle time of construction work, in order to establish more practical design and construction methods.

# Shaking table tests on caisson-type quay wall with stabilized mound

## Essais à table vibrante sur les murs de quai de type caisson avec butte stabilisée

Mizutani T.

*Geotechnical Engineering Field, Port and Airport Research Institute*

Kikuchi Y.

*Professor, Department of Civil Engineering, Tokyo University of Science*

**ABSTRACT:** Caisson-type quay walls were one of the major types of quay walls in Japan. It was desired to increase the front-water depth of them, because vessels coming alongside them become larger and larger. The authors have been studying on a new construction method for the improvement. The method consisted of two steps. Step 1 was to solidify a part of rubble mound beneath a caisson and step 2 was to cut it to increase the front-water depth of the caisson. A series of shaking table tests were conducted to study the seismic behavior of caisson-type quay walls improved by the new method. This paper will introduce the test results and discuss the factors which affected the seismic behavior of the caisson-type quay walls with stabilized mound.

**RÉSUMÉ :** Les murs de quai de type caisson constituent l'un des types majeurs de murs de quai au Japon. On a désiré augmenter la profondeur frontale face à la mer car les navires venant accoster le long des quais deviennent de plus en plus gros. Les auteurs ont étudié une nouvelle méthode de construction afin d'apporter des améliorations. Cette méthode est constituée de 2 étapes. La 1ère étape consiste à solidifier une partie de la butte de gravats sous le caisson et la 2ème étape à le découper afin d'augmenter la profondeur frontale du caisson. Une série d'essais à table vibrante a été menée afin d'étudier le comportement sismique des murs de quai de type caisson qui ont été améliorés grâce à cette nouvelle méthode. Cette étude présente les résultats des essais et analyse les facteurs qui affectent le comportement sismique des murs de quai de type caisson avec butte stabilisée.

**KEYWORDS:** caisson-type quay wall, front-water-depth enlargement, shaking table test

## 1. INTRODUCTION

In recent years, there has been increasing demand to reduce costs for public works in Japan. Correspondingly, great efforts have been directed toward using and upgrading existing infrastructures efficiently. In this context, the authors have been studying methods for enhancement and improvement of existing port facilities.

Because the caisson-type quay wall (see Figure 1) is one of the major types used in Japan (OCDI 2009), it is desirable that this type quay wall have more front-water depth to better accommodate the larger and larger vessels coming alongside. A method often employed for this improvement is to construct a new pier front onto the caisson quay wall as shown in Figure 2. It is impossible, however, to adopt this method for a caisson quay wall when there is not enough frontal space: thus, a new improvement method applicable to such situations is being developed. In the new method, a rubble mound beneath a caisson is solidified then cut to increase the front-water depth of the caisson as shown in Figure 3.

The authors conducted a series of shaking table tests to study the seismic behavior of caisson-type quay walls improved by the new method.

## 2. TEST METHOD

A model of a caisson quay wall was built in a sand box whose inside dimensions were 85cm in length, 35.4cm in width and 65cm in height. Figure 4 shows a schematic view of the model. The gravel layer at the bottom of the sand box was part of the box (for drainage). It was compacted sufficiently and it was assumed that the deformation of the gravel layer would not affect test results. A non-woven fabric was put on the surface of the gravel layer for sand prevention. The tests focused on the vibrational property and deformation mode of the quay walls

with a stabilized mound; the model ground was dry for simplicity.

Figure 1. Typical cross-section of the caisson-type quay wall.

Figure 2. Construction of a new pier to enlarge the front-water depth of the caisson-type quay wall.

Figure 3. The new method to enlarge the front-water depth of the caisson-type quay wall without change in the face line of the quay wall.

tilted; the data were not processed because the accuracy of the measurement of acceleration would be less.

For the test results with 100Gal (gray marks in figures), it could be said that the amplification was small and that there was no large difference among the tests. The amplitude of seaward acceleration was slightly larger than that landward.

In the case of the test with 300Gal (black marks in figures), the amplification tendency differed among the test cases. In the case of quay walls with Type 1 and Type 2 blocks, the acceleration amplitudes at the crown of the caisson were smaller than in the test without blocks both seaward and landward; the stability of the caisson was improved by the blocks. In the case of Type 3 blocks, the amplitude seaward was larger than in the test without blocks at the crown of the caisson, while the amplitude landward was smaller. It was remarkable that the amplitude at the head of the Type 3 block (a5) was much larger in both directions.

Figures 8 and 9 show the phase delay of the acceleration observed in the tests. The phase delay was calculated in the same way as acceleration amplitude. Figure 8 and 9 show that there was no large delay in the case of the tests with 100Gal. Large delay was detected in the landward acceleration observed in the tests with 300Gal acceleration as shown in Figure 9. In the tests with Type 1 and Type 2 blocks, the delay was the same as in the test without any blocks. On the other hand, delay of acceleration landward in the case of the test with Type 3 blocks was much larger than in the case without blocks.

One of the causes of the large acceleration amplitude and delay observed in the test with Type 3 blocks could be the instability of the blocks because the shape was vertically long.

Figure 8. Phase delay of acceleration seaward.

Figure 9. Phase delay of acceleration landward.

#### 4. DISPLACEMENT OF QUAY WALL

The trace of the top-left corner of the caisson in Figure 4 was calculated from displacement measured by d1-d3 for each case. Figure 10 shows the trace observed during the final step of

shaking. The maximum acceleration of the input wave for the final shaking was different among the tests as mentioned before. Tilt angle of the caissons was also calculated from the data of displacement meter; Figure 11 shows the tilt angle observed during the final step.

Figure 12 shows the deformation of the quay wall models observed after the tests. A few millimeters of settlement of the foundation ground were observed in all cases. Sand dropped into clearance gap between the rubble mound and the sand box; the boundary between the mound and the backfill ground was not clear. Figure 12 shows the boundary in outline.

In the case of the model without blocks, the caisson moved seaward with forward inclining as shown in Figures 11 and 12; the large deformation observed with the input wave whose maximum acceleration was 500Gal and the test was aborted (see Figure 12). The caisson in the test with Type 4 blocks showed similar behavior as in the test without blocks. Thus the improved quay wall with Type 4 blocks was comparable in seismic resistance to the quay wall before improvement in spite of the front-water-depth enlargement. Figure 11 shows the tilting of the caisson with Type 4 blocks smaller than the caisson without blocks. The caisson with Type 4 blocks was displaced with small rotation as shown in Figure 12. It could be said that even small blocks like Type 4 had a certain degree of effect on caisson stability.

Figure 10. Trace of the top-left corner of the caisson.

Figure 11. Relationship between tilt angle and lateral displacement of the caisson.

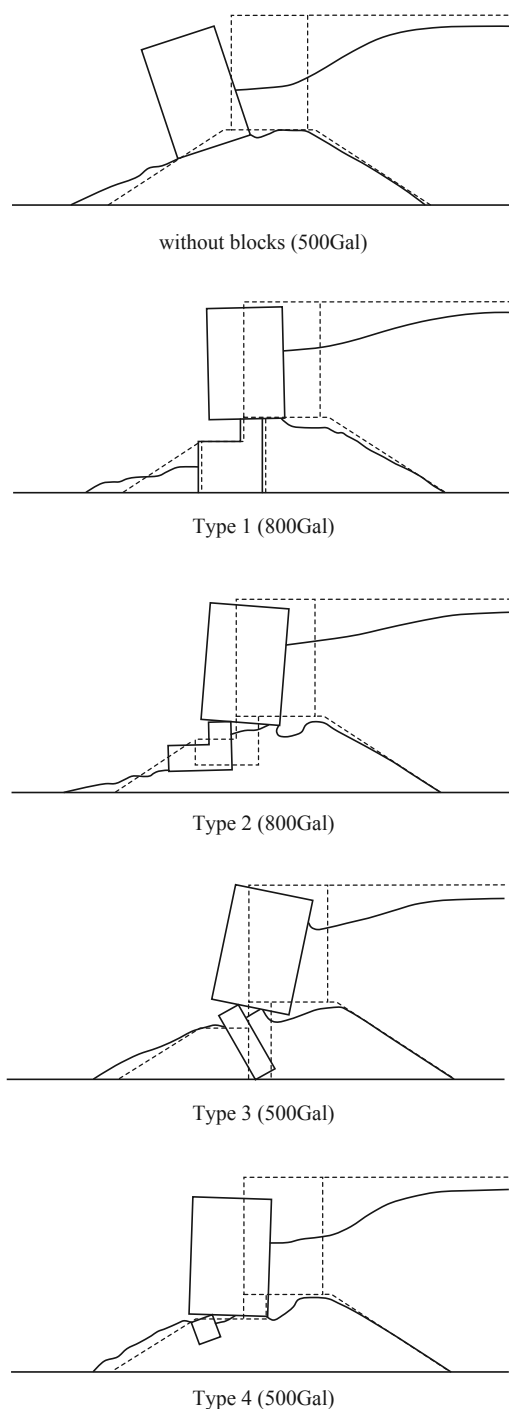

Figure 12. Deformation of the quay wall models after the tests.

Figure 13. Factors affected the behavior of the improved quay walls.

The caisson with Type 1 blocks had small backward inclining after 500Gal shaking as shown in Figure 11, and was displaced seaward over the block by 800Gal shaking (see Figure 10). After the tests, the tilt angle of the caisson returned to about zero degree. The caisson with Type 2 blocks had backward inclining after 500Gal, the same as the caisson with Type 1 blocks; however, during 800Gal shaking, the blocks moved seaward together with the caisson and the backward inclination of the caisson remained (see Figure 12).

In the case of the model with Type 3 blocks, the blocks leaned seaward, and the caisson had significantly large backward inclining after 500Gal shaking. One of the causes of this result could be the lack of stability of the blocks. The inherent stability of the blocks would be an important factor of the new improvement method.

Based on the final deformation shown in Figure 12 and the results of measurement mentioned above (especially from the observed displacement), it could be said that six factors affected the behavior of the improved quay wall: (1) collapse of foreside slope rubble mound, (2) dimensions of solidified area and ground condition beneath solidified area, (3) displacement of solidified area, (4) settlement of rubble mound and differential settlement between solidified area and rubble mound, (5) leaning of caisson, and (6) displacement of caisson. The numbers correspond to those indicated in Figure 13. These factors correlated strongly with each other, making it was difficult to clarify which was the dominant factor on the behavior of quay walls.

## 5. CONCLUSION

A series of shaking table tests were conducted to study the seismic behavior of caisson-type quay walls improved by the new method. It was derived from the results of the model tests that six factors affected the behavior of the caisson-type quay walls improved by the new method. Further study will be continued to evaluate the effect of each factor, and the design methodology of the new-type quay walls will be discussed base on the results.

## 6. ACKNOWLEDGEMENTS

This work was supported by the Kanto Regional Development Bureau, Ministry of Land, Infrastructure, Transport and Tourism in Japan, and was a part of cooperative research between the Port and Airport Research Institute and the Japan Dredging and Reclamation Engineering Association. The authors greatly appreciate their contribution.

# Inspection of structural health of existing railway retaining walls

Inspection de l'état structurel des murs de soutènement des voies de chemin de fer existantes

Nakajima S., Shinoda M., Abe K.

Railway Technical Research Institute, Japan

**ABSTRACT:** This study aims to develop an inspection method of a structural health of the existing retaining walls. This paper begins with the brief introduction of the current state of the existing retaining structures. Second, applicability of the percussion test for the evaluation of structural health of existing retaining wall is examined by conducting a large numbers of the percussion test on retaining walls at the site. It was found from the percussion test that structural health of the ashlar wall could be quantitatively evaluated by the percussion test while it was found to be difficult to apply the percussion test for the quantitative evaluation of the leaning type retaining wall. Third, applicability of the small scale vibrator, which was newly developed to improve the disadvantage of the percussion test as the inspection method of the retaining wall, was examined through the prototype scale model test on the existing leaning type retaining wall. It was found from the series of model test that the vibration tests were effective in evaluating the characteristics of dynamic properties of the retaining walls, which were affected by structural health of the retaining walls. This result indicated that the small scale vibration tests could be applicable to evaluate the structural health of the existing retaining structures.

**RÉSUMÉ :** Cette étude vise au développement d'une méthode d'inspection de l'état structurel des murs de soutènement existants. L'article commence par une brève présentation de l'état actuel des structures de soutènement existantes. Il se poursuit par l'exposition de l'analyse de l'applicabilité des essais aux chocs à l'évaluation de l'état structurel des murs de soutènement existants conduits sur des murs de soutènement sur le terrain. Ces essais aux chocs ont montré qu'ils permettaient une évaluation quantitative des murs de soutènement de type en béton mais qu'ils ne se prêtaient guère à l'évaluation des murs de soutènement de type incliné. Une troisième partie est consacrée à l'applicabilité d'un vibreur à faible échelle nouvellement mis au point qui permet de palier les inconvénients des essais aux chocs comme méthode d'inspection des murs de soutènement. Un appareil prototype a été utilisé pour l'inspection des murs de soutènement de type incliné. La série d'essais modèles conduite a mis en évidence que les essais aux vibrations permettaient de bien évaluer les caractéristiques des propriétés dynamiques des murs de soutènement affectés par leur état structurel. Les auteurs concluent que les essais aux vibrations à petite échelle peuvent être appliqués dans l'évaluation de l'état structurel des murs de soutènement existants.

## 1 BACKGROUND

In Japan, there are many old existing railway structures and it enhances the importance of the proper maintenance methodology. For the proper management of the railway structures, it is important to detect deformations of the structures in early stage. Once deformations are observed, continuous observations and retrofitting works are also important. As for the Japanese railway structures, it has already developed to evaluate a structural health of bridge piers quantitatively, which makes it possible to maintain structures efficiently. On the other hand, a visual inspection is still conducted to evaluate a structural health of the existing retaining walls because quantitative inspection method for the existing retaining wall has not yet developed. It is required to evaluate a structural health of the existing retaining walls quantitatively because a result of the visual inspection is highly dependent on the subjective judgment of an inspector.

Based on the background above, this study aims to develop an inspection method for the condition rating of the existing retaining walls.

## 2 CURRENT STATE OF THE RAILWAY RETAINING STRUCTURE

### 2.1 Maintenance standards in Japan

There are approximately 30 thousand kilometers of the railway lines in Japan, which are operated by many railway organizations (seven Japan Railway companies, over 100 private railway companies and several local governments).

Japanese railway organizations maintain their structures safety conditions by referring to the Japanese maintenance code of Maintenance Standards in Japan (RTRI, 2007). General procedure for structural maintenance in the Management standards and relationships between the soundness and the structure state are shown in Figure 1 and Table 1.

As indicated in Figure 1, "General Inspection" is conducted to all of the railway structures within the intervals of two years mainly by visual inspection. On the other hand, "Individual

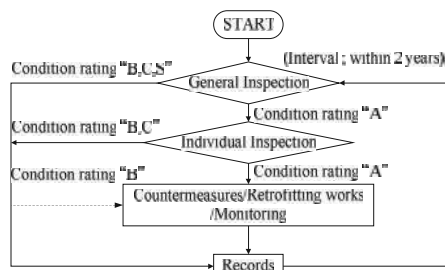

Figure 1. Maintenance procedure according to the Maintenance standards in Japan

Table 1. Relationships between rated condition and structure state

Condition rating	Structure state
A	State that threatens operational safety, safety of passengers, public safety, guarantee of regular train operation, or deterioration that might cause this state
B	Deterioration that might result in a future soundness rank of A
C	Slight deterioration
S	Good condition

Inspection” is performed to the specific structures in which severe deterioration are detected at the time of the General Inspection by means of detailed visual survey or using measuring equipments. As discussed in BACKGROUND, this study aims to develop a methodology which can be used for the condition rating of the retaining walls quantitatively as an alternative method of detailed visual survey.

### 2.2 Survey on current state of Japanese railway retaining walls

A preliminary survey on current state of Japanese railway retaining structures was conducted. In the preliminary survey, information of typical types of retaining walls in Japan was extracted from the database of the “Structural Management Supporting system (SMS)” (Oyado et al. 2010). In total, the data of 7,989 sites could be extracted. Figure 2 shows the relationships between the type of retaining wall and construction length, which could be obtained using the efficient 1,657 sites data. Construction length of the leaning type retaining wall stands first among all the types of the retaining walls and it accounted for 38.3 % of the efficient data. The percentage of the masonry and ashlar block retaining wall reaches to 37.8 % as well. It was found from the above survey that the leaning type and masonry or ashlar block retaining wall occupies 76.1 % of the total construction length and it indicated the importance of the management of these structures.

### 2.3 Deformation of retaining walls

Deformation of the railway retaining structures can be divided into two groups; one is the deformation due to destabilization, the other one is the deformation due to deterioration. Typical deformation of the railway retaining structures is schematically illustrated in Figure 3.

Settlement, inclination, swelling, difference in level and difference at construction joint due to external thrusts can be categorized to the deformation due to the destabilization. Exfoliation of concrete, clogging of the drainage facilities is categorized to the deformation due to the deterioration. Cyclic load due to the train passing, increase of earth pressure due to the additional construction of the embankment, increase of dynamic earth pressure due to the earthquake, increase of water

Figure 2. Relationships between construction length and types of retaining wall

Figure 3. Typical deformation of retaining wall

pressure due to the change of the water level in backfill soil are thought to be the source of the external thrusts, which could cause the deformation due to the destabilization.

On the other hand, deterioration is thought to be caused by the cyclic change of the thermal or humid condition during the long period of its use. Deformation due to the destabilization could be secondary source of the deformation like backfill loosening, bearing capacity failure. Therefore, early detection and retrofitting work against the deformation due to the destabilization are highly important, while it has not yet been developed a methodology to detect such phenomenon by the nondestructive tests. Based on the discussion above, development of a nondestructive evaluation method of the existing retaining wall is attempted in this study.

## 3 APPLICATION OF PERCUSSION TEST FOR CONDITION RATING OF RETAINING STRUCTURES

### 3.1 Percussion test

In Japanese railway field works, nondestructive evaluation of the bridge substructure has been carried out by conducting a percussion test (Nishimura et al. 1989) . In the percussion test, the natural frequency of the bridge pier is measured with high accuracy and it is used for the evaluation of the structural health of the pier. This method was based on the knowledge that the natural frequency of the bridge substructure decreased with the damage of the structures and increased with the reinforcement.

Natural frequency of the bridge piers is evaluated by carrying out a spectrum analysis using measured free vibration, which is recorded by velocity sensors. Free vibration is induced by hitting the top of the piers using an iron ball. In practice, current performance of bridge pier can be evaluated by comparing the measured natural frequency with the one of immediately after the construction or the criterion of the potential natural frequency. Potential natural frequency is the experimentally-based proposed value by Railway Technical Research Institute so as to be used for the site where the natural frequency immediately after the construction was not recorded.

### 3.2 Site test results

A series of site test was carried out so as to examine the applicability of percussion test for the condition rating of retaining wall. In the series of site tests, leaning type and ashlar wall are highlighted because construction length of these types of retaining wall was much longer than the other types of walls. As summarized in Table 2, 52 site tests were carried out by selecting the deformed and sound retaining walls so as to investigate into the difference of the vibration characteristics of retaining wall. Percussion test was conducted by hitting the iron ball at the top of the retaining wall and vibration was measured by the velocity sensors attached at the top, middle and bottom of the retaining wall.

Figure 4 shows an example of test result obtained from test No. 3. Predominant frequency of 26.6 Hz could be evaluated based on the changes of phase angle, while the peak amplitude was not clearly observed. This behavior indicates that natural frequency based condition rating, which has been adopted in the condition rating of the bridge substructure, was difficult possibly because the mode of vibration of retaining walls are generally more complicated than the originally bridge substructures. As an alternative index for the condition rating of the retaining wall, the authors proposed the value of spectrum area  $S_a$ , which could be evaluated by integrating the Fourier's spectrum of the amplitude as schematically illustrated in Figure 4b), while frequency range of 3 to 40 Hz was selected in this study. Figures 5 and 6 show the relationships between results of condition rating based on visual inspection and the values of

spectrum area. In the cases of ashlars wall shown in Figure 5, the values of spectrum area Sa of retaining walls rated as “A(deformed)” were generally larger than the ones of retaining walls rated as “B(no deformation)”, which shows the validity of spectrum area for the condition rating of retaining walls.

In the cases of the leaning type retaining wall shown in Figure 6, a good correlation between the result of visually inspected condition rating and the values of spectrum area could not be found. In the sites No. 6, 20, 21 and 24, the values of spectrum area was much larger than the other sites although they were rated as “B (no deformation)”, which might imply that the progress of the deformation at the part in which is difficult to detect by visual inspection (e.g. subsoil, backfill, etc.). On the other hand, at the sites 27, 26, 25 and 3, the values of spectrum area were not necessarily larger than the other sites although they were categorized as “A(deformed)”.

Percussion test has some problems (Nakajima et al., 2012) ; 1) heavy weight of iron ball (safety, portability) , 2) scattering of impact force depending on inspectors (repeatability) and 3) attenuation of impact force especially in high frequency range(limited range of input frequency). In applying to the condition rating of retaining wall, second and third problems would make it difficult to rate the condition of the retaining wall properly especially in the case of the leaning type retaining wall. Therefore, the authors developed a small scale exciter (Shinoda et al., 2012), which could apply constant sweep sinusoidal excitation under mechanically manipulation, which could solve second and third problems. A prototype scale loading test on leaning type retaining wall model was conducted so as to examine the applicability of the newly developed small scale exciter.

#### 4 PROTOTYPE SCALE LOADING TEST

Cross section of constructed leaning type retaining wall with height of 4.3 m and width of 1.5 m is shown in Figure 7. In Figure 7, the outline of the developed small scale exciter is also summarized. Retaining wall was constructed on the stiff base layer while its backfill consisted of the cobbles, sand backfill with degree of compaction  $D_c$  of 90 % and densely compacted gravelly sand. In the loading test, the retaining wall was subjected to the cyclic loading and unloading processes by applying the vertical load at the surface of the backfill using the hydraulic jack while their amplitude were gradually increased as shown in Figure 8. Gravelly sand layer inclined 30 degrees

Figure 5. Relationships between condition rating by visual inspection and value of spectrum area (Ashlars wall)

Figure 6. Relationships between condition rating by visual inspection and value of spectrum area (Leaning type retaining wall)

from the horizontal direction so as to apply horizontal load to the retaining wall efficiently.

In the loading test, cyclic loading and unloading processes were applied to the leaning type retaining wall model (Case 1). A soil nailing reinforcement with diameter of 60 mm and length of 4000 mm was installed after horizontal displacement at the wall top exceeded 50 mm. As the second case (Case 2), the model wall reinforced with the top nailing was subjected same loading and unloading processes with Case 1. Lastly, the model wall with top and bottom nailing, which was installed after Case 2, was subjected to the same loading processes while the maximum amplitude of load was applied to the wall in the end

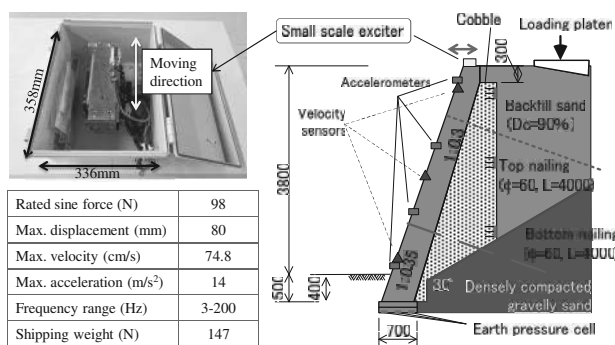

Figure 7. Cross section of model and outline of developed exciter (unit in mm)

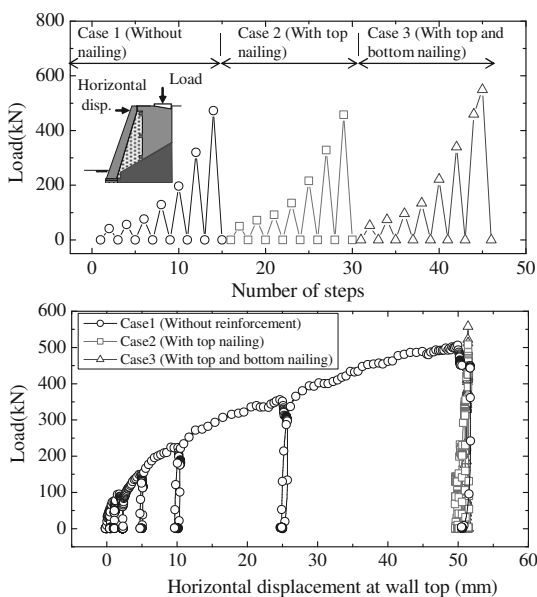

Figure 8. Loading process and load-displacement relationships

of loading process (Case 3). The loading and unloading processes in each case were summarized in Figure 8.

At every loading and unloading process, sets of percussion test with a set of velocity sensors and vibration tests using the developed small scale exciter with a set of accelerometers were conducted so as to investigate into the difference of vibration characteristics obtained from each test. Vibration test was conducted by applying the sinusoidal sweep excitation to the retaining wall model by the small scale exciter fixed at the top of the retaining wall, while the constant amplitude of 1000 gals with frequency range of 3 to 100 Hz and sweeping rate of 3 Hz/sec were adopted as the test condition.

Figure 8 also shows load-displacement relationships obtained from the loadcell installed at the hydraulic jack and displacement transducer at the top of the retaining wall. As clearly shown in Figure 8, the increment of the wall top displacement was drastically reduced by adding the soil nailing although the same amplitude of loading processes were applied to the wall. Displacement increment during a set of loading and unloading processes in Cases 1, 2 and 3 were 50mm, 1.0mm and 0.5 mm respectively.

Figure 9 shows relationships between the number of step and the results from the percussion test and vibration test, while the values of spectrum area of frequency range of 3 to 40 Hz were plotted in the vertical axes. It should be emphasized that the spectrum area evaluated from the percussion test results Sa[p] has the dimension of velocity (cm/sec) because it was evaluated from the integration of the relationships between the Fourier's amplitude of velocity (cm/sec\*sec) computed from records of the velocity sensor at the top of the wall and the frequency

Figure 9. Cross section of model (unit in mm)

(1/sec). On the other hand, the spectrum area calculated from the vibration testing Sa[v] did not have any dimensions because it was evaluated from the transfer function of the top accelerometer against the input acceleration.

It was found from Figure 9 that the values of Sa[p] and Sa[v] increased with the number of step. Moreover, the effect of the nailing could be also detected as the reduction of the values of Sa[p] and Sa[v] in Cases 2 and 3 as compared with Case 1. The difference between Sa[p] and Sa[v] could be found especially in loading and unloading process. The values of Sa[v] increased in the loading process and reduced in the unloading process, which indicated that the spectrum area Sa[v] based condition rating using the vibration testing with the small scale exciter could detect a minor change of the stability of the retaining wall. The value of Sa[p], however, could not detect a minor change during single loading and unloading process, which was possibly because the input force could not be kept constant. It was found from the results of the site tests and prototype scale loading test that the percussion test and the vibration testing could be applicable, while vibration testing could detect a minor change of the stability of the retaining wall.

## 5 SUMMARY

It was attempted in this study to develop a inspection method of the existing retaining wall. It was found from the preliminary survey on the current state of Japanese railway retaining wall that condition rating of the leaning and the ashlar wall are important because of their huge amount of existing structures. Based on the site test and prototype scale loading test, it was found that the percussion test and vibration test using the spectrum as an index could be applicable for the condition rating of existing retaining walls.

**ABSTRACT:** The objective of this study is to examine the mechanism of settlement induced by deep excavation through finite element analysis. The USC model was selected for this purpose through the calibration of different soil constitutive models. A series of parametric studies were then performed. It was found that in addition to the excavation depth, excavation width, the soft clay thickness and depth to the hard soil are also related to the settlement influence zone. A simple method derived from the basal heave failure mechanism is proposed to predict the settlement influence zone. One case history and one hypothetical excavation with the 80 m thick soft clay were used to verify the proposed method. For comparison, the existing empirical formulae were also used for prediction.

**RÉSUMÉ :** L'objectif de cette étude est d'examiner le mécanisme de tassement induit par une excavation profonde à travers l'analyse d'éléments finis. Le modèle USC a été choisi à cet effet par le calibrage de différents modèles de sol. Une série d'études paramétriques a ensuite été réalisée. Il a été constaté qu'en plus de la profondeur et de la largeur de l'excavation, l'épaisseur et la profondeur de l'argile molle sur le sol dur sont également liées à la zone d'influence du tassement. Une méthode simple dérivée du mécanisme de rupture par soulèvement basal est proposée pour prédire la zone d'influence du tassement. Une étude de cas et un travail d'excavation hypothétique de l'argile molle sur 80 m d'épaisseur ont été utilisés pour vérifier la méthode proposée. À titre de comparaison, les formules empiriques existantes ont également été utilisées pour la prédiction.

**KEYWORDS:** Deep Excavation, Soft Clay, Settlement, Constitutive Model, Settlement Mechanism

### 1 INTRODUCTION

The finite element method and empirical methods are often used to predict the ground settlement induced by deep excavation. The finite element method usually gives better predictions for wall deflection than for ground settlements unless small strain characteristics of soil are taken into account. Ideally, empirical methods should be able to predict ground settlements well because they are mainly derived from field observations of case histories. However, most of them yield poor prediction in ground settlement because settlement mechanism is unclear, case histories adopted is limited, and the excavation depth is the only parameter used in formulas.

The objective of this paper is to investigate the mechanism of ground settlement induced by deep excavation under the plane strain condition through finite element analysis. The study focuses on the settlement under the normal excavation condition, that is, no dewatering induced settlement, no excessively long construction duration causing the occurrence of creep, and no serious construction defects. A suitable soil constitutive model was selected through calibration process. Then a series of parametric studies were performed and the settlement mechanism is proposed.

### 2 CALIBRATION OF SOIL CONSTITUTIVE MODELS

Since "settlement influence zone" is not rigorously defined, the authors proposed the conception of the primary influence zone (*PIZ*) and the secondary influence zone (*SIZ*) on the basis of the principles of mechanics and regression analysis of excavation case histories (Hsieh and Ou 1998). The settlement curve is steep in the *PIZ* where buildings receive more influence and in the *SIZ* the slope of the curve is gentle and its influence on buildings is insignificant. Finite element analyses are used to capture the characteristics of *PIZ*.

Four soil constitutive models including the Hardening Soil (HS) model, Hardening Soil with Small Strain (HSS) model,  $\phi=0$  Mohr-Coulomb (MC) model, and Undrained Soft Clay (USC) model, were adopted. Of these, the HS and HSS model are the effective stress model and the  $\phi=0$  MC model and USC model are the total stress model. Both the HSS model and USC model take into account that the soil exhibits high stiffness at small strain.

Though the USC model is a total stress model, it considers the variation of undrained shear strength with principal stress rotation, variation of Young's modulus with the increase of stress level, high stiffness of soil at small strain, and rational way to determine the undrained shear strength (Hsieh and Ou 2011). Similar to Duncan and Chang's model, the tangent Young's modulus ( $E_t$ ) in the primary loading is derived as

$$E_t = E_{ur}(1 - R_f SL)^2 \quad (1)$$

where  $R_f$  is the failure ratio,  $SL$  is the stress level,  $E_{ur}$  is the unloading/reloading Young's modulus.

The  $E_{ur}$  should degrade with the increase of strain or stress level. The degraded Young's modulus is assumed to follow a hyperbolic function as

$$\frac{E_{ur}}{E_i} = 1 - \frac{SL - SL_i}{m + n(SL - SL_i)} \quad (2)$$

where  $m$  and  $n$  are the degradation parameters relative to the stress level,  $E_i$  is the Young's modulus at small strain,  $SL_i$  is the stress level corresponding to the threshold value of the small strain or the initial yield strain.

An elastic surface, ES, is defined to represent the small strain characteristics for the state of stress inside the elastic surface. Figure 1 shows the relationships of stress and strain and of

elastic, yield and failure surfaces. Thus, A total of seven parameters are required for the USC model, i.e.,  $s_{uc}$  (undrained shear strength from  $K_0$ -consolidated undrained compression test),  $E_i$  (Young's modulus at small strain)  $\epsilon_s$  (threshold of small strain)  $R_f$  (failure ratio)  $K_{ss}$  (ratio of the undrained shear strength from undrained shear strength from  $K_0$ -consolidated undrained compression test to that from undrained shear strength from  $K_0$ -consolidated undrained extension test) as well as  $m$  and  $n$  (degradation parameters).

The TNEC case history was used for calibration (Ou et al. 1998). Figure 2 shows the comparison of wall deflections and ground movements obtained from field observation and those from finite element analysis using different models. Except for the  $\phi=0$  MC model where  $E_u/s_u$  was assumed to be 400 according to the local experiences, other soil parameters such as undrained shear strength,  $E_{50}^{ref}$ ,  $E_{ur}^{ref}$ ,  $E_{oed}^{ref}$ ,  $G_0^{ref}$  were determined from laboratory tests.  $\gamma_{0.7}$  were calibrated to be  $5 \times 10^{-5}$ . Details of the soil parameter evaluation can be found in Lim et al. (2010). Though wall deflections can be predicted well for all models, only the USC model can yield ground settlements close to field observations (Figure 2). Moreover, a hypothetical excavation with an 80 m thick soft clay where its properties were assumed to be the same as the third soil layer of the TNEC case was used for further calibration. The USC model gives a more reasonable prediction in wall deflection and ground settlements than other three soil models (Figure 3). The USC model is thus adopted for parametric studies.

Figure 1. Concept of the USC model (a) Stress-strain behavior (b) Relationship of failure, yield and elastic surfaces.

Figure 2. Comparison of settlements from field observation with those from analyses for TNEC

Figure 3. Comparison of settlements from various soil models for a hypothetical excavation with 80 m thick soft clay

### 3 PARAMETRIC STUDIES AND MECHANISM OF SETTLEMENT

A wide range of assumed excavation cases including excavation depth of 9 to 20 m, excavation width of 20 to 60 m, normalized undrained shear strength ( $CK_0UC$ ) of 0.28 to 0.34, depth to hard rock of 25 to 50 m was analyzed using the USC model. A typical parametric result, variation of movements with the excavation width, is shown in Figure 4, indicating that the  $PIZ$  changes with the excavation width. The excavation depth, excavation depth, thickness of soil clay and depth to hard rock are all affecting the  $PIZ$ . Based on the parametric results, we have found the following relationship

Figure 4. Variation of ground settlement with excavation width (B) for  $s_{uc}/\sigma'_v=0.3$ .

When the rock-like soil is very deep, i.e.,  $H_g$  is very large

$$\text{If } \sqrt{B^2 + H_e^2} \leq 2 H_e, PIZ \approx 2 H_e$$

$$\text{If } \sqrt{B^2 + H_e^2} > 2 H_e, PIZ \approx \sqrt{B^2 + H_e^2}$$

When the rock-like soil is of the limited depth, i.e.,  $H_g$  is relatively small

$$\text{If } \sqrt{B^2 + H_e^2} \leq 2 H_e,$$

$$2 H_e \leq H_g, PIZ \approx 2 H_e; 2 H_e > H_g, PIZ \approx H_g$$

$$\text{If } \sqrt{B^2 + H_e^2} > 2 H_e,$$

$$\sqrt{B^2 + H_e^2} \leq H_g, PIZ \approx \sqrt{B^2 + H_e^2};$$

$$\sqrt{B^2 + H_e^2} > H_g, PIZ \approx H_g.$$

The above results are summarized below:

$$\text{When } \sqrt{B^2 + H_e^2} > 2 H_e \text{ (wide), } PIZ = \min(\sqrt{B^2 + H_e^2}, H_g) \quad (3)$$

$$\text{When } \sqrt{B^2 + H_e^2} \leq 2 H_e \text{ (narrow), } PIZ = \min(2 H_e, H_g) \quad (4)$$

Figure 5. Basal heave failure mode and PIZ.

Comparing Eq. 3 and Figure 5 may show that the  $PIZ$  matches the failure zone or potential failure zone. The  $PIZ$  also matches the strain contours from the analysis of the TNEC excavation at stage 7 ( $H_e=11.8$  m) and that of the plastic-points when the strength is reduced to induce basal heave (Figure 6). This is because the strain in the  $PIZ$  should be very large, which in turn induces a relatively large settlement. Therefore, for excavation in soft clay, the  $PIZ$  is assumed to be the potential basal heave zone but limited by the non-soft clay, such as silt, sand etc (Figure 5). For simplification,  $(B^2+H^2)^{1/2}$  in Eq. 3 is replaced with the excavation width,  $B$ . Eq. 3 is thus rewritten as

$$PIZ_1 = \min(H_f, B) \quad (5)$$

where  $H_f$  is the thickness of the soft clay.

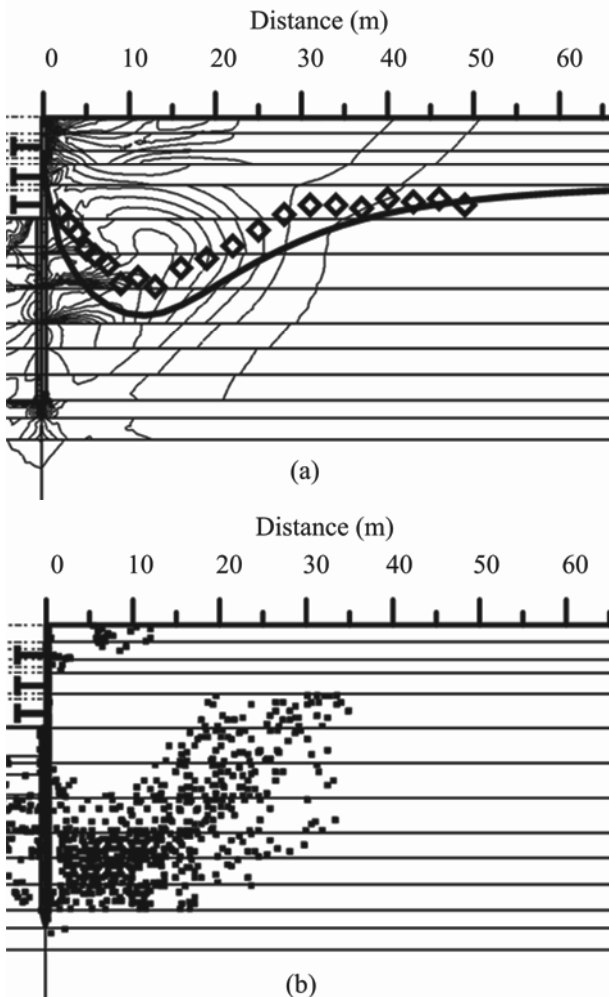

Figure 6. Excavation at Stage 7 for TNEC (a) Strain contours (b) Plastic points when the strength is reduced to cause basal heave.

The relationship in Eq. 4 indicates that the  $PIZ$  matches the active zone based on two times the excavation depth. This is because when excavation begins, the wall moves toward the excavation zone and the active zone also occurs behind the wall. Based on the stability analysis, the embedment depth of the wall is usually equal to the excavation depth. The  $PIZ$  is coincident with the active failure zone but limited by the rock-like soil. The above equation can be rewritten as

$$PIZ_2 = \min(2H_e, H_g) \quad (6)$$

where  $H_g$  is the depth of rock-like soil.

Both  $PIZ_1$  and  $PIZ_2$  are the failure zone or potential failure zones. Therefore, the  $PIZ$  is the maximum of the potential failure zones. The method for predicting concave and spandrel types of ground settlement by Hsieh and Ou (1998) is then modified, in which the  $PIZ$  derived in this study replaces the  $2H_e$ , as shown in Figure 7. Details of the derivation can be found in Ou and Hsieh (2011).

Figure 7. The proposed method for predicting the ground surface settlement.

#### 4 VERIFICATION

The TNEC case history and the ground settlement obtained from finite element analysis of the hypothetical excavation with the 80 thick are used for verification. In the TNEC case history, at stage 5,  $2H_e=17.2$  m. If the cobble-gravel soil is regarded as a rock-like soil,  $H_g=46$  m. Concerning the active failure zone,  $PIZ_2=17.2$  m. With the depth of the bottom of the soft clay ( $H_f$ ) being 37.5 m, for the potential basal heave failure mode,  $PIZ_1=37.5$  m. Thus, the  $PIZ$  is 37.5 m. At stage 7,  $2H_e=23.6$  m,  $H_g=46$  m,  $PIZ_2=23.6$  m;  $B=40$  m,  $H_f=37.5$  m,  $PIZ_1=37.5$  m. Thus, the  $PIZ$  is 37.5 m. Similarly, the  $PIZ$  at the final stage ( $2H_e=39.4$  m), is inferred to be 39.4 m. Figure 8 show the comparison between the proposed method (Ou and Hsieh 2011), Hsieh and Ou (1998) and Clough and O'Rourke (1990). The proposed method satisfactorily conforms to the field measurements, while those from other two methods are not.

In the hypothetical excavation with the 80 m thick soft clay, the excavation depths at stages 5, 7 and final are also 8.6, 11.8 and 19.7 m, respectively. The excavation width=40m. The hard soil is located at 80 m. Using the method similar to those in the TNEC case, the estimated  $PIZ$  for stages 5, 7 and final are all equal to 40m. Figure 9 shows the comparison of settlement obtained from the USC analysis with those from the three methods. The proposed method is able to give a more reasonable prediction in the settlement of  $PIZ$  than the other two methods.

Figure 8. Verification of the proposed method for TNEC excavation.

Figure 9. Verification of the proposed method for the hypothetical excavation with the 80 m thick soft clay.

## 5 CONCLUSION

The objective of this paper is to investigate the mechanism of ground settlement induced by deep excavation under the plane strain condition through finite element analysis. The study

focuses on the settlement under the normal excavation condition, that is, no dewatering induced settlement, no excessively long construction duration causing the occurrence of creep, and no serious construction defects. The USC model was selected to perform parametric studies to find the dominating factors affecting settlement influence zone based on the calibration of a well-documented case history and a hypothetical excavation with 80 m thick soft clay using various soil models. It is found that the primary influence zone is mainly the active failure zone or the potential failure zone due to basal heave. A method is then proposed to estimate the primary influence zone from the relevant parameters such as two times excavation depth, excavation width, depth to rock-like soil layer and depth of the bottom of the soft clay. Case studies reveals that the proposed method improves the prediction of settlement for excavations whose twice the excavation depth are very different than excavation width, depth to rock-like soil layer and depth of the bottom of the soft clay. The methods of Clough and O'Rourke and Hsieh and Ou only yield moderately good prediction results for the settlement at the final stage for most of the cases and largely poor predictions at the intermediate stages, which can be treated as single case histories because the excavation depth is the only parameter used in the formula.

# Establishing a high risk construction pit in a hurry

## L'établissement d'une excavation profonde à risque élevé en court temps

Philipsen J.  
Ramboll, Denmark

**ABSTRACT:** In order to establish a cut & cover road tunnel in Copenhagen, a deep construction pit is established. The future tunnel will run below four railway lines and alongside a fifth, the latter being in poor condition. Since all five railway tracks are vital for the infrastructure in the region, it was not possible to close down all lines during the construction period simultaneously. In fact only two fixed and extremely short closures were allowed for in the construction schedule. This paper presents the thought processes and considerations of the parties involved during the design and planning phase and contains a description of the outcome, that is, the chosen solutions and structural elements.

**RÉSUMÉ :** Afin de construire un « cut & cover » tunnel routier à Copenhague, une excavation profonde est réalisée. Le futur tunnel est construit sous quatre lignes de chemin de fer et à côté d'une cinquième, cette dernière étant en mauvais état. Étant donné que les cinq voies ferrées sont vitales pour l'infrastructure de la région, il n'était pas possible de fermer toutes les lignes au cours de la période de construction en même temps. En fait, seulement deux fermetures fixes et extrêmement courtes ont été accordées par les autorités. L'article présente les considérations faites par les acteurs concernées lors de la conception et la phase de planification du projet et une description des résultats et les solutions choisies.

**KEYWORDS:** Construction pit, Temporary retaining structures

### 1 INTRODUCTION

In Copenhagen a cut & cover tunnel is being established as a part of the new road Nordhavnsvej connecting an existing motorway with the city center of Copenhagen. The construction period is 2011-2015.

The tunnel is a traditional concrete twin tube box tunnel with two road lanes in each tube, build bottom up in a dry construction pit. The length of the tunnel is about 650m.

The alignment of the future tunnel runs below four railway lines at ground level, along a fifth railway line in an old fragile tunnel, below a busy main road and into a narrow path between existing buildings. Figure 1 shows the horizontal alignment and some of the key structures

Figure 1. Horizontal alignment and key structures.

The existing railway lines connect a large part of northern Copenhagen and Zealand to the City centre of Copenhagen, the capital's airport and subsequently to Sweden via the fixed link across the Øresund, which means that they are vital for the infrastructure in the region. Consequently it was not possible to close down all lines during the construction period simultaneously. Only two extremely short main closures were allowed for at each end of the construction schedule.

Figure 2 shows a photo of the 5 railway lines taken from east towards west.

Figure 2. Picture taken prior to project start up showing the 5 railway lines.

The client (the Municipality of Copenhagen) chose Ramboll to be the client's consultants, preparing the detailed design of all permanent works, while the design of the temporary structures was chosen to be split in two parts with different premises and responsibilities.

In the central and most complex part of tunnel alignment - which means at the railway crossing - the client chose a contract form whereby the contractor (Pihl-Zueblin JV) and Rambøll should sit together and optimize the temporary structures at the railway crossing with due consideration, of course, to economy and safety, but most of all with reference to the time schedule.

In the remaining parts of the alignment (the ends) the contractor designed the temporary structures, which e.g. included retaining walls and temporary bridges across the construction pit to facilitate the main road to be open during the complete construction period.

This present paper focuses solely on the temporary retaining structures in the railway crossing which the parties - in close corporation - identified as the optimal.

## 2 OVERALL GEOMETRY

The vertical alignment of the tunnel is governed by the alignment of the existing rails which are not allowed to be changed. This means that the depth of the construction pit is determined from the height of the future permanent tunnel structure and a required soil cover between the railway tracks and the tunnel roof. The width of the construction pit is about 20m

Figure 3 shows a plan and a longitudinal section at the railway crossing (from St. 5075 to St. 5230).

Figure 3. Plan and longitudinal section at the railway crossing.

As shown in Figure 3 the existing railway lines lies in a dell in the terrain. This dell is dug out in the glacial deposits when the railway lines were established.

## 3 GROUND CONDITIONS

The ground conditions at the railway crossing – and for the Nordhavnsvej project in general - are characteristic for the Copenhagen area.

### 3.1 Soil

Below a thin layer of fill, the intact soil generally consists of a 10-20m thick quaternary layer of firm clay till with encapsulated layers of melt water sand and gravel. Underneath the quaternary soils limestone is met where the upper 3m is assumed to be glacially disturbed.

As shown in Figure 4 the number of geotechnical investigations in the railway crossing is significant.

Figure 4. Plan of geotechnical investigations.

The soil parameters are determined from shear vane tests and SPTs carried out in the boreholes, triaxial and oedometer tests

performed in the laboratory on the clay till, VSPs and a priori knowledge of the soil conditions in general.

The sections in St. 5075, St. 5130 and St.5160 shown in Figure 4 indicates the three cross sections being design profiles/representatives for the railway crossing. Figure 5-6 show the assumed geological strata at these three sections

Figure 5. Geological stratum at St. 5075.

Figure 6. Geological stratum at St. 5130.

Figure 7. Geological stratum at St. 5160.

### 3.2 Ground water

At Nordhavnsvej the primary and secondary aquifers are separated. The primary aquifer is the limestone and the secondary aquifer is in the quaternary soils. The water levels are more or less coincident situated a few meters below original glacial ground level except at the railway crossing where the dell in the ground level causes the ground water level down to the terrain.

For the construction of the Nordhavnsvej tunnel it is necessary to lower the ground water level in the limestone temporarily to be able to build the permanent structures. Due to limitations on the allowance of lowering the ground water level in the secondary aquifer, a significant lowering and re-infiltration management system was established.

## 4 STRUCTURAL SOLUTION

Because of the requirement, that all four crossing railway lines must be in service in the complete construction period except for a few short closures, a number of different solutions to

respect that were considered during the early stages of the project, including pipe arching, top down and the chosen solution, being construction of four temporary steel bridges carrying each a railway line across an open construction pit, facilitating the tunnel to be build bottom up.

Since the railway lines cross the construction pit with rather small angles, the bridge spans are between approx. 40m and 70m. The bridges are prefabricated steel bridges founded on 2-5 bored piles below each bridge placed inside the pit, the retaining walls and concrete foundations with transition slabs at each end.

For safety reasons the bridges are connected in pairs to provide footpaths. Figure 8 shows a cross section in the bridges.

Figure 8. Cross section in temporary bridges.

The type of retaining wall is determined by the constructability in the very hard clay till and the limestone, containing significant amounts of boulders and flint respectively.

In the tender material a solution with steel sheet piles placed in a cement-bentonit slurry trench was prescribed, but during the optimization phase the contractor suggested to use secant pile walls, type hard-firm, since this method is already used outside the railway crossing and consequently well tested before constructing the retaining walls during the railway closure.

The secant piles are established with the Kelly method, cased until 0.5m below excavation level (diameter 1180mm) and below that uncased to the bottom (diameter 1080mm). The walls are staggered so that the firm piles are stopped 1.5m below excavation level. Hard piles are reinforced with 14 or 18pcs. K40 longitudinal reinforcement and K14 spiral shear reinforcement.

To avoid significant crushing works on the secant piles after establishing the tunnel, HEB profiles are casted into the top of the reinforced secant piles or the capping beam and timber lagging is used as infill, forming fixed soldier pile walls, which can easily be cut down and removed respectively. Figure 9 shows one of the encastered soldier pile walls.

Figure 9. Encastered soldier pile wall.

The support system in the railway crossing consist of two levels of walings and steel tube props, supplemented by ground anchors to balance the system where the ground level is significantly different on the two sides of the construction pit.

Where the terrain is at railway level, the upper waling is a concrete capping beam placed on top of the secant piles and attached to the piles by 5 threadbars per reinforced pile as shown in Figure 10. The solution is chosen because it is fast to wash away the upper (poor) concrete in the secant piles, place the prefabricated reinforcement cages for the capping beam and get it all casted together.

Figure 10. Connection between reinforced secant piles and upper capping beam.

The props in the upper support system are all steel types with 25mm thickness and diameters ranging from 610mm to 820mm and placed unevenly with distances of about 6-8m. The location of the props are of course governed by the capacities of the capping beams and props, but also by the location of the concrete beams spanning from the capping beam to the foundation piles supporting the rail bridges. Figure 11 shows the upper support system and support beams for the bridges and Figure 12 shows a picture of one of the support beams.

Figure 11. Upper support system and support beams.

Figure 12. Picture of support beam.

The props and walings in the lower support system are very temporary. As soon as the bottom slab of the tunnel is established, the props and walings are removed. Consequently a steel solution with double HEB-profiles and steel tube props is chosen, since the establishing and removing of this system is less time consuming than any concrete solution.

## 5 DESIGN

The design of the retaining walls and the support systems have been carried out using 2D numerical approaches since the effect of asymmetric loading is considerable; different terrain levels, different ground water levels and different loads on each side of the construction pit leading to props pushing excess force from one side to the other. For ULS analyses FEM have been used and cross checked with subgrade reaction models. In SLS small strain stiffness has been considered in FEM analyses.

To ensure that any 3D effects – like the partial loads from trains - were considered realistically in the 2D models, small 3D

FEM models were established and the results were incorporated in the 2D models.

Like for the geological strata, three representative structural cross sections were developed. The sections appear in Figure 13.

Figure 13. Representative structural cross sections.

The longitudinal reinforcement in the secant piles is checked to behave elastically in SLS, while in ULS and ALS plastic behavior is accepted. The shear reinforcement in the piles are designed using the crack sliding model for a circular cross sections, which is a further development of the plasticity-based crack sliding model originally developed for rectangular beams.

The distribution of sectional forces in props and walings are like the retaining wall design based on numerical methods, in this case spring models taking the stiffness of both the soil and the structural elements into account.

In addition to the load cases considered in the design of the secant pile walls the support systems are designed to withstand temperature loads on the props and the two ALS situations; unintended impacts from a single load and failure of a prop or anchor.

## 6 MONITORING

Due to strict requirements for deformations of the railway tracks and the aim to avoid structural damage to existing structures, a rather comprehensive monitoring program with accompanying action lists were developed. The monitoring includes; monitoring of rotations and deflections of the secant pile walls via measuring points and inclinometers installed on and in singled out piles, monitoring of forces in certain struts and ground anchors and monitoring of movements of foundations, railway sleepers and terrain in general. Furthermore of course the ground water heads in both the primary and secondary

aquifers are monitored. All monitoring data are stored in a database.

The measured deformations and forces are continuously compared to the expected magnitudes determined in the SLS analyses. In the analyses a number of combinations of different ground water and load conditions are investigated, leading to so called trigger levels for each measuring item in each construction stage. The trigger levels are threshold values of when certain actions must be taken or measures must be done. The trigger levels are presented on a number of drawings, so that they can easily be compared to the monitored conditions on site. Figure 14 shows an example of how the trigger levels are displayed (wall deflections when excavating for establishing of the lower support system at St. 5200).

Figure 14. Example of trigger level display.

The monitoring is as a starting point performed with measurements on daily basis, but since most the measurements are performed automatically the frequency can easily be raised if any unexpected development in deformations and/or forces is recorded or lowered if no critical development is recorded.

## 7 CONCLUSIONS

To be able to construct the future Nordhavnsvej tunnel in Copenhagen, a construction pit with crossing railway lines and a tight construction schedule has been established.

Through corporation between Client, contractor and consultant the mission of not violating short and fixed closures was accomplished. Figure 15 shows a picture of the project stage in December 2012, where installation of the lower support system was ongoing.

# Innovative Solution of King Post Walls combined with CSM Panels

## Solution Innovante de Parois Berlinoise combinée avec des Panneaux de CSM

Pinto A., Tomásio R., Godinho P.  
JetSJ Geotecnia Lda

**ABSTRACT:** The aim of this paper is to present the main design and execution criteria related with the innovative solution of earth retaining walls combining the King Post Walls (Berlin) with the CSM (Cutter Soil Mixing) panel's technology. A case study where the solution was applied is presented, confirming the solution excellent overall performance.

**RÉSUMÉ :** Dans cet article sont présentés les critères principaux de conception et d'exécution de la solution innovante qui combine des parois de soutènement (Berloinoise) avec de panneaux de CSM (Cutter Soil Mixing). Un cas d'étude avec ce type de solution est présenté, confirmant l'excellente performance globale de la solution.

**KEYWORDS:** cutter soil mixing, Berlin wall

## 1 INTRODUCTION

The traditional and widespread King Post Walls (Berlin) technology has some disadvantages, mainly the excavation schedule as well as the confinement reduction of the supported soil during the excavations works, mainly in cohesionless soils (Figure 1). In order to overcome this disadvantage, the Berlin solution can be combined with the CSM technology, which acts as a preliminary treatment of the supported soil.

Figure 1. View of the confinement reduction of the supported soil during the excavation works using the Berlin Wall technology.

As an example of this combined solution the case of the enlargement of a railway platform, in order to accommodate the new infrastructures at the connection between two main railway lines in Lisbon, Portugal, is presented (Gomes Correia et al., 2013), following previous works using the CSM technology (Pinto A. et al., 2011). For this purpose it was necessary to perform several excavations with 13m of maximum depth. Due to neighbourhood conditions, three retaining structures (M1, M2 and M3) were built using the combination of Berlin wall with the CSM technology. In this paper the case of the M3 wall is presented, with 13m height and about 66m wide (Figure 2).

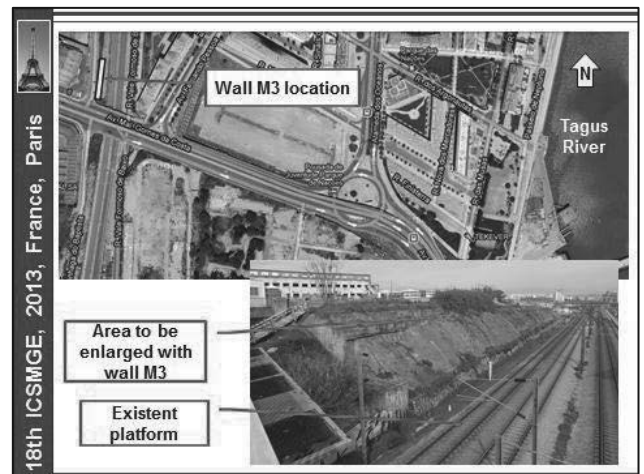

Figure 2. Wall M3 location.

## 2 MAIN CONDITIONS

### 2.1 Geological and geotechnical conditions

The local geological conditions were heterogeneous. The excavation works intersected, from the surface, heterogeneous landfills and Miocene medium dense to dense sands and sandstones. The ground water table was located about 5m above the final excavation level (Figures 3 and 6).

### 2.2 Other conditions

The main neighbourhood conditions included the existent railway lines (under operation and connecting the two Portuguese main cities), several industrial and sensitive buildings, located behind the walls, as well as the important viaduct of the Marechal Gomes da Costa Avenue, over the railway lines, pointing out the importance to control the walls deformation during and after the excavation works (Figure 4).

Geotechnical Conditions						
Geotechnical zone	Ground	SPT n	$\gamma$ kN/m <sup>3</sup>	E kPa	$\phi$	$c'$ kPa
ZG1	Fills	-	19	10.000	22	0
ZG2	Medium compacted sands	20	20	20.000	33	0
ZG3	Dense sands and sandstones	60	21	35.000	35	0
CSM panels			22	1.000.000	600	35

Ground water table was observed at a depth of about 10m, some times above the final excavation level

Figure 3. Main geotechnical conditions.

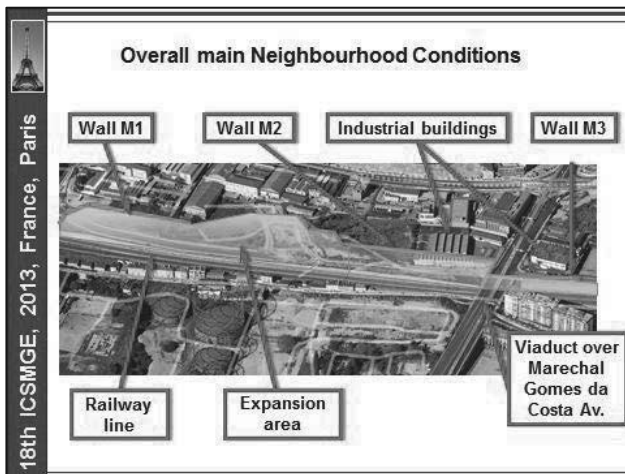

Figure 4. Overall main neighbourhood conditions.

### 3 ADOPTED SOLUTION

In order to allow the excavation works minimizing the ground loss of confinement effect, soil - cement panels with a maximum depth of about 18m and a cross section of 2,4 x 0,5m<sup>2</sup>, including 0,20m of overlapping, were preliminarily built using the CSM technology. The panels were reinforced with vertical IPE240 hot rolled steel profiles (Euronorm 19-57), spaced in average 1,1m, in order to resist to the earth and ground water pressures, as well as to assure a better control of the retaining structure deformations (Figure 5).

Figure 5. Execution of the soil - cement panels using CSM technology.

The steel profiles were placed inside the soil - cement panels, before the cement started the curing process, and were braced by four or three levels of permanent ground anchors, applied at the reinforced concrete capping beam, as well as at the distribution beams (Figures 6, 7 and 8).

Figure 6. Final cross section of the wall M3.

Figure 7. Plan of the wall M3 current section.

Figure 8. Plan of the wall M3 at the distribution beams section.

As already stated, according to the innovative solution combining the Berlin wall with the CSM technology, the soil - cement panels were designed in order to be integrated on the final earth retaining solution, including the 0,2m thickness lining reinforced concrete (RC) wall and beams (capping and distribution), and also to minimize the water inflow to the

excavation platform (Figure 7, 8 and 9). The preliminary ground improvement effect due to the soil - cement panels allowed the execution of the excavation works without any restrictions, with big advantages on the excavation works schedule, as well as on the RC wall finishing face (Figure 9).

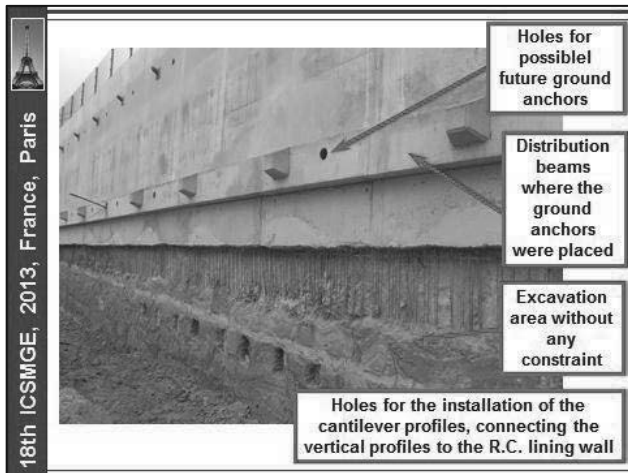

Figure 9. Plan of the wall M3 at the distribution beams section.

The combination of the soil - cement panels with the lining RC wall allowed the construction of a safe and economical solution, overcoming the main disadvantages of the Berlin wall solution (initial solution proposed for the same Project) and spreading the solution application field to almost every kind of geological and geotechnical scenarios, as well as to complex and sensitive neighbourhood conditions.

#### 4 MAIN CONSTRUCTION PHASES

One of the main advantages of the adopted solution was the possibility to reduce the excavation works overall schedule and also to decrease the loss of confinement of the excavated soil and, consequently, to decrease the wall and the neighborhood structures and infrastructures deformations.

The main construction phases are presented on the Figures 10 to 15. As already stated, it should be pointed out the big advantage of the full width excavation, in each level, only possible due to the soil - cement panels ground improvement effect, leading to a big optimization of the construction overall schedule. Due to the versatility of the CSM technology, it should also be pointed out the possibility to apply this solution to almost every kind of geological and geotechnical scenarios, ranging from heterogeneous landfills and soft soils to medium weathered rocks, like the sandstones intersected on present site.

Figure 10. Phase 1.

Figure 11. Phase 2.

Figure 12. Phase 3.

Figure 13. Phase 4.

A tight quality control and quality assurance of the main geotechnical works: soil - cement panels using CSM technology and permanent ground anchors, was implemented, including UCS tests on soil - cement cores and suitability and reception tests on permanent ground anchors (Gomes Correia et al., 2013).

Figure 14. Phase 5.

Figure 15. Phase 6.

## 5 DESIGN

All the soil - cement panels were design in order to achieve an unconfined compression resistance of at least 4,0MPa and a Young Modulus of 1GPa. Due to the soil and water chemical properties, pozolanic cement was adopted. For the design of the adopted solution FEM analysis was carried out, using Plaxis 2D software. The maximum estimated horizontal displacement was about 64mm due to the most critical seismic action (Figure 16).

Figure 16. Horizontal displacements according to the FEM model.

## 6 MONITORING AND SURVEY PLAN

Considering the innovative aspects of the described solutions, a tight monitoring and survey plan was applied, taking into account the need to perform the construction in safe and economic conditions, for both the site and the neighbourhood conditions. In order to accomplish this goal the following equipment's /devices were installed: inclinometers (11un.), topographic targets (65un.) and ground anchors load cells (22un.). Measurements confirmed the excellent overall behavior of the adopted solution, confirming the importance of the previous confinement on the supported soil due to the soil - cement panels, leading, in general, to lower deformations than the ones predicted at the design stage, in spite of some anomalous movements, as presented on Figure 17.

Figure 17. Comparison between predicted FEM deformations and inclinometer readings for static actions.

## 7 MAIN CONCLUSIONS

As main conclusions it is possible to point out the following advantages of the adopted solution:

- Good confinement of the excavated soils, due to the preliminary ground improvement effect of the soil - cement panels, allowing a very high and safe construction rate;
- Low deformations as confirmed by the monitoring.
- Good wall finishing face and water tightness.
- Environmental advantages associated to the CSM technology, minimizing the excavated ground volume.
- Application field to almost every kind of geological and geotechnical scenarios, as well as to complex and sensitive neighbourhood conditions.

## 8 ACKNOWLEDGEMENTS

The authors are grateful to the owner of the walls, REFER, for his permission to the presentation of this paper. The construction works were performed by OBRECOL (general contractor) and GEORUMO (geotechnical contractor).

# Unusual Geotechnical Solutions at the Leixões Cruise Terminal

## Solutions géotechniques inhabituelles au terminal de croisières de Leixões

Pinto A., Pita X., Neves M.

JetSJ Geotecnia Lda

Vaz J.

Dimstrut – Engenharia de Estruturas Lda

**ABSTRACT:** The aim of this paper is to present the main design and execution criteria related with both cofferdam and foundations solutions, using soil-cement panels, micropiles and bored piles in several applications, at the new Leixões Cruise Terminal, located at the Leixões Port, in Portugal. The Terminal building is being built with one basement on a marine environment, over very difficult geological and geotechnical conditions, which demanded the use of some unusual and integrated geotechnical solutions.

**RÉSUMÉ :** Dans cet article sont présentés les principaux critères de conception et d'exécution associés aux solutions des parois de soutènement et des fondations, utilisant panneaux de sol - ciment, micropieux et pieux forés, pour le nouveau Terminal de Croisières du Port de Leixões, au Portugal. Le bâtiment, avec un plancher au-dessous du niveau de l'eau est placé dans une ambiance maritime. Ce scénario complexe a demandé l'utilisation de quelques solutions géotechniques peu communes et intégrées.

**KEYWORDS:** cutter soil mixing, piles, micropiles.

### 1 INTRODUCTION

The construction of the new Cruise Terminal at Leixões, at the North of Portugal, as a consequence to the constant increase of the cruise traffic, was a challenge from both the geotechnical and structural point of views, mainly due to very difficult and unusual conditions, ranging from the geological and geotechnical scenario to the existent and under operation Leixões Port infrastructures, mainly the South break water, as well as the existent boarding deck (Figures 1 and 2).

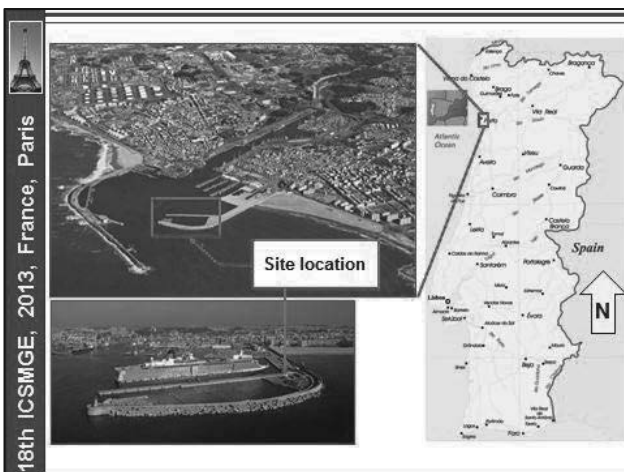

Figure 1. Site location.

According to the Terminal Project it was necessary to build one basement bellow the water table, including several earth retaining structures in order to allow the excavation works on dry conditions leading to a global cofferdam effect. For this purpose soil - cement panels, using CSM technology, reinforced with steel profiles, micropiles (both for foundation and cut off effect) and the existent sheet piles were used. Also pointed out are the adopted special foundations of a very complex structure, including bored piles and micropiles (Figure 3).

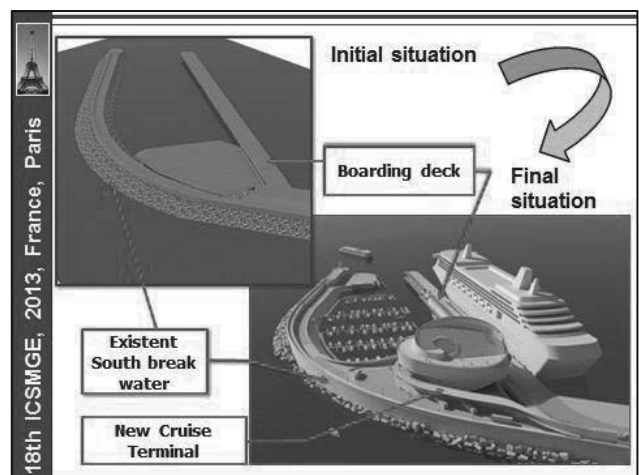

Figure 2. Existent and final situations.

Figure 3. Perspective of the Cruise Terminal building.

2 MAIN CONDITIONS

2.1 Geological and geotechnical conditions

The local geological conditions were homogeneous, but very complex. The excavation works intersected, from the surface, level +5,0m, sandy and silty materials, correspondent to the hydraulic embankment created for working platform purpose. The embankment fill is resting over the bed rock, weathered schist, as previously to the construction of the embankment the existent alluvial material was dredged (Figures 4 and 5).

Figure 4. Geological profile.

The water table level ranged from +4,0m to -0,25m according to the Atlantic Ocean tide (Figure 5).

Main Geotechnical Parameters					
Geotechnical Zone	Ground	$\gamma$ [kN/m <sup>3</sup> ]	E [kPa]	$\phi$ [°]	c' [kPa]
ZG1	Sandy and silty fill	16	15.000	20	5
ZG2	Break water stones (rip rap)	22	60.000	25	10
ZG3	Schist	20	120.000	50	100

Water level ranged from +4,0m (high tide) to -0,25m (low tide)

Figure 5. Adopted geotechnical parameters.

2.2. Other conditions

The main neighbourhood conditions included the existent infrastructures, under operation, mainly: the South side break water, accommodating several infrastructures, and the East side cruises boarding deck, a reinforced concrete slab supported by reinforced concrete bored piles. When the embankment was constructed, a sheet pile wall was installed at the boarding border face, in order to improve the hydraulic embankment confinement (Figure 6).

The South side cofferdam walls, as well as of the South side special foundations had to intersect the break water rip rap (8kN to 130kN). This situation was confirmed as an important issue mainly for the execution of the cofferdam walls, as well as for the construction of the bored piles.

Figure 6. Main neighbourhood conditions: boarding deck.

3 ADOPTED SOLUTIONS

3.1 Global cofferdam

In order to allow the excavation works on dry conditions, three main retaining structures solutions were adopted (Figure 7).

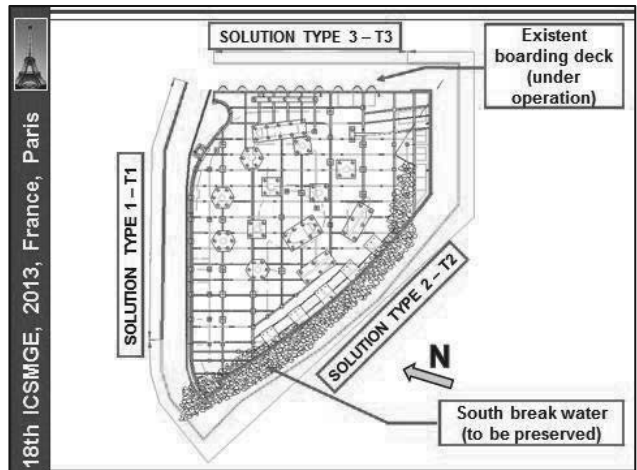

Figure 7. Adopted solutions for the global cofferdam.

Solution type 1 (T1): soil - cement panels with a cross section of 2,4 x 0,5m<sup>2</sup>, including 0,20m of overlapping and 1m of embedment at the bed rock, performed using the CSM technology (Figures 8 to 11), taking into account the experience obtained on previous works (Pinto et al., 2011).

Figure 8. Solution T1 – initial and final cross section.

The soil - cement panels, with UCS resistance not lesser than 4MPa, were reinforced with vertical IPE330 steel profiles (Euronorm 19-57), spaced 0,55m in average, in order to resist to the earth and water pressures, as well as to ensure a better control of the deformations. The steel profiles were placed inside the panels, before the cement started the curing process and capped by a reinforced concrete beam (Figure 8 to 11).

Figure 9. Solution T1 – view.

Figure 10. Solution T1 – plan.

The soil - cement panels will be demolished from the internal structure foundation level to the top, in order to allow the reinforced concrete (r.c.) wall with a very good finishing face, being visible from the adjacent marina, (Figure 12).

Figure 11. Solution T1 – view of soil-cement panels after excavation.

**Solution type 2 (T2):** soil - cement panels with a cross section of 2,4 x 0,5m<sup>2</sup>, including 0,20m of overlapping on a height of approximately 6.5m, correspondent to the previous excavation depth, performed in order to replace the break water rip rap by a sandy fill. The panels were built using the CSM technology. Below the soil - cement panels the cofferdam cut off effect was assured through a curtain, performed using alternated slurry cement injections through steel tubes and micropiles N80  $\phi$ 114,3x12mm, those also with foundation purposes and sealed 4m on the bed rock (Figures 12 to 15).

Figure 12. Solution T2 – initial and final cross section.

Figure 13. Solution T2 – view.

Figure 14. Solution T2 – plan.

Figure 15. Solution T2 – soil - cement panels after excavation.

Solution type 3 (T3): the existent sheet pile wall was integrated on the global cofferdam, using a bracing system, steel ties, connected to the head of the boarding deck foundation piles (Figure 16).

Figure 16. Solution T3 – view of the sheet pile wall after excavation.

### 3.2 Foundations

For the foundations of the Terminal building reinforced concrete bored piles ( $\phi 800\text{mm}$  and  $\phi 1200\text{mm}$ ) and steel micropiles N80  $\phi 139,7 \times 12\text{mm}$  were adopted. Micropiles were used also to resist to both light compression and tension loads, when the structure self-weight was not enough to equilibrate the hydrostatic pressures. Micropiles were designed against corrosion taking into account a sacrificial thickness. All the piles and micropiles were capped by a reinforced concrete raft, cast against an impervious membrane.

## 4 DESIGN

For the design of the adopted solutions, earth retaining structures and foundations, 2D, including axisymmetric, FEM analysis was carried out, using Plaxis software (Figure 17).

## 5 MONITORING AND SURVEY PLAN

A monitoring and survey plan was applied taking into account the need to perform the construction in safe and economic conditions, including inclinometers and topographic marks. Measurements confirmed the excellent overall behavior of the adopted solution, with the exception of a local area at solution T1, demanding the implementation of strengthening measures:

inclined steel struts connecting the capping beams to the foundations piles (Figure 18).

Figure 17. 2D FEM analysis for section T1.

Figure 18. Horizontal displacements at topographic marks - solution T1.

## 6 MAIN CONCLUSIONS

Taking into account the complex scenario of the presented work, it is possible to point out the following points:

- Good water tightness, mainly due to the cofferdam effect assured by the embedment of the soil - cement panels at the bed rock, as well as due to the injections cut off curtain.
- Low deformations, confirmed by the monitoring results.
- Peripheral r.c. walls with very good finishing faces.

Also very important was the control of both costs and construction schedule.

## 7 ACKNOWLEDGEMENTS

The authors are grateful to the owner of the Terminal building, APDL (Administração do Porto de Leixões), for his permission to the presentation of this paper. The construction works were performed by OPWAY and FERREIRAS (general contractors) and GEORUMO and HAGEN (geotechnical contractors).

# Aspects on designing and monitoring a deep excavation for a highly important structure

Aspects de conception et de suivi d'une excavation profonde d'une très importante structure

Popa H., Manea S., Batali L., Olteanu A.

*Technical University of Civil Engineering of Bucharest, Geotechnical and Foundations Department, Romania*

**ABSTRACT:** Building large and deep excavations in urban areas is always a complex problem. The geotechnical investigation should be very detailed and the design rigorous. As well, the monitoring of such a work is mandatory. The paper presents a retaining structure from Bucharest, Romania for a deep excavation of 66 x 127 m size in plan and a maximum depth of over 16 m. This open pit was required for building the infrastructure of the largest Cathedral in Romania, the National Redemption Cathedral. The paper presents aspects regarding the geotechnical investigations and interpretation, soil parameters, calculation of the diaphragm wall, anchors and dewatering system, as well as displacement monitoring.

**RÉSUMÉ :** Les excavations profondes et de grandes dimensions réalisées en milieu urbain représentent toujours un problème complexe. L'investigation géotechnique doit être très détaillée et la conception rigoureuse. De même, le suivi d'un tel ouvrage est obligatoire. L'article présente une structure de soutènement de Bucarest, Roumanie pour une fouille de plus de 16 m de profondeur et ayant 66 x 127 m dimension en plan. Cette excavation a été nécessaire pour construire l'infrastructure de la plus grande Cathédrale de Roumanie, la Cathédrale de la Rédemption du Peuple. L'article présente des aspects concernant l'investigation géotechnique et son interprétation, les paramètres du sol, le calcul de la paroi de soutènement, des ancrages et du système de rabattement de nappe, ainsi que le suivi des déplacements.

**KEYWORDS:** retaining structure, diaphragm wall, deep excavation.

## 1 INTRODUCTION

At the present, in Bucharest is under construction the larger orthodox cathedral in Romania, the National Redemption Cathedral. The location of the Cathedral is in the city centre, next to another very large building, the People's House, on a high area called the Arsenal Hill.

The size of the future Cathedral is: length and height of more than 120 m and a width of over 60 m. The Cathedral basement has 2 stories and the total surface of the future cathedral plus the adjacent buildings is of about 11 000 sqm. Figure 1 presents the photo of the concept design of the future cathedral.

Figure 1. Concept design of the future National Redemption Cathedral.

Based on previous analyses of various foundation solutions it was chosen as final solution a cellular raft (basement walls as part of mat) of 4 – 6 m thickness. The raft thickness plus the basement height led to the necessity of excavating a pit of up to

16 m depth. Taking into account the pit depth, as well as its large size (~ 127 m x 66 m) it was chosen as retaining structure a diaphragm wall supported by anchors.

The Cathedral project, including also the deep excavation retaining structure has been submitted to a national contest for choosing the best option.

Paper presents aspects regarding the geotechnical investigation of the site, the design of the diaphragm walls, construction and monitoring the deep excavation.

## 2 SITE INVESTIGATION

Geotechnical investigation was performed in two stages:

- a preliminary geotechnical study (2008) based on which several preliminary projects were drawn in order to participate to the national contest;
- after selecting the best project, a new detailed geotechnical study was performed by the Technical University of Civil Engineering of Bucharest for the final design of the Cathedral foundations and open pit diaphragm walls.

This geotechnical study comprised the following site investigations: 8 boreholes 25 – 70 m deep, SPT tests, hydro-geological measurements (permeability, analysis of the groundwater flow regime).

Laboratory tests comprised static and cyclic triaxial tests, for determining both shear strength and dynamic parameters of soils. As well, were carried out tests with various stress paths, with unloading – reloading cycles for determining the calculation parameters for the retaining wall. Table 1 presents the main soil parameters obtained from the site and laboratory investigations.

Table 1. Geotechnical parameters

layer	thickness, m	$E_{oed}$ , MPa	$\frac{E_d}{G_d}$ , MPa	$k_o$	$\phi'$ , °	$c'$ , kPa	$N_{SPT}$
1 man-made fill	0.6-2.8	-	-	-	-	-	-
2 silty clay	11.4-16.2	7-16	$\frac{56.5}{19.5}$	0.6-0.7	16-23	51-92	10-34
3 sand, gravel	0.9-6.9	30*	-	0.4	35*	-	16-33
4 clay	10.5-16	8.3-11.7	$\frac{54.5}{18.9}$	0.7	9-20	61-113	11-39
5 sand	6.7-7	40*	$\frac{57.8}{20.2}$	0.5	30*	-	23-59
6 clay	21.7-27.8	-	$\frac{71.2}{-}$	-	14	141	-

\* - values estimated from SPT tests.

where:

- $E_{oed}$  – oedometric modulus, corresponding to 0.2-0.3 MPa stress interval;
- $E_d, G_d$  – linear deformation modulus and shear modulus for 300 kPa stress;
- $k_o$  – at rest earth coefficient;
- $\phi', c'$  - drained shear strength parameters;
- $N_{SPT}$  – number of blows from SPT test.

Hydro-geological study emphasized two aquifers: a free level aquifer (layer 3) and a second confined aquifer (layer 5). The excavation will be 2 – 3 m below the groundwater level.

### 3 RETAINING STRUCTURE

#### 3.1 Geometrical and technological characteristics

The deep excavation was retained using diaphragm walls 80 cm thick, with variable length, from 20 m to 24 m. The lower level of the wall remained constant (+60.50 m), while the upper level varied according to the architectural details of the basement and adjacent buildings (+84.50 m along the long sides and +80.50 m along the short sides of the pit).

Figure 2 presents a layout of the diaphragm wall enclosure and the final excavation levels.

Figure 2. General layout of the diaphragm wall enclosure

The natural ground level varies on the site around +87.0 m, so for the working platforms required for the diaphragm walls execution, a sloped excavation was realized. The final

excavation levels are +72.7 m and +70.7 m (for the 6 m thick raft area), respectively, which led to a maximum excavation level of approx. 16.3 m below the ground level.

It can be seen that the foundation level of the raft is in the sand and gravel layer (layer 2).

The temporary support of the diaphragm wall was ensured using 2 or 3 levels of anchors. The total length of the anchors was comprised between 20 m and 25 m. In the corners were used metallic struts and wale beams.

Figure 3 presents a cross section through the diaphragm wall for the sides with 3 anchor levels.

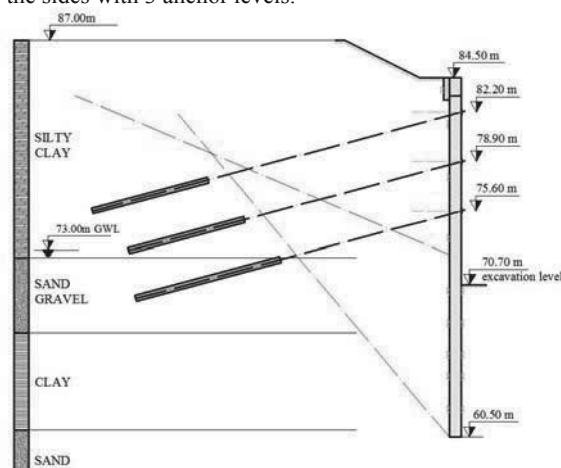

Figure 3. Cross section through the diaphragm wall

For the anchors on 3 levels the characteristics are the following:

- Anchors level 1: +82.20 m
  - inter-axis distance: ~ 1.75 m
  - number of strands in each anchor: 4
  - maximum pull-put force / anchor estimated by calculation (ULS) = 200 kN
- Anchors level 2: +78.90 m
  - inter-axis distance: ~ 1.75 m
  - number of strands in each anchor: 4
  - maximum pull-put force / anchor estimated by calculation (ULS) = 250 kN
- Anchors level 3: +75.60 m
  - inter-axis distance: ~ 1.20 m
  - number of strands in each anchor: 6
  - maximum pull-put force / anchor estimated by calculation (ULS) = 320 kN.

As it can be seen on figure 3, the lowest level of the pit base is 3.0 m below the groundwater level. The soil permeability and the ground level differences led to a water flux in the enclosure of about 90 l/s, unevenly distributed, being higher on the Southern side. Considering these conditions, a dewatering system was designed, comprising 12 wells disposed along the enclosure sides.

#### 3.2 Diaphragm wall calculation

Diaphragm wall calculation was done based on Eurocode 7 (SR EN 1997-1:2004 and the Romanian National Annex SR EN 1997-1/NB). According to the National Annex in Romania, the calculations were performed for design approaches 1 and 3, approach 2 not being recommended by this document.

As well, according to the Romanian technical norm for retaining structures (NP 124-2010), the seismic action was considered on the wall. The seismic coefficient was decreased considering the temporary character of the retaining structure, according to the same technical norm.

Figure 4 shows some of the results obtained for the stresses in the diaphragm wall, corresponding to the side with 3 levels of anchors, for ULS calculation. Calculations were performed

according to technological stages (excavation and installation, anchors pretension) up to the final excavation level.

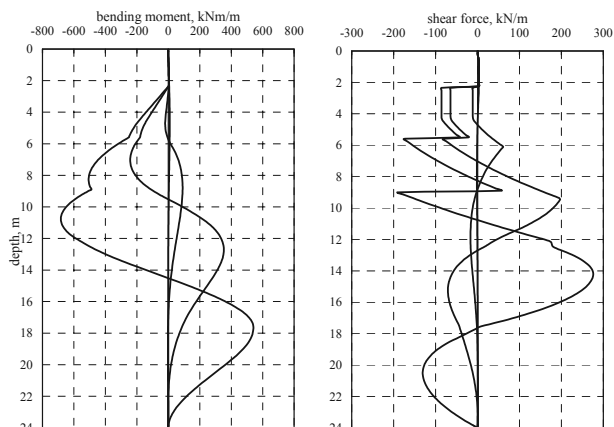

Figure 4. Bending moment and shear force in the diaphragm wall

Figure 5 shows the horizontal displacements of the wall corresponding to the same calculation stages (SLS calculation). It can be seen that the maximum displacements are less than 10 mm, which was confirmed by the inclinometer measurements, presented figure 11.

Figure 5. Horizontal displacements of the diaphragm wall

### 3.3 Aspects during the diaphragm wall execution

Figures 6...9 present some photos taken during the execution of the deep excavation.

Figure 6. Installing the reinforcement cage of the diaphragm wall

Figure 7. Installation of the first level of anchors

Figure 8. Final stage of excavation

Figure 9. Lead waterproofing

As it can be seen in photo figure 9, prior to build the raft a waterproofing layer has been laid on the excavation base. Considering the life time of the cathedral of minimum 500 years, the waterproofing was done with lead, being the only solution guaranteed on such long time. From this point of view, this solution is new for Romanian civil engineering.

### 3.4 Monitoring the diaphragm wall

The enclosure monitoring was performed by measuring:

- vertical displacements of the wall - measured at the linking beam level using geodetic methods;
- horizontal displacements of the wall - measured at the linking beam level and along the wall depth using inclinometer measurements;
- outflow from the dewatering wells;
- groundwater level inside and outside the enclosure.

Regarding the inclinometer measurements, these were carried out using 6 tubes located in various areas and along different sides of the diaphragm wall (4 on the sides with 3 anchors level and 2 along the sides with 2 anchor levels). A cross section showing the position of the inclinometer tube inside the diaphragm wall is presented in figure 10.

Figure 10. Inclinometer location inside the diaphragm wall

The monitoring of the anchored structure was carried out from April 15 2011 until January 12 2012. The activity during the 9 months of monitoring was according to the technological stages of the excavation works and retaining structure.

The frequency of monitoring activity was established according to preliminary stages of infrastructure works. Due to the construction progress, changes in construction technology flow on site (adjacent traffic infrastructure, frequency and tensioning of anchors system, etc.), weather changes (temperatures on 2012 winter) the frequency of the measurements was increased.

Figure 11. Inclinometer measurements for the diaphragm wall

The main purpose of monitoring activity was to verify design assumptions regarding the deformations of the structure, but also to provide detailed information on the effect induced by the anchors on the retaining wall.

Figure 11 presents a graph of the measured lateral displacement of the wall for the side with 3 anchor levels.

According to measurements, the maximum horizontal displacement of the diaphragm wall didn't exceed, on all sides, 10 mm, confirming the estimation by calculation.

#### 4 CONCLUSIONS

Designing and building a retaining structure for a deep excavation in urban area is always a challenge, taking into account the associated risks. The characteristic parameters of interaction are numerous and their control difficult. For this reason the approach of such works should be done carefully during all stages: geotechnical investigation, design, execution and service.

Paper presents a case study for a deep excavation in centre Bucharest required for the construction of the Redemption Cathedral, which was approached according to Eurocode 7. Considering its size and the supporting system using anchors, this excavation is among the largest in Romania. The anchor supporting system allowed a space-free enclosure and the infrastructure works took place very rapidly.

The work was classified as in geotechnical category no. 3, which imposed a complex approach also from geotechnical investigation, as from design point of view. The execution was permanently monitored and the measurements were compared with the calculations, allowing a rapid intervention if the real behavior would be different from the estimated one.

# FEM-aided design of a novel device for soil anchoring

## Conception assistée par éléments finis d'un nouveau système pour l'ancrage des sols

Prisco di C., Pisanò F.  
*Politecnico di Milano*

**ABSTRACT:** In this paper the pull-out performance of an innovative system for soil anchoring is mechanically interpreted on the basis of a preliminary finite element investigation. The system consists of a tie rod equipped with thick steel sockets, extruding into the soil to increase the overall pull-out bearing capacity. The effectiveness of the anchorage comes from two correlated strength mechanisms: a direct one, associated with the shear/flexural strength of the sockets themselves; and an indirect one, in the form of a remarkable increase in the normal confinement on the tie rod and hence in the available shear strength. Finally, the numerical results are exploited to conceive a design-oriented analytical model for the prediction of the pull-out bearing capacity.

**RÉSUMÉ:** Dans cette article, le comportement en tension de un nouveau système pour l' ancrage dans les sols est interprété sur la base de une analyse préliminaire avec les éléments finis. Dans le système il y a une bar en métal avec des puntons qui s'extrudent dans le sol pour augmenter la capacité totale de l'instrument. L'efficience de l' ancrage dérive de deux mécanismes résistants: un qui peut être définis direct, associe a la résistance des puntons, et un indirect, associe à l'incrément du confinement sur la bar. Les résultats numériques ont été utilisés pour définir un model interprétatif du fonctionnement du system d' ancrage.

**KEYWORDS:** soil anchoring, pull-out, soil–structure interaction, finite element analyses, plasticity

## 1 INTRODUCTION

The analysis and the design of soil anchors are of major interest to geotechnical engineers in many practical applications, including retaining structures, transmission towers, marine pipelines, etc. For these purposes, the employment of the Finite Element Method (FEM) is progressively increasing, as it overcomes the limitations of most empirical/analytical approaches (Das 1990) in dealing with complex geometries and material non-linearities. On the research side, only a few papers present numerical results about soil anchoring systems, compared to the available experimental data and analytical predictions (see for instance Rowe and Davis (1982a,b), Merifield and Sloan (2006)).

This paper summarizes a recent research activity (di Prisco and Pisanò 2012) concerning the study of a novel device for soil anchoring. This latter is formed by a tie rod equipped with thick steel sockets, which are extruded into the soil to ensure a remarkable pull-out capacity.

To investigate the soil–structure interaction (SSI) mechanisms determining the effectiveness of the system, FEM simulations of pull-out tests have been performed. Then, based on the critical analysis of the numerical outcomes, an analytical model for the estimation of the pull-out capacity has been set up. Despite the approximations introduced, the good agreement between analytical and FEM results is believed to represent the starting point for the conception of a reliable design procedure.

## 2 FEM SIMULATION OF PULL-OUT TESTS

The novel setup of the anchoring device under consideration is characterized by the presence of internal steel sockets along the tie rod shaft, to be extruded - after the rod installation - into the soil by means of a hydraulic system. Recent in situ pull-out tests have highlighted how socket extrusion ensures a very large bearing capacity (Santoro 2009), much larger than in the usual case of grouted anchorages.

Figure 1 sketches the installation of the anchoring system, composed of the tie rod and the extruded steel sockets, while Figure 2 illustrates the telescopic structure of the sockets. The system is rather flexible in terms of geometrical configuration as the number, the location, and the orientation of the sockets can be freely designed; its installation is extremely fast and inexpensive.

Figure 1. The anchoring system.

Figure 2. The steel sockets.

### 2.1 FEM model

The geometrical configuration for numerical analyses has been kept as simple as possible, but sufficiently accurate to reproduce the most relevant structural details. If the four sockets

were located at the same vertical level (they are not to allow room for the extruding hydraulic circuits), the anchor would be characterized by four (vertical) symmetry planes. Although this is not exactly true, it has been here assumed for computational convenience that the different socket elevations only slightly violate such symmetries: accordingly, only a quarter of the whole geometry has been considered and discretized.

The FEM mesh employed is shown in Figure 3. The discretization – performed by adopting quadratic tetrahedral elements - is finer around the sockets and the tie rod, i.e. where the solution is expected to exhibit the largest gradients. The external soil boundaries have been placed sufficiently far from the anchor, so as to not affect the global pull-out response.

Since the main purpose of this preliminary study was the highlighting of SSI mechanisms, for the sake of simplicity no sophisticated material models have been considered. In particular, the soil mechanical behaviour has been modelled by means of a simple Mohr-Coulomb perfectly-plastic constitutive relationship with non-associated flow rule (i.e. with different friction and dilatancy angles), while a von Mises perfectly-plastic associated model has been adopted for the anchor structural members. A linear variation along the depth has been introduced for the soil Young modulus, to account for the stiffening induced by the increase in normal confinement. Moreover, as is commonly done in SSI analyses, a widthless perfectly-plastic interface layer has been interposed between the anchor and the surrounding soil to allow both shear and tension detachments.

Figure 3. FEM model.

Apparently, the length of the tie rod, i.e., the socket extrusion depth, greatly influences the pull-out capacity of the anchor: as deeper anchors are considered, larger discrete models should be defined, implying an increase in computational costs. Conversely, in order to investigate how the strength contribution coming from the steel sockets is affected by the initial stress state, an approximate approach has been here adopted for the first preliminary analyses. In particular, to simulate a real higher embedment, the same model in Figure 3 has been used for different physical depths, by using an equivalent “embedment surcharge”  $q_{emb}$  on the top of the reduced model (obviously, this assumption neglects the frictional pull-out resistance provided by the missing upper soil).

### 2.2 Main inferences from FEM analyses

In what follows, the main observations derived from the analysis of the preliminary FEM results (with embedment surcharge) are qualitatively summarized.

All the pull-out tests have been performed by imposing a prescribed upward displacement  $\delta$  at the top of the tie rod, recording the corresponding reaction forces to quantify the global resistance provided by the neighboring soil. While the total pull-out force readily results from the top reaction forces, two distinct contributions can be recognized and estimated on the basis of the FEM outputs. In particular, the global capacity has been split into a first frictional component mobilized along the tie rod, and a second contribution directly carried by the steel sockets.

Figure 4. Total displacement contour plot at the onset of failure.

As an example, Figure 4 illustrates the contour plot of the total displacement (absolute value) at the onset of the collapse. The global failure mechanism takes place in the form of a soil wedge surrounding the anchor and moving upward as the anchor itself is pulled-out. Such a failure mechanism is further illustrated in terms of the plastic shear strain in Figure 5: the shear strain concentrations take place along the tie rod and close to the sockets, so that the formation of a failure wedge is apparent.

Figure 5. Plastic shear strain contour plot at the onset of failure.

Figure 6 shows, for four different  $q_{emb}$  values, the pull-out curves (force vs. displacement) estimated for the whole anchorage, i.e. four times the force computed for the quarter anchor (this would rigorously hold if the steel sockets were at the same elevation). In all the cases considered, the mechanical response of the anchorage is overall ductile and the limit pull-out load (horizontal plateau) is achieved after quite large displacements. Besides the expected increase in the bearing capacity at larger  $q_{emb}$ , it is also worth noting that, owing to the aforementioned spatial variation of the soil Young modulus, the limit load is achieved at about the same displacement level  $\delta$ .

Figure 6. Pull-out responses at increasing embedment surcharge.

Both the above frictional and socket strength contributions have been separately evaluated for all the FEM analyses performed. The obtained values – not reported here for the sake of brevity – show that the lateral frictional forces and the contribution provided by the steel sockets are quantitatively comparable. Such large lateral forces could not be explained by assuming a standard  $k_0$  distribution for the confining stress ( $k_0$  stands for the at rest earth pressure coefficient) all around the tie rod. In contrast, the numerical simulation shows a significant increase in confining stresses as the anchor is pulled-out, up to values much larger than the at rest ones. Figure 7 illustrates the final contour plot of the radial stress, in which the severe perturbation of the initial (linear) at rest distribution is evident.

In the light of these considerations, the influence of the steel sockets on the global pull-out capacity can be said to be twofold. First, the sockets directly sustain a portion  $F_{socket}$  of the external load owing to their shear/flexural strength: henceforth, this will be referred to as the “direct effect”. Besides this, an “indirect effect” stems from the formation of a global failure mechanism with a remarkable increase in the radial stress around the tie rod and, therefore, in the mobilizable shear force  $F_{lateral}$ . For any future design purpose, the necessity of a reliable estimation of both  $F_{socket}$  and  $F_{lateral}$  is self-evident.

7. Radial stress contour plot at the onset of failure.

### 3 A DESIGN-ORIENTED ANALYTICAL MODEL

In this section a design-oriented analytical model is defined to estimate each resisting component contributing to the total pull-out capacity of the anchor. The accuracy of the model has been also assessed by comparing the analytical results with the outcomes from full-size FEM analyses, i.e. with no embedment surcharge.

Apparently, the near presence of the tie rod prevents the sockets from being interpreted as isolated deeply buried pipes, so that the force exerted by the soil on each socket (and viceversa) cannot be evaluated via the well-known concept of “uplift coefficient” (or even “break-out coefficient” - see for instance, Rowe and Davis (1982a,b), Merifield and Sloan (2006), White *et al.* (2008)). In contrast, it has been numerically observed that the soil between a single socket and the tie rod behaves as if it was rigidly connected to the anchor, giving rise to a sort of “corkscrew mechanism”.

Figure 8. Simplified static scheme for the anchoring system.

To evaluate at the same time both  $F_{socket}$  and  $F_{lateral}$ , the simplified vertical wedge mechanism in Figure 7 (left picture) is considered (the shear force  $T_{int}$  coincides with  $F_{lateral}$ ). For the sake of simplicity, the two half-sockets are assumed to be positioned at the same elevation, so that a cylindrical reference frame  $(\rho, \theta, z)$  can be setup to describe an axisymmetric stress/strain state within the soil wedge (axisymmetric conditions are indeed expected beyond a given distance over the sockets). The right picture in Figure 8 illustrates the reference static scheme, i.e. the forces acting both on the tie rod and the

soil wedge (the rod weight is neglected and boundary reaction forces are not visualized).

From the analysis of all numerical results the following conclusions have been drawn:

1. except for local disturbances next to the sockets, all the stress components are almost linearly distributed along the vertical  $z$ -axis;
2. the vertical direct strain component  $\varepsilon_z$  is much less than the other two ( $\varepsilon_\rho$  and  $\varepsilon_\theta$ ), so that  $\varepsilon_z = 0$  can be assumed;
3. the normal force  $N_{ext}$  in Figure 8 can be approximately evaluated by assuming a  $k_p$  linear distribution for the radial stress  $\sigma_r$  along the outer side of the soil wedge ( $k_p$  stands for the passive earth pressure coefficient);
4. the inner and the outer  $\sigma_r$  distributions can be linearly related through a dimensionless constant  $\lambda$ ;
5. the failure distributions of the mobilized friction angle  $\phi_{mob} = \arctan(\tau_{z\rho} / \sigma_\rho)$  along the inner and outer sides of the soil wedge exhibit a mean value less than the soil friction angle  $\phi$  and approximately equal to:

$$\tan \phi_{mob}^{lim} = \frac{\cos \phi \cos \psi}{1 - \sin \phi \sin \psi} \quad (1)$$

where  $\psi$  is the soil dilatancy angle.

Relationship (1) stems from the fact that, during the pull-out process, the aforementioned soil wedge undergoes a sort of “axisymmetric simple shear loading”. In other words, the loading conditions of the soil elements around the tie rod are highly constrained and similar to those a soil specimen experiences within a so-called simple shear apparatus: as was recently discussed by di Prisco and Pisanò (2011), this implies the material dilatancy to significantly affect the limit shear stress.

The above considerations lead to the formulation of the following system of equations:

$$\begin{cases} T_{int} + F_{socket} = T_{ext} \\ T_{int} = N_{int} \tan \phi_{mob} \\ T_{ext} = N_{ext} \tan \phi_{mob} \\ N_{int} = \lambda N_{ext} \end{cases} \quad (2)$$

with the unknowns  $N_{int}$ ,  $T_{int}$  ( $= F_{lateral}$ ),  $T_{ext}$  and  $F_{socket}$  ( $N_{ext}$  is simply obtained by integrating the  $k_p$ - $\sigma_r$  distribution along the outer surface of the soil wedge). While the equations in system (2) hold at any stage of the loading process,  $\phi_{mob} = \phi_{mob}^{lim}$  is to be set at failure – i.e. when the limit frictional capacity is attained along the sides of the soil wedge.

For system (2) to be solved, the determination of the coefficient  $\lambda$  introduced in the previous assumption 4 is required. For this purpose, an original procedure has then been conceived: this is based on the solution of a classical rock engineering problem, concerning the determination of the elastic stress state around a circular cavity (Jaeger *et al.* 2007). For this purpose, an axisymmetric boundary value problem has been posed by assuming that: (i) the soil wedge in Figure 8 is internally elastic; (ii) the direct strain  $\varepsilon_z$  is nil; and (iii) the vertical stress gradients are much lower than those along the radial direction. While the problem formulation and the solution strategy can be found in di Prisco and Pisanò (2012), the obtained  $\lambda$  expression is reported here:

$$\lambda = \frac{\pi}{4} R(L - z_s) \left( \frac{c_1}{2} - \frac{c_2}{2R^2} \right) \quad (3)$$

where:

$$\left\{ \begin{array}{l} c_1 = \frac{8(R+l)}{\pi(L-z_s)[l^2 + 2lR + 2(1-\nu)R^2]} \\ c_2 = \frac{8R^2(R+l)(2\nu-1)}{\pi(L-z_s)[l^2 + 2lR + 2(1-\nu)R^2]} \end{array} \right. \quad (4)$$

In expressions (3) and (4),  $R$  and  $L$  are the radius and the length of the tie rod, while  $l$  and  $z_s$  stand for the length and the elevation (with respect to the bottom of the tie rod) of the steel sockets.

The straightforward solution of system (2) allows of estimating both  $F_{socket}$  and  $T_{int}$  ( $=F_{lateral}$ ). The soundness of the above assumptions has been verified for all the performed simulations and, in particular, for the full-size analyses (3 m and 7 m embedment) a satisfactory agreement in terms not only of total pull-out force (errors less than 10%) but also of the single contributions has been found. Further confirmation is given in Figures 9 and 10, where the analytical predictions for the radial (a, circular marked line) and shear (b, square marked line) stresses along the inner side of the soil wedge are compared with the FEM results (black solid line).

Figure 9. FEM and analytical stress distributions for the full-size model with 3m-embedded sockets.

Figure 10. FEM and analytical stress distributions for the full-size model with 7m-embedded sockets.

#### 4 CONCLUSIONS

The pull-out performance of an innovative soil anchoring system has been numerically investigated through FEM analyses. The anchoring device is composed of a tie rod and a set of steel sockets, the latter to be extruded into the soil; former in situ tests have shown the steel sockets largely improve the pull-out performance of the anchorage. The device installation is fast, flexible and inexpensive, while in most cases additional soil grouting becomes optional.

In this work, vertical pull-out tests have been first simulated to explore the SSI mechanisms determining the pull-out capacity of the device, whence the following conclusions have been drawn:

- the steel sockets contribute to the global pull-out capacity in a twofold manner. In a direct way, they sustain a significant part of the total load owing to their shear/flexural strength; they also provide an indirect contribution, by increasing the lateral confinement and the mobilizable friction along the tie rod;
- in all the cases considered, failure develops up to the free surface through a global mechanism involving a cylindrical vertical soil wedge;
- the pull-out strength increases for deeper anchors. Its dependence on socket depth has been found to be, within the investigated range, almost linear;

A simplified analytical model was then proposed to simultaneously estimate the strength contributions – both direct and indirect – given by the sockets. This relies on a set of simplifying hypotheses suggested from the results of FEM simulations, and provides results in good agreement with the numerical outcomes. Although only vertical pull-out tests were considered, the above inferences are believed to apply for inclined anchors as well, since only a slight influence of the initial in situ stresses was found.

The proposed model clarifies the mechanical working conditions of the anchoring system and provides practitioners with a preliminary design framework. In the near future, further efforts will be devoted to analyse the device in the case of more complex geological conditions and, as more experimental results become available, to validate numerical/analytical predictions with respect to in situ measurements.

# Structural Optimization in Geotechnical Engineering

## Optimisation de la structure dans la géotechnique

Pucker T., Grabe J.

Hamburg University of Technology, Institute of Geotechnical Engineering and Construction Management

**ABSTRACT:** Structural optimization methods are used for a wide range of engineering problems. In geotechnical engineering however, only limited experience exists with these methods. The possibilities and difficulties in applying such techniques to geotechnical problems are discussed in this paper and the adaption of the commonly known SIMP-method (Solid Isotropic Material with Penalization) to geotechnical problems is introduced. An application example is used to demonstrate the potential of structural optimization in geotechnical engineering.

**RÉSUMÉ :** Des méthodes de l'optimisation de la structure sont employés dans beaucoup de disciplines d'ingénieurs. Mais il y a quand-même peu d'expériences dans le domaine de la géotechnique. Les possibilités et les difficultés de l'application de ces procédures d'optimisation dans la géotechnique sont discutées dans cet article. L'application de la méthode SIMP est présenté. Un exemple est présenté pour montrer le potentiel de l'application de cette méthode.

**KEYWORDS:** topology, optimization, optimisation

### 1 INTRODUCTION

Structural optimization methods are used for a wide range of engineering problems, for instance in aviation and automotive engineering. In geotechnical engineering however, only limited experience exists with such methods. The possibilities and difficulties in applying these techniques to geotechnical problems are discussed in this paper and the adaption of the commonly known SIMP-method to geotechnical problems is introduced.

#### 1.1 Structural Optimization

Structural Optimization can be classified in three categories. The first category is called topology optimization and describes the main geometry of a design. Topology is a mathematical field used to describe geometrical structures. A geotechnical example of different topologies to stabilize a slope is shown in Figure 1.

Figure 1a) shows the design problem. Different constructions can be used to solve this task, for example a gravity wall (Figure 1b), a single anchored wall (Figure 1c) or a grouted anchored wall (Figure 1d). These three constructions differ in their topology. Some topology optimization algorithms can be found in Bendsøe (1995) or Allaire (2005).

Once a topology is chosen, the shape of the topology can be optimized with regard to the design problem. Concerning the design problem in Figure 1, the topology in Figure 1d is chosen. Figure 2 shows different possibilities to optimize the shape of the topology in Figure 1d during the category shape optimization, for example the variation of the anchor positions (b), of the anchor inclination (c) or the anchor length (d). The variations in Figure 2 b)-d) can be varied regarding an optimization task, for instance the minimization of the bending of the wall or minimization of the installation costs. The application of shape optimization algorithms in geotechnical application has been shown in Kinzler (2007) and Grabe et al. (2010, 2011).

The third category is the dimension optimization of each construction part. Within this category every cross section and dimension is determined. Neither the topology nor the shape can be changed by the dimension optimization. The dimension optimization is the most widely applied category of structural optimization in geotechnical engineering. The shape optimization of Figure 2 results in the shape shown in Figure 3. For this example, possible parameters for the dimension optimization are given in Figure 3.

## 2 NUMERICAL OPTIMIZATION ALGORITHM

An iterative algorithm is used to solve the optimization problem numerically. First a topology is created and second its load-displacement behavior is determined using a finite-element analysis. In the next step, the results of the finite-element analysis are interpreted and transmitted to a topology optimization algorithm, which creates a new improved topology. Afterwards step two is performed again.

The SIMP-Method (Solid Isotropic Material with Penalization) after Sigmund (2001) is used as topology optimization algorithm. The algorithm is based on the idea, that the material of the optimized structure already exists in the design domain  $\Omega$ , but is not optimally distributed. Therefore, the material is equally distributed in the design domain  $\Omega$  at the beginning of the optimization process. The material distribution changes during the optimization process and the material compacts in areas where it is needed to achieve the optimization task.

The design domain  $\Omega$  is discretized with finite elements. The material parameters are specified individually for each element depending on the material distribution. The virtual density  $\rho$  at a point  $a$  has to be between 0 and 1, see Equation 1.

$$\rho(a) = \begin{cases} 0 \rightarrow \text{no material} \\ 1 \rightarrow \text{material} \end{cases} \quad (1)$$

Regarding a geotechnical application, for example a foundation made of concrete, a finite-element with  $\rho(a) = 0$  is a soil element and with  $\rho(a) = 1$  is a concrete element.

Using the SIMP-Method, the objective function is the minimization of the compliance of the structure in the design domain  $\Omega$ . Thus, the stiffness of the structure is maximized. The compliance of the structure can be expressed using the internal energy of the system. The internal energy  $c$  of an elastic material is defined by Equation 2.

$$c(\mathbf{x}) = U^T K U \quad (2)$$

In Equation 2  $U$  is the global deformation tensor,  $K$  the global stiffness matrix and  $\mathbf{x}$  the tensor of design parameters. The virtual density  $\rho(a)$  matches the design parameters of  $x_i$  of the tensor  $\mathbf{x}$  at point  $a$ .

The minimization of the compliance is restricted by two constraints. The first constraint ensures that the observed system is in equilibrium an every step of the optimization process. Using the finite-element method, this constraint is ensured by Equation 3.  $F$  is the global tensor of the external forces.

$$K U = F \quad (3)$$

The second constraint ensures that the volume of the material distributed in the design domain remains constant during the optimization process, see Equation 4.  $V_\delta$  is the volume of the structure.

$$\int_{\Omega^{mat}} 1 d\Omega = V_\delta \quad (4)$$

Additionally, the design parameters  $x_i$  are limited by an upper and an lower bound, such that the optimized material parameters lie within to the physically possible range.

The optimization task for minimal compliance design can be written using Equation 5.  $U_e$  is the element deformation tensor,  $K_e$  the element stiffness matrix,  $\rho_e$  the element virtual density,  $\delta$  the volume fraction,  $V_\delta$  the structure volume and  $V_0$  is the volume of the design domain. The values of the material distribution are limited by  $x_{min}$  to avoid singularities during the finite-element analysis. Using the algorithm for geotechnical application, this limit is not necessary because the stiffness of an element belongs to the soils stiffness at  $x_i = 0$  and cannot tend to zero.

$$\left. \begin{array}{l} \min : \quad c(x) = U^T K U = \sum_e^N (\rho_e)^p U_e^T K_e U_e \\ \text{subject to:} \quad \left. \begin{array}{l} K U = F \\ V_\delta = V_0 \cdot \delta \\ 0 < x_{min} \leq x \leq 1 \end{array} \right\} \end{array} \right\} \quad (5)$$

The penalty  $p$  controls the material change-over to ensure complete material change for example from soil to concrete, see Figure 4.

The improved topology in every iteration step is determined using the method of optimal criteria, see Equation 6 (Bendsøe 1995). A positive move-limit  $m$  and a numerical damping coefficient  $\eta = 0.50$  are introduced, see Bendsøe (1995). The move-limit  $m$  limits the change of the topology in each iteration step. The sensitivity of the objective function is expressed in Equation 7. Using the Lagrangian multiplier  $\lambda$ ,  $B_e$  is defined in Equation 8.

$$\rho_e^{new} \begin{cases} \max(\rho_{min}, \rho_e - m), & \text{if } \rho_e B_e^\eta \leq \max(\rho_{min}, \rho_e - m) \\ \rho_e B_e^\eta, & \text{if } \max(\rho_{min}, \rho_e - m) < \rho_e B_e^\eta < \max(1, \rho_e + m) \\ \min(1, \rho_e + m), & \text{if } \min(1, \rho_e + m) \leq \rho_e B_e^\eta \end{cases} \quad (6)$$

Figure 4: Change-over of the Young's modulus  $E$  of two different materials depending on different values of the penalty term  $p$

### 3 APPLICATION

#### 1.2 Numerical model

The presented topology optimization algorithm is applied to a vertically loaded strip footing foundation. The topology underneath the foundation is to be optimized. The initial width of the foundation is 2 m and the height is 1 m. The load-settlement behavior is simulated in a 2D finite-element analysis. The discretization of the model is shown in Figure 5.

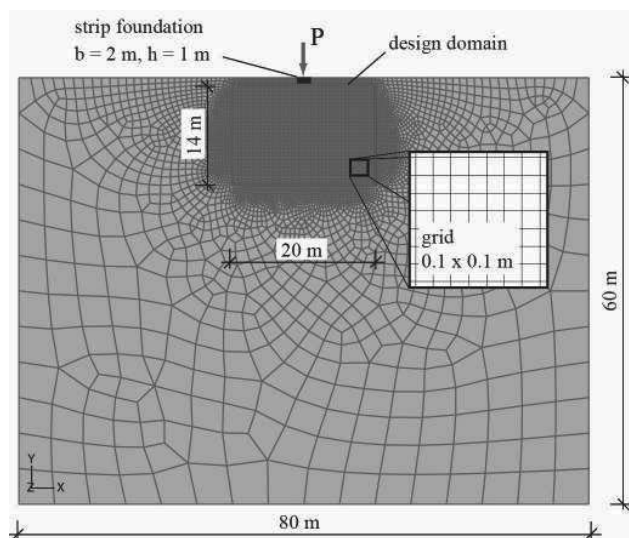

Figure 5. Discretization of the FE-model of a strip foundation with a width of 2 m and a height of 1 m, vertically loaded with 500 kN at the loading point P

The foundation is vertically loaded with 500 kN. The soil and the improved material underneath the strip foundation is modeled using the hypoplastic constitutive model after von Wolffersdorff (1996) with the extension of intergranular strain after Niemunis and Herle (1997). Detailed information can be found in Pucker and Grabe (2011).

$$\frac{\partial c}{\partial \rho_e} = -\frac{\partial c}{\partial \rho_e} p(\rho_e)^{p-1} U_e^T K_e U_e \quad (7)$$

$$\frac{\partial \rho_e}{\partial V} = \frac{\lambda}{\partial V} \frac{\partial V}{\partial \rho_e} \quad (8)$$

#### 1.3 Optimization

Three optimizations are performed at different material volumes. The material volume is 2%, 5% and 10% of the design domain. The design domain is 20 m of width and 14 m of height, see Figure 5.

#### 1.4 Results

In Figure 7 the optimized topologies with 2%, 5% and 10% material volume are illustrated. Regarding the 2% material volume, mainly the area at the foundation edges are compacted. Since the foundation can be considered to be rigid, the optimization results can be explained with the theory of a rigid foundation on an elastic half-space, according to which high stresses will occur at the edges of the foundation. The optimization algorithm compacts the material mainly in these areas.

Figure 6 shows the displacement of the soil underneath the foundation with the unoptimized (Figure 6 a) and the optimized (Figure 6 b) structure with a volume of 5%. The settlements can be reduced up to 50%.

Figure 6. Vertical displacement before (left) and after (right) the topology optimization with 5% material volume

Figure 7. Optimized foundations with a) 2% material volume, b) 5% material volume, c) 10% material volume

The influence of the material volume on the improvement is shown in Figure 8. Figure 8 top shows the material volume over the vertical load  $P$  at different settlements. The applicable load at a settlement restriction about 1 cm cannot be significantly improved using more than 2% material volume. Regarding higher settlement restrictions, the increase of the material volume also increases the applicable load  $P$ .

The same results can be obtained from the load settlement curves of the improved foundations in Figure 8 bottom. The main improvement is reached with a material volume about 2%.

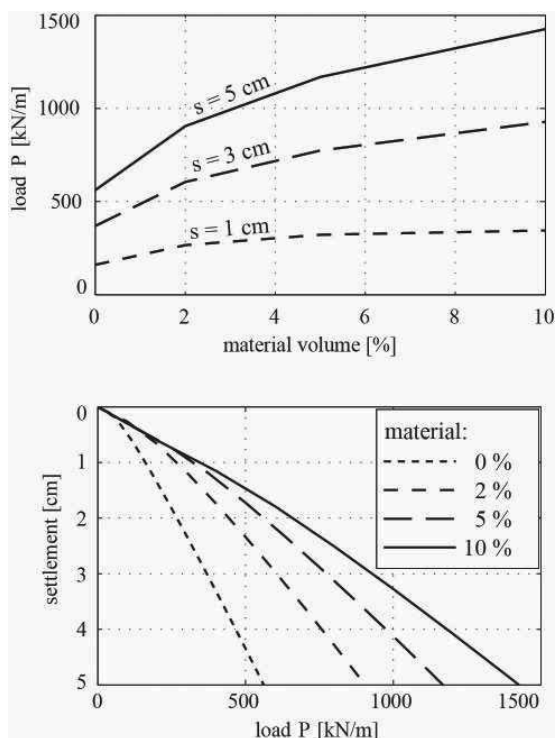

Figure 8. top: load  $P$  over material volume at different settlement restrictions; bottom: load-settlement curves of the optimized foundation topologies

### 1.5 Practical realization

The practical realization of the optimized topologies can be quite difficult. The optimized topologies of the presented example can be realized using the jet grouting method. This method allows the realization of every possible topology restricted by the minimum diameter of a jet grouting body.

Another possibility to realize such topologies is the interpretation of the topologies and the conversion of the topology into standard geotechnical construction parts. The realization of the topology with 2% material can be done using a classical strip foundation topology in combination with micro piles, see Figure 9.

Figure 9. Possible practical realization of the topology with 2% material volume

## 2 CONCLUSION

The application of topology optimization in geotechnical engineering was presented. The applied SIMP-Method is suitable for geotechnical problems. In the presented example, the settlements of a strip foundation could be reduced up 66%.

Topology optimization in geotechnical engineering has a great potential and can lead to innovative and efficient designs.

# Role of the facing on the behaviour of soil-nailed slopes under surcharge loading

## Rôle du parement sur le comportement des pentes de sol cloué sous surcharge

Sanvitale N., Simonini P., Bisson A., Cola S.

Department of Civil, Environmental and Architectural Engineering - University of Padova - Italy

**ABSTRACT:** Soil nailing is an economic and efficient method to reinforce soils, involving the insertion of threaded bars into natural unstable slope for increasing the overall stability or into cut slopes during the top-down process of excavation. The retained soil, the resisting reinforcements and the external facing are the main components of a soil-nailed structure. Their composite interactions determine the performance of soil-nail construction in terms of deformations and stability. Even if the international codes deal about the possibility of use rigid or flexible external facing, the role of facing stiffness is not sufficiently studied and evaluated. To this aim, some tests with various facing types, differing in stiffness and continuity, were carried out so far in 1g small scale physical model. The experimental results show the importance of both flexional and axial stiffness of facing in controlling the deformation of the wall during excavation and the maximum surcharge applicable at the rear of wall.

**RÉSUMÉ:** Le clouage du sol est une méthode économique et efficace pour renforcer le sol en place: il consiste en l'insertion de barres d'acier filetées ou d'autres barres dans les pentes naturelles instables ou dans des talus au cours du processus de l'excavation pour augmenter la stabilité globale. Le sol soutenu, les barres résistantes et le parement extérieur sont les principales composantes d'une structure du sol cloué. Leurs interactions mutuelles déterminent la performance du *soil nailing* en termes de déformations et de stabilité. Même si les codes internationaux considèrent la possibilité d'utiliser des parements extérieurs rigides ou flexibles, le rôle de la raideur du parement n'a pas été suffisamment étudié et évalué. Avec ce but ont été réalisées des épreuves dans un modèle physique avec des parements différents en rigidité et continuité. Les résultats expérimentaux soulignent l'importance de la raideur en flexion et en traction-compression du parement extérieur dans le contrôle de la déformation de la paroi pendant l'excavation, et la valeur maximale de la charge applicable à l'arrière du mur.

**KEYWORDS:** soil nailing, facing, retaining wall, soil reinforcement, physical model.

## 1 INTRODUCTION

Soil nailing is an economical and efficient reinforcement technique used as a remedial measure in unstable natural slopes or as retaining structure for excavated slopes. In comparison with other retaining structures, soil nailing permits to reduce the excavated soil volume, saving construction materials and realization time. Its first applications were proposed in France for the Couterre project (Plumelle et al. 1990) and in Germany (Stocker 1976). Even if many studies and researches have been already performed and several national codes or guide lines exist, the role of facing in controlling the deformation of excavated front or the slope overall stability is not completely understood yet.

On this matter, the new code EN 14490:2010 indicates the possible use of three types of facing which are:

- *hard facing* which has to fulfil the function of stabilizing the slope between the nails and shell therefore be dimensioned to sustain the maximum expected destabilizing forces;
- *flexible facing* designed to provide the necessary restrains to the areas of slope face between the bearing plates as well as the erosion control;
- *soft facing* with the primary function of controlling slope erosion in conjunction of vegetation.

Even if the EN 14490:2010 reports some examples for the three types of facing, it does not give precise indications on how to evaluate the forces applied by soil on facing or the stiffness of facing.

In order to improve the understanding of the role of facing on the resistant mechanisms of soil nailing, this paper presents

the results of an experimental program carried out on a 1g small scale physical model of sandy slope reinforced with soil nailing and brought to collapse by surcharge loading: in the tests six facings, differing for continuity and stiffness, were utilized to restrain the soil between nails.

## 2 PHYSICAL MODEL

The model face is 39.5 cm wide and 40 cm high, with a wall dip angle of 80° (Figure 1). The soil is medium-fine sand from Adige river with the following characteristics (Gottardi and Simonini 2003): mean particle diameter  $D_{50} = 0.42$  mm, non-uniformity coefficient  $C_u = D_{60}/D_{10} = 2.0$ , specific bulk weight  $G_s = 2.71$ , minimum and maximum dry specific weight  $\gamma_{d,min} = 13.6$  kN/m<sup>3</sup> and  $\gamma_{d,max} = 16.5$  kN/m<sup>3</sup>, peak friction angle  $\phi_{peak} = 42-43^\circ$  and critical friction angle  $\phi_{crit} = 35^\circ$ .

The sand is prepared in homogeneous layers into a caisson with pluvial deposition method reaching a relative density of about 85%. During deposition the caisson is maintained inclined at 20° to deposit homogeneously the sand also at rear of facing and to simplify the nail installation. In the meanwhile, the cover is fixedly bonded in vertical position, using four wooden blocks behind which will be subsequently removed to simulate the excavation.

The deposition is temporarily stopped to install the nails in 4 horizontal lines and 3 vertical lines, with spacing  $s_v = 10.2$  cm and  $s_h = 13.2$  cm respectively.

The nails are 32.5 cm long aluminium tubes, with an external diameter of 6 mm and covered with 1 mm thick layer of glued Adige sand. They are perpendicularly connected to the

Figure 1 Perspective view of 1g physical model.

facing with a 1.2 cm annular rod and a small steel pin.

The monitoring system includes:

- A load cell between to the vertical jack and the plate to measure the load;
- Three vertical displacement transducers recording the plate settlements;
- A digital camera taking lateral images of the model during the entire test. By applying the Particle Image Velocimetry (PIV) technique (White et al. 2003) to the image sequences it is possible to reconstruct the evolution of displacement during the test;
- A laser scanner for monitoring the frontal displacement of the face at some significant load steps. Since the scanner takes about 1 min to complete the scansion, the loading sequence must be temporarily stopped. A small load reduction, due to the occurrence of the soil viscous strains, was observed in this short time interval;
- Eight strain gauges, glued pair by pair, at 2.3, 10.4, 18.5 and 26.7 cm from the face, on the nails located along the central vertical section at 15.3 and 25.4 cm from the top (the central ones). They permit to reconstruct the distribution of axial strain and, consequently, of axial stress along nails.

In order to evaluate which stiffness – i.e. the axial or the flexional ones - mostly influences the soil nailing behaviour during excavation and subsequent plate loading, six tests were performed with different facing types (Table 1 summarises the geometrical and mechanical properties of the various coverings). Four facings, covering the entire excavated front, were: *a*) 4 mm-thick plate of Polymethyl methacrylate (PMMA); *b*) a 0.25 mm-thick sheet of brass (BRASS); *c*) a steel mesh formed by 1-mm wires, perpendicularly welded at 6 mm spacing (MESH); *d*) a steel net formed by 0.24 mm-diameter wires, perpendicularly woven (NET). Three of these continuous coverings have an axial stiffness with the same order of

magnitude but a flexional stiffness decreasing about one order from one to another facing, while the fourth is very deformable both in axial and flexional sense.

The other ones are two discontinuous facing constituted by rectangular tiles in PMMA (obtained by cutting a PMMA cover like that used in test *a*): in these cases the covering ratio, defined as the ratio between the total covered area and the total extension of facing, are respectively equal to 95% (PMMA95) and 25% (PMMA25). Due to this discontinuity the axial stiffness vanishes, so these covers are flexional stiff (like the test *a*) but without any axial stiffness.

Since the soil forming the model is dry sand without cohesion, to avoid the collapse of sand among the tiles or across the mesh holes, a very light and low-resistant geo-synthetic behind them was set up. The same geo-synthetic was also inserted at the rear of the other facings to reach homogeneous test conditions.

After the models being completely set up, they were driven to failure in three steps: 1) application of a uniform load  $q$  of 24 kPa on the plate; 2) removing one by one of four wooden blocks, simulating the front excavation; 3) application of an increasing uniform load on the plate up to failure.

### 3 MODEL RESPONSE DURING EXCAVATION

Figure 2 depicts the vertical displacements of the plate,  $\Delta y_p$ , during the 4 steps of excavations in the all the tests. Even if the plate horizontal displacements,  $\Delta x_p$ , (obtained from the PIV analysis of digital images) are not reported here for brevity, they show a similar trend with the same magnitude order of vertical settlements – i.e.  $\Delta y_p/\Delta x_p \approx 1$ . Moreover, since the plate is located just at the rear of facing, the horizontal plate displacement may be considered equal to the horizontal displacement of the front tip.

Note that the vertical displacement does not exceed 0.5 mm (equivalent to 0.13% of the slope height) in tests *a* and *b* with very rigid facings (PMMA and MESH), while the maximum displacement, equal to about 2 mm and equivalent to 0.5% of the height, is observed in the tests *d* and *e* with very deformable facing (NET and PMMA25).

It is also interesting to observe that in the test with PMMA95, with discontinuous covering, the displacement does not exceed the 0.27% of the height: this means that the high flexional stiffness of PMMA tiles prevents the soil near to the face to move laterally.

Figure 3 reports the tensile force distribution along the monitored nails at the end of the excavation. Even if the tensile force is determined in few points, it is possible to recognize the typical bell-shaped distribution observed in many applications and described in the international practical guides (i.e. FWHA 2003, Geoguide7 2008). As known, the slope of the lateral segments depends on the shear stresses mobilized at the interface soil-nail in the active and passive zone respectively.

Table 1. Mechanical characteristics of facings adopted in the physical model.

Model	Facing	Covering ratio (%)	Thickness/ Wire Diam. (mm)	Wire spacing (mm)	Young modulus E (GPa)	Axial stiffness EA/m (N/mm)	Flexional stiffness EJ/m (Nmm <sup>2</sup> /mm)
a	PMMA	100	4	-	3.2	12800	17066.67
b	MESH	100	1	6	210	26180	3318.06
c	BRASS	100	0.25	-	126	31500	236.25
d	NET	100	0.24	1.02	70	3105*	22.66
e	PMMA95	95	4	-	3.2	-	-
f	PMMA25	25	4	-	3.2	-	-

\* The axial stiffness of canvas is the mean values obtained from to traction tests performed on two 178mm x 25mm samples.

Figure 2. Average plate vertical displacement during four excavation steps in all the tests.

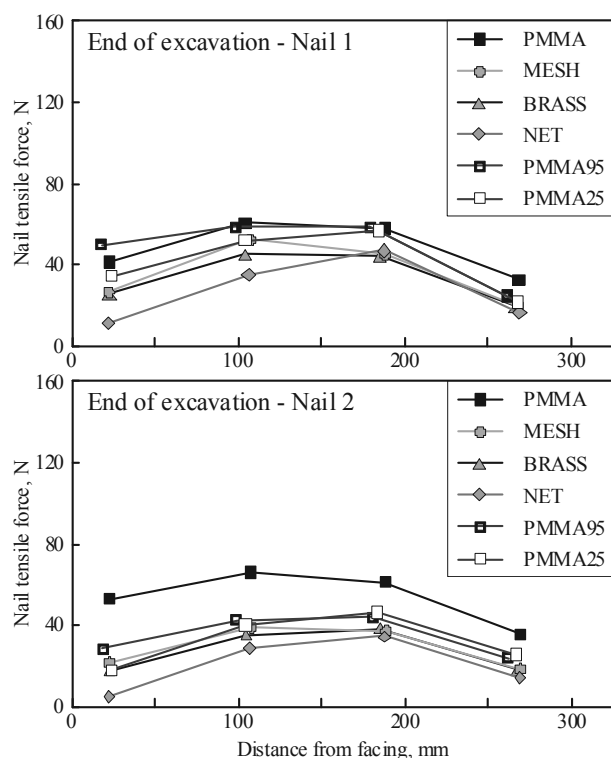

Figure 3. Distribution of tensile force along the monitored nails at the end of excavation: (a) upper nail; (b) lower nail.

The stiffness of facing strongly influences the characteristics of tensile force distribution, such as the slope of two lateral segments, the tensile force at the connection with facing,  $N_{head}$ , and the location  $X_{max}$  of maximum traction,  $N_{max}$ .

The highest  $N_{head}$  is reached in tests *a* and *e* (PMMA and PMMA95), with  $N_{head}$  gradually decreasing according to the facing deformability: the lowest values are due to tests with NET and PMMA25. On other hand, the difference  $N_{max} - N_{head}$  and consequently the slope of segment in the active zone, is less for tests with PMMA and PMMA95, gradually increasing with facing deformability. Finally,  $X_{max}$  is located closer to the face in tests with PMMA and PMMA95, while it moves itself from face using deformable covering (NET and PMMA25).

This means that if a rigid facing prevents the soil behind the face to dilate, limiting, as previously explained, the face horizontal displacements. In addition it also reduces the relative soil-nail displacement in the active zone and the increase of shear stress mobilized at this interface. On the contrary, to reduce the face deformation, the nails have to be more stressed by higher soil pressure acting at the rear of facing, because the

soil could not reach the active state condition with the mobilization of the minimum horizontal stress.

#### 4 MODEL RESPONSE DURING PLATE LOADING

Figure 4 plots the load applied to the plate during the phase *c* vs. the mean vertical displacements of the plate. Temporary reductions of the load are evident in the graph and they are due to the temporary stops of loading piston for performing the laser scanner of the front.

Figure 5 compares the spatial distribution of the cumulated shear strains at collapse in tests with PMMA, NET and PMMA25 (for brevity we choose only the most meaningful images): the shear strain distribution is determined by applying the PIV analysis to the lateral images of models.

In all the model tests, failure appears to be combined with localization of shear strain along one or more narrow bands. The mostly well-defined band moves from the plate edge (the one opposite to the face) towards the face base intercepting all the nails and delimiting the wedge pushing on facing: the wedge is characterized by a size related with the maximum load reached in the test: the greater is the maximum load, the larger is the wedge. Other bands, less clear, individuate a wedge like those that typically form below shallow foundations.

Figure 6 plots the distribution of tensile force along the monitored nails when a load of 5,45 kN is applied on the plate: note that at this load level the model *d* is approaching the collapse, and some problems affect the strain-gauge readings (localization of plastic strain in nail n.1 and detachment of one strain-gauge in nail n.2) and the correct evaluation of tension value. Moreover, data from test PMMA95 are not reported in Figure 6, because some problems occurred in the electrical connections induce to consider them not reliable.

These results permit to point out the important role played by the facing. The maximum load supported by the retaining system with rigid facing PMMA,  $P_{max,a}$ , is about five times greater than the load supported in test with NET,  $P_{max,d}$ , that represents the minimum load measured in all the tests. Other models support loads in the range  $0.83-0.97P_{max,a}$  with higher values in tests with MESH and PMMA95, the most rigid covers.

From the comparison suggested in Figure 6 it is evident that the collapse of model *d* is due to the overcoming of the pull-out resistance in the passive zone of soils. The relative soil-nail displacements, cumulated in the active zone as consequence of facing buckling, induced the increase of tensile gradient in the section of nails close to the face. Consequently, also the maximum traction increases significantly:  $N_{max}$  in test *d* is 3-4 times greater than that determined in all other tests. This high tensile force has to be compensated by the frictional resistance along the nails in the passive zone. This is evident from Figure 6, because the slopes of the tensile profile in the most internal part of the nails are greater than those characterizing the results

Figure 4. Load on the plate vs. mean settlements during loading phase up to collapse.

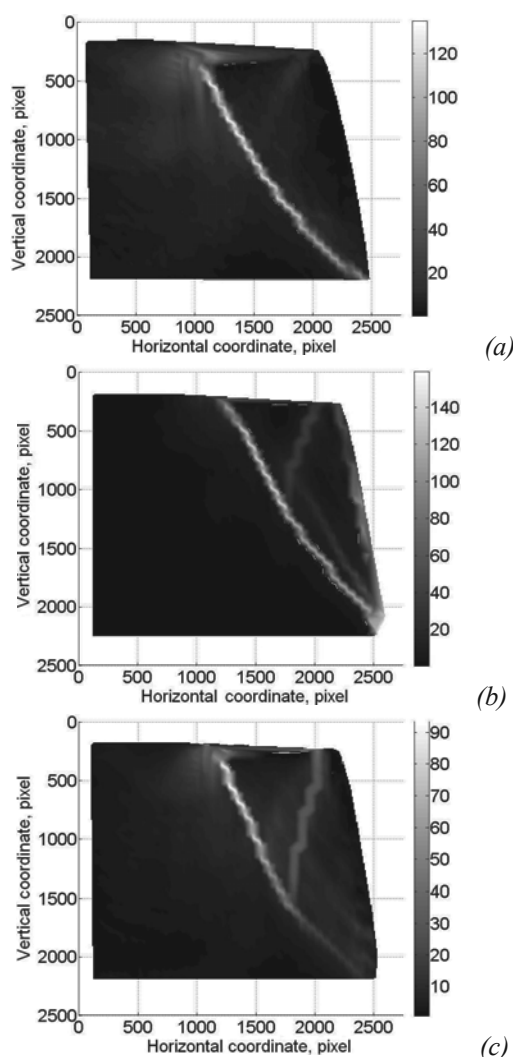

Figure 5. Total shear strain distribution at the face collapse, determined by mean of PIV in tests with PMMA (a), NET (b) and PMMA25 (c).

of other tests. It is important to note that the points marked by an asterisk in Figure 6 are largely overestimated, because approaching the failure the nails underwent to large and concentrated flexional plastic strains, also for the presence of rupture wedge of shallow foundation, and, in this strain state the relationship strain-stress is not linear yet.

Of course the tensile force distributions along nails for all the tests at failure are similar to those recorded for model *d*, even if they are not here reported for sake of brevity.

## 5 FINAL REMARKS

From the experimental results discussed above it is possible to observe that both flexional and axial stiffness influence the performance of a soil nailing system in excavation and at collapse. If the facing has no continuity, its flexional stiffness can hinder the front deformation during excavation, thus limiting the mobilization of shear stress along nails. In addition, if the facing is flexionally deformable but characterized by low axial deformability, horizontal displacements of the front too can be controlled. In both of the cases, at the end of excavation, the system has still a high level of safety in relation to the global stability problem. On the contrary, the largest deformations accumulated with excavation can reduce the safety margin.

Figure 6. Distribution of tensile force along the monitored nails when the load on plate is equal to 5.45 kN (collapse load of test with NET): (a) upper nail; (b) lower nail. Notes: 1) the tensile data indicated with asterisk (\*) are determined from strain-gauge readings at a load of 5.30 kN because at greater loads the nails experimented plastic strains in these positions; 2) The trends indicated with (?) are only presumed, not measured, due to the detachment of the 2<sup>nd</sup> strain-gauge.

## 6 ACKNOWLEDGEMENTS

We want to thank the Dalla Gassa s.r.l. (Cornedo Vicentino, Italy), which sponsor this research, and Dr. D.Pilotto and M.Miuzzi for the valuable help given in the experimental tests.

# Comparative study of different deep excavation retaining systems

## Etude comparative de différents systèmes de soutènement de fouilles profondes

Josifovski J., Gjorgjevski S.

Department for Geotechnics, Faculty of Civil Engineering-Skopje, University Ss. Cyril and Methodius - R. Macedonia

**ABSTRACT:** In the past period a building expansion and rapid construction in highly urbanized city centre of Skopje (capital of the R. Macedonia) has been witnessed. In most cases the structures are small administrative buildings which do not exceed 800m<sup>2</sup> with underground often used for offices or parking. This has been an inspiration to investigate the comparative advantages of different deep excavation retaining systems. In fact three designer tasks, very similar by many parameters, had been used to draw the general conclusions. The selected construction sites are located closely to each other, thus share similar ground conditions. The following retaining systems were considered: (1) system of soldier H piles with lagging, (2) reinforced concrete diaphragm wall, (3) secant pile wall with primary (reinforced concrete) and secondary (concrete) piles. Although systems are different in general they can still be compared, especially from the economic point of view. All retaining systems had been calculated numerically and controlled according to the Eurocode provisions. The concluding remarks offer a preferred solution for underground construction on narrow and build-up sites.

**RÉSUMÉ:** Le centre-ville très urbanisée de Skopje (capitale de la république de Macédoine) a été témoin ces derniers temps de nombreuses constructions de bâtiments neufs. Dans la plupart des cas, ce sont de petits bâtiments administratifs qui ne dépassent pas 800m<sup>2</sup> avec des sous-sols souvent utilisé pour des bureaux ou le parking. Cela a été l'occasion d'enquêter sur les avantages comparatifs des différents systèmes de soutènement de fouilles profondes. En fait, trois principes de soutènement, très semblables par de nombreux paramètres, ont été utilisés pour tirer des conclusions générales. Les chantiers de construction sélectionnés sont très proches les uns des autres avec des conditions de sol similaires. Les systèmes de soutènement suivants ont été considérés: (1) Système de poutres en H soudée après-coup, (2) paroi moulée en béton armé, (3) pieux sécants avec pieux primaire (béton armé) et secondaire (béton). Bien que les systèmes soient différents, en général, ils peuvent encore être comparés, en particulier du point de vue économique. Tous les systèmes de soutènement ont été calculés numériquement et contrôlés selon les dispositions Eurocode. Les conclusions offrent une solution pratique pour la construction souterraine en zone densément construite.

**KEYWORDS:** deep excavation, retaining system, supporting elements, finite element analysis.

## 1 INTRODUCTION

The problem of deep excavation in highly urbanized area such as the city centre of Skopje has proved to be quite formidable engineering task. In particular the greater depth and the built-up surrounding make it especially difficult. The ever growing prize of a square meter has led to extensive utilization of the underground. Such an idea has been very attractive for the investors which always look for the most economic solution of the underground works, generally constrained by the excavation depth and retaining system.

The tendency to optimize the structures has been an inspiration for the authors to investigate the comparative advantages of different deep excavation retaining systems and their supporting elements. The objective has been to offer a qualitative study which considers all relevant aspects of the underground construction in urban areas.

The paper presents case studies of three different retaining systems used to secure the excavation pits which do not exceed 800m<sup>2</sup> in base. All of them are located in the area of around 2km, thus share similar ground conditions. There are different limitations and/or specifics on every site, as to the surrounding e.g. existing structures or very frequent streets. The depth of the excavation pit varies from 6.5 to 18m. All retaining systems had been calculated numerically and controlled according to the Eurocode provisions.

### 1.1 System of soldier H piles with lagging

In the first case example a 7m deep pit should be excavated for the construction of the new National theatre. Larger part of the structure has been already finished, only the part adjacent to the street is left to be erected. The excavation pit is rather narrow only 3.05m in width (enlarging to 6.1m) and 36.65m long, see Figure 1.

Figure 1. Site location No.1 in front of the new National theatre.

The task has been to secure the pit from only one side (namely from the frequent street which connects the main city square) allowing undisturbed traffic and pedestrian communication. As solution a temporary structure of soldier H piles with lagging has been proposed. The supporting system uses rickers and struts (positioned on -2.0m and -4.65m from the top) acting upon the foundation of the existing structure. There were several arguments in favour of this solution, foremost it is light and suitable for a temporary structure, does not take a lot of space and last but not least it is relatively cheap.

Figure 2. Site location No.1 with RW as soldier H piles with lagging.

The structure is modular consisted of eighteen soldier H piles placed on every 2m with total length of 7.5m. The piles are embedded with depth 0.5m. A steel IPE 40 profile has been chosen according to DIN 1025 B1.5 and DIN 17100 specifications.

The ground profile from 0 to 3m is defined by a layer of fill with pieces of construction material such as bricks and mortar. From 3 to 7.5m there is clayly silt with smaller pieces of construction debris with the following material properties: unit density as  $\gamma=19\text{kN/m}^3$ , cohesion as  $c=5\text{kPa}$ , angle of internal friction as  $\phi=28^\circ$  and Compressibility modulus as  $M_v=8000\text{kPa}$ . A standard traffic load with  $q=16.67\text{kPa}$  acting on the far away and  $p=5\text{kPa}$  on the nearby strip has been assumed.

The problem is calculated using the finite element method using plane and beam element. The structural elements of the wall are assumed to be linear with smeared stiffness as in equivalent plane-strain model. The soil is discretized by Mohr-Coulomb material behaviour. A plot of the total displacements is shown in the Figure 3.

Figure 3. Shading plot of the total displacements.

The maximal total displacement is 64mm registered in the toe of the wall while on the top(-surface) it is around 10 times smaller.

The results of the analysis of soldier H pile wall are presented in the Figure 4.

Figure 4. Diagram of (a) Active earth pressure, (b) Axial force, (c) Shear force and (d) Bending moment.

The steel cross sections are calculated according to the provisions in EC3 with  $\gamma_s=1.15$ . A steel type „Fe235“ with allowable stress of 204MPa has been used.

The rickers prop the wall at -2.0m and are positioned at angle of 23.5 degrees with length of  $L_k=6.65\text{m}$ . They are designed as a rectangular hollow section [100.50.5. The struts prop the wall at -4.65m with length of  $L_s=6.1\text{m}$ . They are designed to accept compression force using rectangular hollow section [150.100.5. Last but not least, the wooden lagging ( $b=25\text{cm}$ ,  $l=182\text{cm}$  and  $t=12\text{cm}$ ) are positioned over the height of 7m between the soldier piles.

Finally, the global stability is controlled using the so-called *phi-c* reduction procedure. A global factor of safety  $F_s=1.37$  has been obtained which is larger than 1.1 as recommended value for temporary structure.

### 1.2 Top to down construction of system with diaphragm wall

Following the site conditions (see Figure 5) a building with five underground floors with depth of -15.86m should be constructed. From two sides there are existing buildings, one of which is adjacent on six floors and one basement while the other one is 3m away with only two floors and shallow basement. From the third side there is very frequent boulevard which leads to the centre and main city square.

Figure 5. Site location No.2 on M.T. Gologanov boulevard.

The base dimension of the excavated pit are 27.65x11.55m not very large around 320m<sup>2</sup>, but due to the difficult surrounding conditions and the great depth it has been decided to use the top to down approach of construction. The diaphragm wall is considered to be a permanent structural element, which in the first phase carries the horizontal (earth) pressure loads while in exploitation it will be responsible also for the loads from the superstructure. Following the top-down procedure the diaphragm will be supported by the previously constructed RC

slabs, thus enabling the further excavation of the pit. The excavation process and slab support construction is described in Table 1 with respect to the depth  $h$ .

Table 1. Excavation phases

Phase	1	2	3	4	5	6	7
$h$ (m)	0.0	-3.5	-6.11	-8.5	-10.9	-13.9	-15.8

The diaphragm RC segments are 2.5m long and 0.4m width organized as primary and secondary. The base plan with depth and sequence of construction is presented in Figure 6.

Figure 6. Base plan of primary and secondary diaphragm segments.

The depth is 16m only in one section its 18m due to the requirement necessary for elevator equipment. The soil profile is established through set of field and laboratory investigations which were used to define the material properties given Table 2.

Table 2. Soil properties

Type	$h$ (m)	$\gamma$ (kN/m <sup>3</sup> )	$\nu$ (/)	$M_c$ (MPa)	$c$ (kPa)	$\phi$ ( $^\circ$ )
N	-1.0	17.0	0.30	3	5	18
GW	-3.5	19.0	0.32	30	0	32
M	-4.0	22.0	0.27	35	100	30
M	-10.0	24.0	0.26	45	150	32
M	-20.0	24.0	0.26	55	200	34

where  $\gamma$  is a unit weight,  $\nu$  is a Poisson's ratio,  $M_c$  is Compression modulus,  $c$  is cohesion and  $\phi$  is angle of internal friction. They are given for every lithological unit: top layer (N) is a man-made embankment brownish silty clay containing pieces of bricks and roots with a thickness of 1m, followed by layer (GW) is sandy gravel with thickness of 2.5m to 3.7m; continuing as a layers (M) which are Neogene's deposits composed by claylike Marls to highly weathered alveoli. The

underground water is detected at -3.2m below ground surface in layers (GW) while the bottom layers are with low permeability and relatively dry.

In order to obtain more realistic behaviour of the deep excavation process secured by diaphragm wall, the problem has been analyzed using the finite element method. The ground stress-strain state during excavation is determined through a plane-strain finite element model. The soil is discretized as elasto-plastic material using a Mohr-Coulomb definition vis-avis the reinforced concrete wall as a linear material. The spatial discretization had been varied depending on the situation and detailing level but in general triangular plane elements with 15 nodes had been used. Two cross sections both in X-X and Y-Y direction had been discretized and calculated. The structural elements were modelled using three node beam elements, see Figure 7.

Figure 7. Finite element model of X1-X1 section.

The underground structure has been calculated for two loading combinations, namely the construction loading situation with pit excavation (in 6 phases = 1-diaphragm wall + 5-floor slabs) and exploitation situation (with permanent + temporary + seismic loads). In Figure 8 the total displacements of underground structure is presented for the second loading combination.

Figure 8. Total displacement of the soil-structure system in X1-X1 section.

The maximal registered displacement is 14mm with predominantly horizontal component (stiff rocking response) due to the seismic loading. According to the stress-strain distribution the internal quantities of the structural elements had been determined. They were used for structural design of elements such as, diaphragm wall, floor slabs and foundation plate. The reinforcement is determined according to the EC2 for C35/45 and S500 (with  $\gamma_c=1.5$  and  $\gamma_s=1.15$ ). The reinforcement of the diaphragm wall is around  $0.8\%A_c$  (area of concrete section). The 47% of the total reinforcement will be used for the diaphragm wall, 18% for the foundation plate and 35% for the floor slabs.

### 1.3 System of secant pile wall

For the same site (see Figure 5) an alternative solution has been analysed with secant pile retaining wall to secure the excavation pit (27.65x11.55m) but this time with depth of 6.5m. In this scenario only two floors are planned to be constructed using a temporary retaining structure. In the first phase the primary, (reinforced concrete) piles with diameter of 0.6m and length of 7.5m spaced exactly 1.2m should be executed. In the next phase the secondary (concrete) piles with the same diameter but shorter depth of 5.5m are constructed. On the top they are connected by a beam with dimensions 0.6x0.4m as shown in Figure 9.

Figure 9. A plan of the secant pile wall in X1-X1 section.

The problem is discretized using three-dimensional finite element model where the soil profile is identical to the one described in Table 2. For the spatial discretization volume elements are used in combination with nonlinear-plastic material definition for the soil and linear-elastic for the concrete. The calculation is used to determine the stress-strain behaviour of the soil-structure interaction system, hence presented through the total displacement in Figure 10.

Figure 10. Total displacement of the soil-structure system in X1-X1 section.

A maximal earth pressure of 33.7kN/m<sup>2</sup> causes horizontal displacement of 9.8mm, which have been considered as acceptable. Furthermore, the diagrams of internal pile quantities are presented in Figure 11.

Figure 11. Diagram of (a) Axial force, (b) Shear force and (c) Bending moments in the pile.

The values of the maximal internal quantities: bending moment  $M=56.81\text{kNm}$ , shear force  $Q=43.64\text{kN}$  and axial force is  $N=-114.8\text{kN}$ . The pile design has been made using interaction (M-N) diagrams for C30/37 providing the following reinforcement: longitudinal  $14\phi 16$  ( $28.2\text{cm}^2$ ) and stirrups  $\phi 8/20\text{cm}$ . Finally, the global stability is controlled where a safety factor  $F_s=1.55$  is obtained.

## 2 CONCLUSION

The solder H pile wall with lagging is rarely used in our practice, although it is highly efficient and cost effective for situations where there is no ground water. Also a greater depth can be reached when combined with adequate supporting system e.g. tieback. Nevertheless, in Skopje there are few locations with low GWL. Although very formidable the systems with diaphragm wall are seldom used, partially because there is almost no experience nor there has been clear cost-benefit analysis. For a long period of time it has been thought that the costs are very height, which with the present study had proven not to be the case. Combined with the top-down method of construction where the wall is permanent structure according to our analyses remains very cost effective solution. The secant pile wall technique, in contrast, is very often used in our practice, sometimes in combination with anchors when greater depth is needed. It represents formidable solution but usually takes a lot of the available space and construction time, also brings high expenses since it is often a temporary structure.

Finally, when comparing all retaining structures we had come to conclusion that the diaphragm wall represents a preferred solution for underground construction in highly urbanized (build-up) areas and situations with high ground water level as it is usually the case in Skopje.

**ABSTRACT:** The paper presents various use of diaphragm walls for the construction of four-level junction in Warsaw. Diaphragm walls were chosen as a best solution for abutments of 2 viaducts and 1 flyover, foundations (barrettes) under 7 pillars, 60 to 100cm thick retaining walls with total length of over 570 running meters. In the paper detailed technical descriptions, geotechnical conditions, predicted theoretical horizontal and vertical displacements of walls for all mentioned diaphragm wall applications are presented. Finally, the comparison of the results of theoretical analysis and real scale monitoring results (displacements measurements and load tests) in accordance with construction stages is presented and discussed.

**RÉSUMÉ :** Cet article présente différentes utilisations de parois moulées pour la construction d'une jonction de quatre niveaux à Varsovie. Les parois moulées ont été choisies comme une meilleure solution pour les butées de 2 viaducs et 1 voie surélevée, les fondations (barrettes) sous 7 piliers, des murs de soutènement épais de 60 à 100 cm avec une longueur totale de plus de 570 mètres. Dans le document des descriptions techniques détaillées, des conditions géotechniques, les prévisions de déplacements horizontaux et verticaux théoriques des murs pour toutes les applications de parois moulées mentionnées sont présentés. Enfin, la comparaison des résultats de l'analyse théorique et les résultats en vraie grandeur (mesures de déplacements et de tests de charge) de la surveillance conformément aux étapes de la construction est présentée et discutée.

## 1 INTRODUCTION

In Poland nowadays, especially before euro 2012, road network and new motorways connecting Poland and Ukraine with Western Europe are being built. Construction of Warsaw bypass is the place where huge multilevel road junctions are built.

The case discussed in the paper is 3 level road junction consisting of 2 flyovers (indicated as E1, E2 at fig. 1) and 2 viaducts (indicated as W1, W2 at fig. 1). The original building permit design assumed that the abutments and columns were to be founded on large-diameter piles with the diameter 120 and 150 cm. The accompanying RC retaining walls and viaduct abutments were to be erected in traditional formwork. The original design assumed that the embedded part of the junction was to be built with a temporary casing in the form of sheet piling with an RC capping beam at the top. The walls were to be anchored with 1 level of soil nails. Permanent structure was

designed as retaining walls connected with water tight foundation plate. During the execution design stage, due to economical and technological reasons, the solution was much simplified - only diaphragm walls were used for all parts of the structure, i.e. for:

- excavation walls – retaining structures,
- foundations – barrettes of viaduct columns as well as barrettes of columns and abutments of flyovers,
- viaduct abutments – T-shaped diaphragm walls.

The new solution allowed the significant shortening of construction works through the use of diaphragm walls as temporary and permanent structure. Figure 1 presents the general arrangement of the discussed road junction and indicates parts of the structure described in the paper.

In the design stage theoretical displacements and bearing capacities of these structures were calculated. During construction, at each of discussed structure parts, the real

Fig. 1 General arrangement

horizontal displacements and settlements were measured and compared to theoretical values calculated in the design stage. It has allowed an assessment of the correctness of the solution.

## 2 GEOTECHNICAL AND HYDROLOGICAL CONDITIONS

The ground in the land plot consists mainly of Quaternary formations: river sediments and glaciofluvial deposits as well as glacial deposits. In the entire area involved in the investment, the near-surface layers below man-made fills consist of medium-dense and dense sands and gravels reaching down to the max. depth of 18.8 m. Below (the layer roof from 10.6 to -18.8 m), there are glacial clays, deposited in the form of stiff sandy clays, clayey sands and, locally, silty clays. The layer of anthropogenic soils is not very thick: maximum thickness: 2.2m, average thickness: about 0.5-1.00 m.

Within the entire area, a continuous ground water table was found in the layer of glaciofluvial sands. The ground water table was located at about -4.5 m below the ground level. Occasionally, the water table was confined by lenses of cohesive soils.

## 3 DIAPHRAGM WALLS AS A RETAINING WALL

Fig. 2 Typical cross-section of the excavation wall; 80cm thick diaphragm walls, anchored using permanent anchors.

Due to variable embedding of the excavation below the ground level, down to the maximum depth of 10 m below the ground level, diaphragm walls with 3 different thickness values were implemented, namely 60 cm, 80 cm and 100 cm. Moreover, different types of protective measures were implemented to ensure stability of casing walls, i.e:

- temporary ground anchors, 600 kN capacity (cross – section 2-2),
- permanent ground anchors, 600 - 700 kN capacity (cross-sections 3-3, 4-4, 5-5),
- permanent ground anchors in the area of T-shaped D-walls, 700 kN capacity (cross section 6-6).

Some parts of walls remained not supported (cantilever walls) due to the small height of excavation (cross-section 1-1) or possible collisions with pile foundations outside the wall (cross-section 7-7).

In total 148 ground anchors were executed (18 temporary and 130 permanent) and 31 permanent ground anchors for abutments.

Diaphragm walls along the entire perimeter of the facility (including the transversal walls) were embedded at least 1 m down into the impermeable layer, in order to minimise the inflow of water into the excavation (fig 2). Due to unbalanced hydrostatic pressure, the ground slab was anchored with

displacement piles in its central part in the deepest excavation (fig 2).

Diaphragm walls were designed to resist loads resulting from soil pressures and from service loads at the ground surface generated by vehicles and stored materials, amounting to  $q=12,0$  kPa in the zone removed by at least 1.5 m from the wall face, and loads generated by heavy traffic, amounting to  $q=30$  kPa. Additionally, the design considered a load generated with vehicle K located on the roadway located in close vicinity of the diaphragm wall, in compliance with standard PN-85/S-10030 Bridges. Loads.

Static analysis of diaphragm walls were made using dependent pressures method (PAROI). 7 typical calculation cross-sections were verified. Typical results of calculations – bending moments and displacements – are shown at fig. 3. Maximum theoretical values of horizontal wall displacements are as follows:

- cantilever D-wall - 6 mm;
- D-wall and temporary ground anchors - 15 mm;
- D-wall and permanent ground anchors - 12mm;
- T-shaped D-walls - 8mm.

Corresponding bending moments amount to 180 kNm/m up to 700 kNm/m.

Fig. 3 Theoretical values of bending moments and horizontal displacements for 80cm thick D-wall with permanent ground anchors (cross-section 5-5) in the final construction stage.

Benchmarks for geodesic measurements were located on the capping beam of diaphragm walls, spaced every 50 m at the maximum. Measurements were carried out for particular stages of execution of works on site, at least once every month or more frequently.

Construction stages were as follows:

- site preparation, sub-base preparation, construction of guide walls and D-walls with RC capping beam – reference measurement,
- excavation 0,5m below the anchoring level – measurement 1,
- execution and stressing of ground anchors – measurement 2,
- final excavation – measurement 3,
- verification of displacements during the execution of driven piles – subsequent measurements.

Particular attention was paid to measurements of wall displacements in the vicinity of works consisting in driving displacement piles in, in order to anchor the ground slab. In the view of the presence of a layer of silty sands, designers were concerned about the impact of dynamic pile driving on the load-carrying capacity of ground anchors, whose bearing plates are

embedded in these sands. The monitoring of displacements of the capping beams of diaphragm walls showed that their maximum value reached 10 mm for an 80 cm thick wall, anchored with permanent anchors. In the case of other cross-sections, displacements were smaller and reached up to 8 mm. No increased displacements of the diaphragm wall were observed during the process of pile driving.

Design works had to face additional difficulties resulting from the very complex shape of the facility, involving 4 abutments (T-shaped D-walls, cross-section 6-6) and curved walls that encased the roundabout (cross-section 5'-5'). Both the excavation bottom and the top of the walls and the capping beam were located in slopes. Due to this fact combined with variable thickness and varied strut methods, almost every single reinforcing cage of a diaphragm wall was of different type. Therefore, the contractor who constructed diaphragm walls was forced to stick strictly to the schedule of execution of particular sections, without any possibility of introducing changes during the works.

#### 4 DIAPHRAGM WALLS AS FOUNDATIONS FOR PILLARS AND COLUMNS

A foundation on barrettes (parts of diaphragm walls) – instead of large-diameter piles ( $\varnothing$  120/150) implemented in the construction design – was designed for 5 supports of the flyover E1 (4 pillars and 1 abutment) and viaducts pillars – viaducts: W1 and W2 (fig.1). The barrettes – as fragments of diaphragm walls – have a very large base. Therefore, they can transmit very high loads. For this reason, they are very useful for structures subjected to very high loads, as in this particular case of bridge structures.

The replacement, for instance, of the support consisting of 11 piles that were 150 cm in diameter with 6 barrettes resulted in a considerable acceleration of works, which brought about a measurable financial result in this particular case. Typical arrangement of the pillar foundation is shown at fig. 4.

Fig.4 Typical pillar foundation arrangement

Barrettes implemented as foundations for pillars had the following dimensions: 0.6x2.80 m and 0.8x2.8m. They were from 10.0 to 15.0 m long. They transmitted vertical forces reaching the max. value of 7600 kN and the bending moment reaching the max. value of 4996 kNm. In total 44 barrettes were erected.

Internal forces and moments for each barrette were calculated using ROBOT software, modelling supports loaded by a possible most unfavourable load combination. Due to unsymmetrical loading of supports each barrette had different loading (both - compression as well as tension) and different bending moments in both directions.

For each of barrettes additional boreholes were made in order to verify geotechnical conditions. Only then the design of lengths and calculation of bearing capacities of barrettes were made. It was considered that barrettes were founded in the stiff sandy clay layer and the shaft friction was calculated considering 2 geotechnical layers along barrettes, i.e. stiff sandy clays and medium dense to dense fine and silty sands.

Base bearing capacities and shaft frictions were calculated basing on the regulations of PN-83-B-02482 Foundations. Bearing capacity of piles and piles foundations.

A base injection system was designed for all barrettes, in order to ensure as high load-carrying capacity of a barrette as possible, while ensuring minimum settlements. In each support, one barrette was selected to be subjected test vertical loads, supposed to confirm the adapted geotechnical parameters were correct. The results of test loading showed that the load-carrying capacity of barrettes was higher than necessary, while the settlements were smaller than admissible.

Vertical loading tests of barrettes was carried out for 6 barrettes that were gradually loaded up to the maximum of 150% of the calculation force. After reaching 100% of design load the barrettes were unloaded in order to measure the resulting permanent settlement. Analogical procedure was used after reaching 150% calculation force. Permanent settlements at the 150% force (i.e. 5286 - 10397 kN) did not exceed 4 mm, while they reached 2 mm for 100% of the calculation force (i.e. 3524 - 6931 kN). The barrette (dimensions: 0.6x2.8m, length: 13.1m) subjected to the greatest load experienced maximum settlement of 4.35 mm at the load of 10397 kN, where permanent settlement reached 2.91 mm. The results of settlement measurements during test loading of barrettes are compiled in table 1.

Table 1. The results of vertical loading tests of barrettes – settlements.

No.	Dimensions	Settlements for 100%Q		Settlements for 150%Q	
		temporary	permanent	temporary	permanent
B8	2,8x0,8 x10,0m	6001 kN		9002 kN	
		3,96mm	1,61mm	7,54 mm	3,53 mm
B12	2,8x0,6 x10,0m	3524 kN		5286 kN	
		1,33mm	0,75mm	2,82mm	1,71mm
B18	2,8x0,6 x10,0m	5889 kN		8834 kN	
		2,36mm	1,32mm	4,56mm	2,69mm
B31	2,8x0,6 x12,0m	5989 kN		8984 kN	
		2,53mm	1,32mm	5,29mm	3,09mm
B24	2,8x0,6 x13,1m	6931 kN		10397 kN	
		1,99mm	1,08mm	4,35mm	2,91mm
B41	2,8x0,6 x14,0m	4594 kN		6891 kN	
		1,80mm	1,14mm	4,17mm	2,84mm

As a part of interpretation of the test loading results auxiliary graphs were plotted as shown at fig. 5, in order to help calculate the bearing capacity of barrettes.

Fig. 5 Static load test result

### 5 DIAPHRAGM WALLS AS VIADUCT ABUTMENTS

The contour of the casing of the lowest level of the junction contained 4 viaduct abutments (viaduct W1 and W2). They were designed as 80 cm thick T-shaped diaphragm walls. Additional limitations were imposed for these fragments of diaphragm walls with respect to both horizontal and vertical displacements, caused by the selection of appropriate bearings. Additional permanent anchors were implemented – fig. 6, in order to minimize horizontal displacements of walls. In total, in the area of viaduct abutments, 31 permanent ground anchors of the 700kN capacity, were erected.

Fig. 6 Typical T-shaped D-wall cross-section for the W2 viaduct abutment.

Due to the fact that abutments were founded in the same stiff sandy clay layer as remaining barrettes made for the foundations of pillars, additional, special loading tests were not carried out for the T-shaped diaphragm walls. Bearing capacities of T-shaped barrettes were calculated by interpolation of the results of tests loadings of individual barrettes executed in the near vicinity of abutments. Additional limitations were imposed for T-shaped diaphragm walls with respect to horizontal displacements. In order to comply with limitations and minimize horizontal displacements of walls additional permanent anchors were implemented. The design load of permanent anchors was verified during acceptance tests. Each anchor was stressed up to 125% of its design load and after stabilization of creeping it was blocked at 80% of its design load. There were no excess permanent or elastic strains of anchor tendons measured, in accordance with regulations of

the code: PN-EN 1537 Execution of special geotechnical works. Ground anchors.

### 6 SUMMARY AND CONCLUSIONS

The results of diaphragm walls (as retaining walls) horizontal displacements measurements confirmed the correctness of static analysis of walls and prediction of their displacements, both made during design stage. Maximum value of horizontal displacement reached 10 mm for an 80 cm thick wall, anchored with permanent anchors and it didn't exceed neither theoretical nor permissible values. In the case of all other cross-sections, displacements were smaller and reached up only to 8 mm.

The results of vertical loading tests made for the barrettes confirmed the value of calculated theoretical bearing capacity being 7600 kN to be correct.

There were no significant horizontal displacements of T-shaped diaphragm walls noted (measured).

The new solution applied in the execution design (replacing the original one from the building permit design) was correct and resulted in significant savings due to the use of only one technology for the foundation and the retaining system (diaphragm walls) of the entire 3 level road junction construction. Most of the savings were obtained as a result of significant shortening of construction works.

# Effects of plane shapes of a cofferdam on 3D seepage failure stability and axisymmetric approximation

Effets des formes planes d'un batardeau sur la stabilité après une rupture par infiltration tridimensionnelle et sur l'approximation axisymétrique

Tanaka T., Kusumi S., Inoue K.

*Department of Agricultural and Environmental Engineering, Kobe University, JAPAN*

**ABSTRACT:** In the excavation of soil with a high ground water level, seepage failure is often a problem. For excavations over a large area, seepage failure is a problem in two dimensions. In contrast, the more the region of a cofferdam is restricted, the greater the seepage flow concentrates three-dimensionally. This three-dimensionally concentrated flow lowers the safety factor for seepage failure more than under the two-dimensional condition. In this paper, seepage failure experiments were conducted under three-dimensional flow conditions for various cases of penetration ratios of sheet piles and analyses of FEM seepage flow and stability against the seepage failure of soil were carried out using the Prismatic failure concept 3D. The critical hydraulic head differences obtained by experiments and the theoretical values are examined for several cases. Effects of plane shapes of a cofferdam on the theoretical critical hydraulic head differences and axisymmetric modeling of three-dimensional seepage failure are also discussed.

**RÉSUMÉ :** Dans le cas de l'excavation d'un sol où le niveau des eaux souterraines est élevé, la rupture par infiltration constitue souvent un problème. Lorsque l'excavation est effectuée sur une grande surface, la rupture par infiltration devient alors un problème en deux dimensions. En revanche, plus la zone du batardeau est limitée, plus le flux d'infiltration se concentre en trois dimensions. Or, comparé à ce qui se passe dans un contexte bidimensionnel, ce flux concentré de manière tridimensionnelle réduit davantage le facteur sécurité lié à une rupture par infiltration. Dans cet article, nous décrivons les expériences sur la rupture par infiltration menées dans les conditions d'un flux tridimensionnel pour divers ratios de pénétration dans des palplanches. Nous y rapportons aussi les analyses du flux d'infiltration et de la stabilité suivant le modèle FEM par rapport à la rupture par infiltration du sol, menées à l'aide d'un concept prismatique de rupture en trois dimensions. Nous avons examiné, pour plusieurs cas, les rapports de niveau hydraulique obtenus dans les expériences et la théorie. Les effets des formes planes d'un batardeau sur les rapports de niveau hydraulique critiques d'ordre théorique et la modélisation axisymétrique de la rupture par infiltration tridimensionnelle y sont également évoqués.

## 1 INTRODUCTION

In the excavation of soil with a high ground water level, sheet piles or diaphragm walls are often used to retain soil and water. Under such conditions, seepage flow occurs through the soil, and seepage failure is often a problem. For excavations over a large area, seepage failure is a problem in two dimensions. In contrast, the more the region of a cofferdam is restricted and the deeper the penetration of the sheet piles, the greater the seepage flow concentrates three-dimensionally within it. The three-dimensionally concentrated flow lowers the safety factor for seepage failure more than under the two-dimensional condition (Nikkei construction, 2001). Such a case must be treated in three dimensions.

In this paper, seepage failure experiments were conducted under three-dimensional flow conditions for various cases of total depths of soil,  $T$ , and penetrated depths of sheet piles,  $D$ , with a plane shape of a cofferdam of 1:2. Analyses of FEM seepage flow and stability against the seepage failure of soil were carried out using the Prismatic failure concept 3D. The hydraulic head differences at deformation in the experiment,  $H_p$ , and theoretical critical hydraulic head differences based on the Prismatic failure concept 3D,  $H_c$ , are examined for the same cases. The theoretical critical hydraulic head differences for various plane shapes of a cofferdam, e.g., short to long length of 1:1, 1:2, 1:3, and 1:4, were calculated, and the effects of plane shapes of a cofferdam on the theoretical critical hydraulic head differences are discussed. The axisymmetric modeling of three-dimensional seepage failure is also discussed.

## 2 THREE DIMENSIONAL EXPERIMENTS

### 2.1 Test apparatus

A test apparatus was designed to study 3D seepage failure of soil within a cofferdam as shown in Figure 1. In the experiment, one quarter of the three dimensional region is examined. The seepage tank is made of stainless steel, 1,000mm wide, 1,300mm high and 1,000mm deep. The front of the tank is made of transparent glass for observation of the behavior of soil particles inside and the right side of the tank is equipped with 283 piezometer holes for the measurement of pore water pressures. A cofferdam is mounted on the right/front side with surface size 200mm×400mm. Seepage water flows through a sand model under the difference in water head  $H$  between the downstream water level at the top of the right-hand-side drainage hole and the upstream water level kept constant by the constant-head device.

### 2.2 Test material and test cases

In seepage failure experiments, uniform fine sand (Lake Biwa Sand 3: under 850 $\mu$ m mesh, 50% grain size  $D_{50}$ =0.283 mm, specific gravity  $G_s$ =2.67 and uniformity coefficient  $U_c$ =1.40) was used. Seventeen tests E0301 to E0317 were conducted. The following notation is used:  $T_1$  and  $D_1$  are the total depth of soil and penetration depth of sheet piles on the upstream side,  $T$  and  $D$  are those on the downstream side,  $d$  ( $=D_1-D$ ) is the excavation depth for the excavation model, and  $D_r$  is the relative density of soil. For a no-excavation model,  $T_1=T$ ,  $D_1=D$  and  $d=0$  are applied.

Figure 1. Schematic sketch showing test apparatus

### 3 EXPERIMENTAL RESULTS

#### 3.1 $H-Q_{15}$ curve and change in shapes of soil surface

Figure 2 shows the  $H-Q_{15}$  curve for test E0317, where  $Q_{15}$  is the discharge at 15 degrees Centigrade. It is observed from Figure 2 that  $Q_{15}$  increases linearly with increasing  $H$  until a certain value  $H_d$ .  $H_d$  value is referred to as the hydraulic head difference at which the  $H-Q_{15}$  curve diverts from linearity. As stated below, at almost the same point as  $H_d$ , the soil surface begins to settle on the upstream side and rise on the downstream side. This is because, just at this point, the soil loosens on the downstream side, the void space enlarges, permeability of the soil grows larger, and discharge increases non-linearly with  $H$ . As  $H$  increases beyond  $H_d$ ,  $Q_{15}$  becomes larger with increasing  $H$  more steeply than before, and the ground finally collapses at the hydraulic head difference at failure  $H_f$ .

Figure 2.  $H-Q_{15}$  curves for test E0317

The heights of the soil surface are measured at several chosen points along the measurement line shown in Figure 3. The measurement line is a bisector of the right angle of the inside corner of the rectangular diaphragm wall. Figures 4 (a)-(c) show the changes in shape of the surface of the sand model along the surface height measurement line with increase in  $H$ , from  $H=4.81$ cm at the first step to  $H=36.78$ cm at one step before failure. The model sand is in a stable state at early steps of  $H$  (Figure 4(a)). When  $H$  increases beyond a certain value  $H_y$ , the model sand changes in shape near the sheet pile wall. The surface of the soil in the vicinity of the sheet pile wall subsides on the upstream side and rises on the downstream side (Figure 4(b)). The value of  $H_y$  is referred to as the hydraulic head difference at onset of deformation. It was found from a series of

Figure 3. Measurement line of the height of soil surface

(a) At the early step of  $H$  ( $H=4.81$ cm)

(b) At the  $H$  value just beyond  $H_y$  ( $H=30.06$ cm)

(c) At the one step before failure ( $H=36.78$ cm)

Figure 4. Changes in shape of surface of sand model along the surface height measurement line with increase in  $H$

Figure 5. A close-up photo of the upstream inverse conical shape at  $H=36.78$ cm (E0317)

tests that the experimental results lead to the interesting conclusion  $H_y = H_d$ .

Subsidence of the upstream soil surface and rising of the downstream soil surface proceed with steps of increasing  $H$ . The upstream soil surface is an inverse conical shape centered at the outer corner of the rectangular diaphragm wall. A close-up photo of the upstream inverse conical shape is shown in Figure 5 at  $H=36.78\text{cm}$  (E0317). The rise in the downstream soil surface occurs uniformly within a certain width from the sheet pile wall. As  $H$  increases and approaches  $H_f$ , the upstream subsidence shows a clear inverse conical shape, and sand particles are observed to roll down the slope of the upstream soil surface (Figure 4 (c)).

#### 4 STABILITY ANALYSES –RESULTS AND DISCUSSIONS–

##### 4.1 Prismatic failure concept 3D

The Prismatic failure concept 3D presented by Tanaka et al. (2012) is used for estimating the stability against seepage failure of soil. In the Prismatic failure concept 3D, we assume that the body of soil lifted by seepage water has the shape of a prism with a certain height and width adjoining the sheet pile wall. The rise of the prism is resisted by the submerged weight,  $W'$ , and frictions  $F_{RL}$  and  $F_{RCR}$  on the left and right sides and  $F_{RF}$  and  $F_{RCB}$ , on the front and back sides. The safety factor  $F_s$  with respect to the rise of the prism, which is subjected to the excess pore water pressure on its base,  $U_e$ , is given as:

$$F_s = \frac{W' + F_{RL} + F_{RCR} + F_{RF} + F_{RCB}}{U_e} \quad (1)$$

For the hydraulic head difference  $H$  between up- and downstream sides, safety factors,  $F_s$ , are calculated for all of the prisms within a cofferdam. The safety factor  $F_s$  takes the minimum  $F_{s\min}$  for a certain prism among all of the prisms. The calculation is iterated for another hydraulic head difference,  $H$ , until the condition whereby  $F_{s\min}$  becomes nearly equal to 1.0 is found.  $H=H_c$  at which the condition  $F_{s\min}=1.0$  is applied is defined as the critical hydraulic head difference. The prism with a value of  $F_{s\min}=1.0$  among all of the prisms for  $H=H_c$  is defined as the critical prism. We could say that the critical prism is separated from the underlying soil at its base when  $H$  exceeds  $H_c$ . Safety factors using the Prismatic failure concept 3D when considering frictions are discussed below.

##### 4.2 Relationship between hydraulic head differences $H_c$ (by theory) and $H_y$ (by experiment)

For Lake Biwa sand 3 of  $D_r=50\%$ , the theoretical hydraulic head difference by the Prismatic failure concept 3D,  $H_{PF}$  [Tanaka et al. 2012] is analyzed taking the anisotropy of the test sand to be  $k_{xy}/k_{zz}=1.20$  [Tanaka et al. 2011]. Figure 6 shows the relationship between  $D/T$  and  $H_c\gamma_w/T\gamma'$  for a no-excavation model. The experimental results are also plotted in Figure 6. It is observed from Figure 6 that the calculated critical hydraulic head differences  $H_{PF}$  are very close to the measured  $H_y$ . The Prismatic failure concept 3D thus proved to be a useful method for calculating critical hydraulic head difference at the onset of deformation of soil within a cofferdam. The same is true of the excavation model.

##### 4.3 Effects of surface shape of a cofferdam on $H_c$

Let us consider a cofferdam whose surface shape is rectangular with the shorter length at  $B$  and longer length at  $L$  (see Figure 7). Four cases of  $B:L=1:1, 1:2, 1:3$  and  $1:4$  are analyzed for constant values of  $B=0.2\text{m}$  and  $W=0.8\text{m}$ . Figure 8 shows the relationship between  $D/T$  and  $H_c\gamma_w/T\gamma'$ . It follows from Figure 8 that:

Figure 6. Relationship between  $D/T$  and  $H_c\gamma_w/T\gamma'$  for no excavation model

- (1)  $H_c$  gives the lowest value in the case of 1:1.
- (2) For the same value of penetration ratio of sheet piles,  $D/T$ , the critical hydraulic head differences,  $H_c$ , are given as follows in order of increasing magnitude:  $1:1 < 1:2 < 1:3 < 1:4$ .
- (3) For the same value of a short length, the more the longer length increases, the smaller the effect of the longer length on  $H_c$  becomes.  $H_c$  in the case of 1:3 almost equals the  $H_c$  in the case of 1:4 for the same value of  $D/T$ .
- (4) For a small value of  $D/T$ , all of the  $H_c$  values are nearly equal in cases of 1:1, 1:2, 1:3, and 1:4.

Figure 7. Plane shape of a cofferdam

#### 5 AXISYMMETRIC MODELING OF THREE-DIMENSIONAL SEEPAGE FLOW

In the experiment, one quarter of the three dimensional region is examined as stated earlier. The surface shape of the cofferdam is rectangular with the shorter length at 1 and longer length at 2. Considering an inscribed circle in the shorter side of the rectangle as shown in Figure 9, an axisymmetric seepage flow through the soil is used to model such a three-dimensional flow.

Let us consider the three dimensional and approximate axisymmetric conditions:  $T=40\text{cm}$ ,  $D=20\text{cm}$  and  $R=20\text{cm}$  for the non-excavation sand models, where  $R$  is the radius of the circular wall in the axisymmetric condition. Figure 10 shows the relationship between the penetration ratio of sheet piles  $D/T$  and the non-dimensional value of  $H_c$ ,  $H_c\gamma_w/T\gamma'$ . It is found from Figure 10 that the three dimensional seepage failure phenomena are well approximated using axisymmetric seepage failure. For further details, the following points may be made:

- (1)  $D/T \leq 0.40$   $H_c$  values are larger in the AXS flow than in the 3D flow; in particular the approximate accuracy with respect to  $H_c$ ,  $(H_{c\text{AXS}} - H_{c\text{3D}})/H_{c\text{3D}}$ , is about +17% for  $D/T = 0.27$ . This

Figure 8. Relationships between  $D/T$  and  $H_c \gamma_w / T \gamma'$  for various plane shapes

Figure 9. Plane figure of the 3D test apparatus (axisymmetric modeling)

Figure 10. Relationship between  $D/T$  and  $H_c \gamma_w / T \gamma'$  (Axisymmetric modeling of 3D flow)

means that assuming that the 3D flow is the same as AXS flow leads to an overestimation of  $H_c$ , and generates unreasonable results with respect to seepage failure.

(2)  $D/T > 0.40$   $H_c$  values are smaller in the axisymmetric case than in the three-dimensional case; the approximate accuracy,  $(H_{c, \text{AXS}} - H_{c, \text{3D}}) / H_{c, \text{3D}}$ , is about  $-9\%$  for  $D/T = 0.67$ . This means that assuming that the 3D flow is the same as AXS flow leads to an underestimation of  $H_c$ , and generates uneconomical designs with respect to the  $H_c$  value.

For the same value of  $D/T$ , the  $H_c$  values are given as follows in order of increasing magnitude:  $B:L = 1:1 < 1:2 < 1:3 < 1:4$  as stated in Section 4.3. The same axisymmetric approximation is

applied in these four cases. So, the difference in  $H_c$  between 3D and AXS flows changes, and the approximate accuracies,  $(H_{c, \text{AXS}} - H_{c, \text{3D}}) / H_{c, \text{3D}}$ , are given as  $-2\%$  (1 : 1),  $-9\%$  (1 : 2),  $-11\%$  (1 : 3) and  $-12\%$  (1 : 4) for  $D/T = 0.67$ .

## 6 CONCLUSIONS

Seepage failure experiments were conducted under three-dimensional flow conditions for various cases of total depths of soil,  $T$ , and penetrated depths of sheet piles,  $D$ , and analyses of FEM seepage flow and stability against the seepage failure of soil were carried out using the Prismatic failure concept 3D (pfc 3D). From discussions, the following results were obtained:

(1) With an increase in the hydraulic head difference between up- and downstream,  $H$ , the discharge at  $15^\circ\text{C}$ ,  $Q_{15}$ , increases linearly for a smaller value of  $H$ , but changes abruptly and non-linearly beyond the point  $H=H_d$ .  $H_d$  is referred to as the hydraulic head difference at an abrupt change of the  $H-Q_{15}$  curve.

(2) In correlation with the above phenomenon regarding the  $H$  and  $Q_{15}$  relationship, the height of the soil surface changes at the front (downstream) and rear (upstream) of the sheet piles. When  $H$  increases beyond  $H_y$ , a downstream rise and upstream drop of the soil surface occur.  $H_y$  is referred to as the hydraulic head difference at the onset of soil deformation.

(3) Sand particles move from up- to downstream sides under the bottom edges of the sheet piles. The upstream soil surface is an inverse conical shape centered at the outer corner of the rectangular diaphragm wall.

(4) The experimental results led to the interesting conclusion that  $H_y=H_d$ .

(5) The hydraulic head differences at deformation in the experiment,  $H_y (=H_d)$ , are nearly equal to the theoretical critical hydraulic head differences based on the pfc 3D,  $H_c$ .

The theoretical critical hydraulic head differences for various plane shapes of a cofferdam, e.g., a short to long length of 1:1, 1:2, 1:3, and 1:4, were calculated, and the following results were obtained:

(6)  $H_c$  gives the lowest value in the case of 1:1.

(7) For the same value of the penetration ratio of sheet piles,  $D/T$ , the critical hydraulic head differences,  $H_c$ , are given as follows in order of increasing magnitude:  $1:1 < 1:2 < 1:3 < 1:4$ .

(8) For the same value of a short length, the more the longer length increases, the smaller the effect of the longer length on  $H_c$  becomes.  $H_c$  in the case of 1:3 almost equals the  $H_c$  in the case of 1:4 for the same value of  $D/T$ .

(9) For a small value of  $D/T$ , all of the  $H_c$  values are nearly equal in cases of 1:1, 1:2, 1:3, and 1:4.

The axisymmetric modeling of three-dimensional seepage failure was discussed, concluding as follows:

(10) With respect to the seepage failure problem, axisymmetric seepage flow through soil within a cylindrical wall can be used to model such a three-dimensional flow. The magnitudes of the critical hydraulic head differences  $H_{c, \text{3D}}$  (in three dimensions) and  $H_{c, \text{AXS}}$  (axisymmetric model) are given as follows for the 3D case of 1:2 and its axisymmetric model:  $H_{c, \text{3D}} < H_{c, \text{AXS}}$  for  $D/T \leq 0.40$ , and  $H_{c, \text{3D}} > H_{c, \text{AXS}}$  for  $D/T > 0.40$ .

# Stability and dewatering problems of deep excavations in Bratislava

Les problèmes de stabilité et d'assèchement des excavations profondes dans la ville de Bratislava

Turček P., Frankovská J., Súľovská M.

Faculty of Civil Engineering, Slovak University of Technology in Bratislava, Slovakia

**ABSTRACT:** Geotechnical design and execution of deep excavations of high-rise buildings in urban areas are presented in the paper. Design of retaining structure and subsoil behaviour based on the results of in situ measurement during execution with the aim to minimise the settlement of high-rise building are discussed. Limited space on the surface and ground conditions in Bratislava are important factors for design of foundations. Quaternary sediments, coarse grained soils, mainly sands and gravels reach down to the depths of 12 to 20 m, Neogene sediments, mainly clays and silty sands with confined ground water level occur deeper. Ground water level occurs from 2 to 6 m below the surface level. Several examples of excavations where the risks of local hydraulic failure were present are analysed. The paper summarizes stability and dewatering problems associated with design and execution of deep excavations in the city of Bratislava.

**RÉSUMÉ :** La conception géotechnique et l'exécution des fouilles profondes de bâtiments de grande hauteur dans les zones urbaines sont présentées dans le document. La conception de structure de soutènement et le comportement du sous-sol sur la base des résultats des mesures in situ lors de l'exécution dans le but de minimiser le tassement des bâtiments de grande hauteur sont discutés. L'espace limité sur la surface et les conditions du sol à Bratislava sont des facteurs importants pour la conception des fondations. Les sols à gros grains du Quaternaire, principalement les sables et graves descendent jusqu'aux profondeurs de 12 à 20 m, les argiles du Néogène et les sables silteux avec une nappe en charge se trouvent plus profonds. Le niveau de la nappe se trouve de 2 à 6 m en dessous du niveau de la surface. Plusieurs exemples de fouilles sont présentés où les risques d'une défaillance hydraulique locale ont été analysés. Le document résume les problèmes de stabilité et d'assèchement associés à la conception et à l'exécution des excavations profondes dans la ville de Bratislava.

## 1 INTRODUCTION

Geological conditions in Bratislava are determined mostly by Quaternary sediments of the Danube river, Neogene sediments and Cenozoic crystalline rocks (biotite granites to granodiorites, diorite and gneisses) of Carpathians. The most important construction activities in last 20 years have been concentrated in the Danube area, with the Quaternary sediments (coarse grained soils, mainly sands and gravels) with thickness of 12 to 15 m, in the city of and in near vicinity of Bratislava. South and southeastward the depth is increasing, up to 400 m under Gabčíkovo (27 km from Bratislava). The Quaternary sediments are underlayed by fine-grained Neogene marine sediments with typical altering of fine grained and coarse grained sediments. Fine grained sediments are classified as clays from firm to very stiff consistency. Coarse grained sediments are classified as dense sands, silty fine sands and clayey sands. Under the Neogene deposits there are the same crystalline rocks as on the northern side of Bratislava (Kopecký, Černý, 2008). Underground water has two main horizons. One is underground water in Quaternary deposits with free water table donated by water from precipitation and from Danube river. The second horizon is groundwater confined in the Neogene deposits. The water is pressurized and recharged by underground water flowing from nearby Male Karpaty Mts.

Limited space on the surface and ground conditions in Bratislava are the important factors for design of foundations. Three examples of deep excavation where the risk of local hydraulic failure was present are analysed.

Legend:  
Cenozoic crystalline rocks:  biotite granites, granodiorites, diorites,  
Quaternary deposits:  slope deposits,  river deposits

## 2 EXCAVATION FOR BUSINESS CENTER ON KARADZICOVA STREET

The first case study is excavation situated on the left side of Danube River in the city centre on Karadzicova street. Foundation pit was constructed for the high-rise building with 30 floors and 3 underground floors. The longer side of the foundation pit with the dimensions of 200x39 m and depth of 11.4 m was adjacent to existing buildings, two sides were

adjacent to streets and only one short site was open to free space. This layout requires minimisation of horizontal deformation of the retaining structure. Furthermore, there was interest to use all space available on the construction lot, i.e. to exclude technologies that would interfere with the ground plan and decrease the usable volume of the underground floors.

In the first section of the foundation pit up to the depth 4.5 m, where dry conditions were expected, the soil nailing was used as support. The jet grouted wall in deeper section was anchored by one level of ground anchors 15 m long, with 25° inclination, the anchor force was 670 kN and spacing of the anchors 1.6 m. The retaining wall was prestressed in vertical direction due to the necessity to carry large bending moments (bending moment of 1332 kNm per meter of wall was expected by full excavation of the pit); this pre-stressing was supposed to limit the horizontal deformation (see fig. 2 and 3).

Figure 2. Cross section of retaining structure made by soil nailing and jet grouting.

According to geotechnical investigation the Neogene soils with high permeability are expected at the excavation base. Therefore a sealed bottom of the foundation pit was proposed by overlapping short columns constructed by jet grouting. This solution proved to positively influence the settlement of the building. Horizontal deformation in the level of the retaining wall 3.3 mm and 19.15 mm in the lower embedded part under the bottom of the excavation (in the direction of the excavation) were expected in geotechnical design. By full excavation the toe of retaining wall was expected to move into the foundation pit by 52.56 mm. Nine inclinometers were installed around the foundation pit in the wall constructed by jet grouting. The example of measurements from inclinometer no. 3, where the highest deformations (not higher than 2 mm in the direction into the pit) were indicated, is on figure 4.

Figure 3. View into the excavation. Retaining structure made by soil nailing and jet grouting.

Similar results with even lower deformations were measured by other inclinometers. This favourable outcome was achieved thanks to high stiffness of the retaining wall prestressed in vertical direction. The stiffness of weak sandy clays under the bottom of excavation has been increased by constructing a horizontal barrier by jet grouting.

Figure 4. Horizontal deformations of retaining structure during construction.

### 3 EXCAVATION FOR RIVER PARK

The second case study is the foundation pit with dimensions of 265x53.5 m and depth of 9.0 m (fig. 5) situated directly at Danube riverside (in the distance of 12 m to Danube river). Retaining walls for foundation pit were designed as a secant pile wall embedded 1m into the weathered rock base. Danube coarse grained soils are well-known by their susceptibility to piping. The analysis of the risk of filtration failures is important in geotechnical design. Risk of the internal erosion (structural erosion) is affected by granularity of gravel or sand soils, situated in this region. Therefore the analysis of seepages effect on safety of construction and its subsoil it is necessary to carefully observe mainly development of filtration velocities or hydraulic gradients, which are decisive from the viewpoint of reviewing filtration stability of soils (Bednárová et al., 2010). According to geotechnical investigation the value of permeability coefficient (hydraulic conductivity) of gravel  $k$  is in the range from  $1.5 \times 10^{-2}$  to  $6.5 \times 10^{-3}$  m/s. The characteristic value of  $k$  equal to  $1 \times 10^{-5}$  m/s was evaluated from the results of water pressure tests. The permeability coefficient  $k = 1 \times 10^{-7}$

m/s was used in pile walls design (representing mainly leakages between the piles). Seepage in the foundation pit consists of wall and bottom rate of seepage. The seepage through the pile wall on section 1 was 0.008 l/s and can be obtained from equation

$$q_{wl} = \frac{k_s}{2 t_s} (H^2 - d^2) = 7.7 \times 10^{-6} \text{ m}^3 \text{ s}^{-1} \quad (1)$$

where  $H$  is the height of the water column,  
 $d$  embedding of the wall under the bottom of the foundation pit.

The predicted flow rate at the pit through walls was 2.12 l/s in the section farther from Danube and 2.23 l/s in the section closer to Danube.

Flow rate through the bottom was determined by the relation

$$Q_b = k i A_d = 0.0567 \text{ m}^3/\text{s} = 56.7 \text{ l/s} \quad (2)$$

The total rate of seepage can be given as

$$Q = Q_{wl} + Q_{w2} + Q_b = 61.55 \text{ l/s} \approx 62 \text{ l/s} \approx 223 \text{ m}^3/\text{h} \quad (3)$$

In case the groundwater level reaches 138.0 m above sea level (i.e. level of the pile heads), the rate of seepage in the pit increases to 266 m<sup>3</sup>/h.

At the beginning of water pumping, static reserve of groundwater from closed space was pumped from the foundation pit besides the inflow. The volume of saturated gravels is 92170 m<sup>3</sup>, of which volume of water by the assumption of 25 % active porosity is 23043 m<sup>3</sup>. This amount of water is presumed to be pumped in 9 days (during excavation works) when pumping more water than 30 l/s over pumped water flow into the foundation pit.

In order to secure dry foundation pit it was recommended to modify the length of the piles according to the actual conditions even though it might result in longer piles in certain sections compared to the design. Seven pumping wells with diameter 600 mm were proposed with recommendation to verify the actual pumped amounts. Contractor did not trust the assumption of the calculation and constructed 10 wells.

During the excavation of the foundation pit, a measuring of the groundwater movement was performed at all 10 pumping wells (water was permanently pumped only from 2 wells).

Parameters of groundwater movement were determined by the single borehole indicator method, based on the principle of diluting the indicator. NaCl was used as the indicator. Evaluating NaCl concentration was performed by the Radelkis OK 104 tool/instrument on battery source, which recorded the conductivity of the saline solution. Sensors of the Radelkis set with prolonged cable were used as detectors. The value of filter speed ( $v_f$ ) in each depth level, as well as the average value for the whole measured wall, was calculated according to the relation

$$v_f = \frac{\pi d \beta}{4 \alpha \delta t} \ln \frac{c_0 - c_p}{c - c_p} \quad (4)$$

where  $d$  is the inner diameter of the borehole ( $d = 0.8$  m);

$\alpha$  - coefficient of drainage impact of the borehole; base on comparable experience the value  $\alpha = 2$  was used;

$\beta$  - ratio used for volume decreasing ( $\beta = 1$ );

$\delta$  - coefficient considering the sealing impact on the ratio of flow concentration ( $\delta = 1$ );

$t$  - time equal to the difference between  $c_0$  and  $c$ ;

$c_0$  - initial concentration of the indicator;

$c$  - concentration in time  $t$ ;

$c_p$  - background of the indication substance before indicating the environment.

Average value of filter speed for the test section can be determined by the relation

$$\bar{v}_f = \frac{\sum v_{fi} \Delta h_i}{\sum \Delta h_i} \quad (5)$$

Evaluated filter speed in all measured objects depend on the location and ground conditions (gravel). No well showed an anomaly of permeability of depth that would indicate increased inflows from certain depth level or from the bottom of the foundation pit. In 2 wells where the water was pumped, filter speed in the range of 1.4 to 4.7 x 10<sup>-3</sup> m/s was measured, while in other cases it was  $v_f = 2.2 \times 10^{-4}$  to 6.7 x 10<sup>-5</sup> m/s. Very low seepage ratio was measured in line where jet grouting by the pile wall was performed, which proves reliability of the sealing system. Depth division of the filter speeds confirmed non-homogeneity of the gravel location (in some depth the sand fraction was missing).

Figure 5. Foundation pit with dimensions of 265 x 53,5 m and depth of 12 m next to Danube river.

Stable pumping at 20 l/s decreased the groundwater head under the level of excavation base. Decreasing the groundwater head in the area of the foundation pit and evaluation of the movement tests by diluting method indicated that lesser amount of water is required to be pumped from the foundation pit than expected amount of water in the project design (62 l/s). In conclusion it was stated that the retaining structure created a foundation pit with required sealing function.

When preparing the base foundation for placing the underlying concrete, the excavation in the north-western corner of the foundation pit deepened for 0.3 m more than was necessary and minor water seepage occurred along the pile wall that held at the same level for several days. It was confirmed by leveling that the groundwater head in the wet area by the pile wall was 0.48 m below the upper edge of the base concrete and held at the same level. Performed test of natural conductivity of the water seepage helped in identifying its origin. Two locations of leakage were confirmed in the wet area along the pile wall. It was evaluated as the water seepage into the foundation pit area through the contact of the piles connection in the wall where the discontinuities in the rock massive were collectors of the water. Drainage to the nearest active pumping well had to be installed in order to solve the problem. At the same time it was necessary to replace existing soil by gravel without the sand fraction in the foundation pit area and thoroughly compact the layers of this soil replacement, in order to eliminate the risk of higher deformations of the future base structure.

#### 4 DEEP EXCAVATION IN PETRZALKA

Quaternary gravel sediments on the right side of Danube were characterized as loose to medium dense coarse grained soils with the values of density index  $I_D$  varying from 0.25 to 0.63

and deformation modulus  $E_{def} = 30$  up to 112 MPa according to geological investigation by dynamic penetration testing up to the depth 40m. Locally in layers with fine-grained gravel with minimal sand filling the value if  $I_D$  was 0.15 and deformation modulus  $E_{def} = 16$  MPa. Average thickness of the quaternary gravels was 13 m. Neogene sediments were represented mostly by sandy clays (*saCl*) with firm filling of clay, with sand locations with addition of fine-grained soil (less than 15 %), to a small extent also with silts of middle plasticity to clays of high plasticity in depths of 19.8 to 20.6 m and 25.3 to 26.4 m. The value  $E_{def}$  determined by dynamic penetration tests was 20 to 28 MPa in Neogene soils.

Contact stress in base foundation of the high building was 500 to 800 kPa. Limit settlement determined the type of foundation (rafts or piles). Based on the information about disproportionately high compressibility of the subsoil, ground treatment by deep vibratory compaction was performed. Base foundation was located in the depth of 4.0 m under the surface. The raft is 1.4 m thick, in deepened parts 2.0 m. Density of compaction points was in raster of 2.2 x 2.4 m for stress of 800 kPa, under pad footings and strip footings in raster 2.5x 2.5 m to 1.75 x 3.5 m for stress of 500 kPa and under pads and strips in raster 1.8 x 1.8 m for stress of 800 kPa. The length of the piles for stress of 800 kPa was in depth of 3.0 m from the working base under the surface 10,0 m (i.e. till the Neogene in the depth of 13.0 m), shortened to 7 m in area with load of 500 kPa.

This arrangement was based on previous comparable experience in Quaternary gravel sediments of Bratislava where the verified deformation modulus of the vibrated gravel columns reached the average value of  $E_{def}$  equal to 500 MPa and increasing of the deformation modulus of average environment was proved by the values  $E_{def}$  from 250 to 300 MPa. The calculation of the average deformation modulus of improved subsoil in the area A in question is according to the relation

$$E_{def} = \frac{A_g E_g + A_s E_s}{A} \quad (6)$$

where  $A_g$  is the area of vibrated stone columns  
 $E_g$  – deformation modulus of the vibrated stone columns  
 $A_s$  – area of the unimproved soil  
 $E_s$  – deformation modulus of the unimproved soil

After constructing the vibrated stone columns, dynamic penetration tests were performed, located in the middle of the vibrated stone columns. Increase in the deformation modulus with depth was also proved, which was taken into account in the calculation of predicted settlement based on the monitored data. Average value of  $E_{def} = 284$  MPa was measured under the base foundation up to depth of 2 m. The predicted final settlements are summarized in the table 1.

Table 1. The values of settlement calculated for different foundations.

Foundation	Settlement s (mm)
Spread foundation without soil improvement	104.46
Spread foundation with soil treatment by stone columns ( $E_{def}$ based on comparable experience)	67.01
Spread foundation with soil treatment by stone columns ( $E_{def}$ based on site testing)	64.55
Pile foundation	73.97

During the construction of the high building the vertical and horizontal deformations were monitored. The measured value of settlement after consolidation process reached 52.2 mm.

## 5 CONCLUSIONS

The key value in the design of high building foundation in deep excavation pits is the limit usability state. Most questions are raised by the simulation of soil deformation characteristics and expected groundwater inflows. Good prognosis of deformations is based on combination of determining correct soil deformation characteristics verified by laboratory and field tests in the whole deformation zone and selecting the right calculation method. The project must respond to the architect's requirements by suitable design, its monitoring and potential modification of stiffness of the retaining structure, subsoil and additional sealing elements.

Geotechnical design and execution of deep excavations of high-rise buildings in urban areas are presented in the paper. Design of the retaining structure and subsoil behaviour based on the results of in situ measurement during execution with the aim of minimising the settlement of high-rise building are discussed. The paper summarizes stability and dewatering problems associated with design and execution of deep excavations in the city of Bratislava. The results of geotechnical calculations have been compared to the results of in-situ measurements.

# Managed remediation of a large Victorian gravity quay wall using the observational method

Stabilisation d'un grand mur de quai de l'époque Victorienne gérée en utilisant la méthode observationnelle

Turner M J, Smith N A  
*Applied Geotechnical Engineering, UK*

**ABSTRACT:** The paper describes on-going work to control the stability of a large gravity quay wall at a port on the western seaboard of the UK, which has had a history of instability dating back over several decades. In 1999 further ground movements of the wall were triggered by leakage from a fractured water main in the quayside behind the wall. This caused severe settlement damage to the quay and associated storage warehouses on the quayside. Monitoring of the affected area of the wall was established in early 2000, with additional ground investigations and instrumentation to supplement existing data. By the end of September 2000 the worst affected parts of the wall were moving outwards at a rate of 10mm/day. The movements were initially arrested by groundwater lowering. Subsequently additional remedial measures consisting of anchors and shear keys were designed and installed to provide physical restraint. The Owner wished to minimise capital expenditure and instead to use an observational approach (Peck 1969) and to respond to the information obtained. The work had therefore attained what was regarded as an acceptable steady state, with continued managed remediation to ensure that the wall's stability is maintained and the Owner can continue to use the berthing facilities.

**RÉSUMÉ:** Le document décrit les travaux en cours pour contrôler la stabilité d'un grand mur de quai dans un port de la côte ouest du Royaume-Uni, qui avait un historique d'instabilité datant de plusieurs décennies. En 1999, de nouveaux mouvements de terrain et du mur furent déclenchés par une fuite d'eau due à une rupture de tuyaux d'alimentation en eau du quai qui étaient derrière le mur. Ceci causa des dommages graves au quai et aux entrepôts de stockage sur le quai. La surveillance de la zone affectée du mur commença au début de 2000, avec addition d'instruments de mesure supplémentaires et investigations complémentaires du sol pour compléter les données existantes. À la fin de Septembre 2000, les zones les plus touchées du mur se déplaçaient vers l'extérieur à une vitesse de 10mm/jour. Les mouvements furent arrêtés par l'abaissement des eaux souterraines. Par la suite d'autres mesures correctives constituées de tirants d'ancrage et de piles pour éviter les glissements furent conçues et installées pour assurer la contention physique du mur. Le propriétaire souhaitait minimiser l'investissement initial et préférerait utiliser une approche observationnelle (Peck 1969) en réponse aux informations obtenues. Le mur était assez stable pour utiliser le quai en continuant l'application opportune des mesures correctives pour assurer la contention du mur, et le propriétaire peut continuer à utiliser les installations d'accostage.

**KEYWORDS:** gravity walls; long-term monitoring; long-term displacements; ground anchors; water pressures; effects of dewatering.

## 1 INTRODUCTION

A section of harbour wall at a port on the western seaboard of the UK has a history of instability dating back over more than thirty years. Measurements taken in the 1980s had indicated that the maximum total horizontal movement of the wall up to that date had been more than 400mm. In 1999 further ground movements of the wall were triggered by leakage from a fractured water main in the quayside behind the wall. This caused outward movements along a length of over 80 metres, and severe settlement damage to the quay and associated storage warehouses on the quayside.

The harbour works were constructed at the end of the 19<sup>th</sup> Century. The wall is a gravity structure of mass concrete and masonry with sandstone "plums". At its top, it is some 17 metres above the harbour bed level; it is about 2 metres wide at its crest, increasing to almost 9 metres at its base. There is a large tidal range at the site.

After the 1999 movements, monitoring of the affected area of the quay wall was established in early 2000, with additional ground investigations to supplement existing data and to confirm the wall dimensions and the ground/groundwater conditions behind the wall. Inclined meters and piezometers were also installed to monitor water levels and the wall behaviour. Survey lines were established perpendicular to the wall and extending back to stable reference markers remote from the wall, with intermediate reference points to measure lateral and vertical movements in the ground behind the wall.

By mid-2000 the monitoring data showed a deteriorating situation, with outward movements of the wall accelerating from an initial value of around 15 to 20mm per month to as much as 100mm/month, and increasing. By the end of

September of that year the worst affected parts of the wall were moving outwards at a rate of 10mm/day, and measures were put in place to stabilise the wall immediately in the short term, together with further works to ensure the stability of the quay wall in the medium term.

This current paper describes these measures and the long term monitoring of the wall over the past decade.

Figure 1. Outline plan of the site.

## 2 BRIEF HISTORY OF THE SITE

The harbour walls were constructed in the dry within a large embayment formed by advancing two curved embankments from the shore to meet at a central point, which would form the entrance to the harbour, as illustrated on Figure 1. This entrance point was closed by a temporary dam for the construction works and the site was drained by pumping. The harbour was then excavated in the dry.

A typical section through the quay wall is shown on Figure 2. The walls were constructed of mass concrete and, in the larger sections, large sandstone “plums” were incorporated into the concrete. The quay was intended for both passenger and livestock traffic. In view of the large tidal range provision was made for loading and off-loading at any state of the tide. This was achieved by constructing access-ways through the wall at two levels. These were connected to subways and stairways on the landward side of the wall. On the seaward side the quay wall was fronted by a heavy timber staging with continuous landings at the necessary levels to give access from the steamers into the subways.

Figure 2. Typical cross-section through quay wall.

As illustrated on Figure 1, the affected quay, known as the ‘South Quay’ was constructed on the harbour side of a central spine embankment within the construction site. To the south of this, the remaining area was planned as a future extension to the harbour, but this extension was never constructed. In the 1970s this area was infilled and a large power station constructed on the site

In the early 1980s surface settlement was noted behind a 40m long section of the quay wall. This was repaired by infilling and releveling to grade. Further repairs were undertaken in 1988, when a maximum settlement of 400mm was reported on the quay surface prior to reconstruction. Following these repair works the quay surface settled a further 30mm of settlement within a year, and the worst-affected area was reported as extending over an 85 metre length of the wall, although the effect was also discernible beyond this. Crane rails which had been relaid along the quayside in 1972 were found to have deviated by up to 100mm towards the harbour over a 100m length of the quay wall.

Detailed surveys taken in 1991 indicated that the South Quay was showing a distinct bulge of as much as 430mm towards the harbour, and the zone of movement extended for some 200m along the wall. Shortly after these measurements were taken, a break occurred in a water main some 13m behind the crest of the wall, due to the continuing outward displacement of the quay wall. At this time a remedial works solution using high capacity ground anchors was proposed, but not proceeded with.

In late 1999 a further major leak occurred from a fractured water main near the centre of the previous movements, causing accelerated wall movements and severe ground settlements beneath the quay itself. The next sections describe subsequent evaluation and remedial works following this particular incident.

## 3 GROUND INVESTIGATIONS AND OBSERVATIONS (2000-2001)

In early 2000 Applied Geotechnical Engineering was requested by the port owner to undertake investigations as to the cause of the movements and to advise on the measures required to stabilise the South Quay wall.

A targeted ground investigation was commissioned, to supplement information available from previous investigations undertaken in 1990/1992. In addition, inclinometers were installed at five locations along the crest of the affected length of wall and were continued through the base of the wall and any superficial soils into bedrock at depth. A further three inclinometers were installed behind the wall to monitor the behaviour of the retained soils. Water observation boreholes were also installed behind the quay wall to monitor groundwater conditions.

In addition a series of “traverse lines” was established perpendicular to the wall and extending back to stable ground well beyond any zone of influence of the wall movements. These were monitored by conventional surveying techniques to determine horizontal and vertical displacements.

### 3.1 Geology and Ground Conditions at the Site

The ground was raised behind the masonry quay walls using the material excavated to form the harbour. Beneath these surface construction materials, the South Quay is underlain by fine to medium grained sands of Quaternary age. In some places these are underlain by soft sandy silty clays. These materials rest upon either Glacial Till (typified as reddish brown, stony, clayey silts), or, more commonly, directly onto bedrock. At the western end of the quay, bedrock consists of sandstones with subordinate marls of Permo-Triassic age. Over the eastern end older sandstones and siltstones of Upper Carboniferous Namurian (Millstone Grit) age are present. The boundary between the two rock formations is formed by a large fault, trending in a NNW – SSE direction, which cuts at right angles across the line of the South Quay, slightly west of its central point, and close to the centre point of the historic movement of the wall. The fault zone was also identified during the construction of the power station to the south.

This fault zone is associated with heavy flows of groundwater under artesian or sub-artesian pressures. Before the power station was constructed a freshwater lake formed in the area of the old proposed harbour extension.

The investigations led to the conclusion that groundwater flows from this source to the south of the South Quay were the root cause of the wall instability, as described below.

### 3.2 Groundwater observations

It was soon apparent from the monitoring data that the movement of the wall was driven by the groundwater held behind it. The rate of drainage of the water below the wall was relatively slow, so that the difference in water levels between the front and the back of the wall was highest at low tide, as shown in Figure 3. At these points the wall would ratchet forward, and not quite recover its original location as the tide level rose. By inference, the effect was greatest at times of high tidal difference (Spring tides).

The water observation standpipes confirmed that close to the quay wall, water levels varied tidally between about +4m OD and +1.4mOD. Some fifty metres south of the face of the quay wall, water levels varied between +2.9 and +2.7m OD with the tide. At a distance of 100 metres groundwater levels were almost static, with very little discernible tidal variation, and were around +3.7m OD.

It was also noted that the salinity of the groundwater changed from south to north. In the south the groundwater was fresh or brackish. Close to the quay wall the salinity altered with the tide. At low tide it was brackish or fresh. At high tide, as

seawater clearly flooded behind the wall, the groundwater became salty.

There was therefore a discernible hydraulic gradient from the power station site in the south, northwards towards the quay wall. It was also clear that the bulk of the groundwater was fresh water, flowing from the power station site towards the South Quay. In addition it was quite possible that concentrated groundwater flow was occurring in the fault zone in the vicinity of the harbour, although in the location of the South Quay the zone was buried beneath a cover of Glacial Till.

Figure 3 Water levels and crest movements, 13-14 Oct 2000.

The analyses showed that the high groundwater level behind the quay wall was the predominant driver of the instability and the observed wall movements.

### 3.3 Wall Movements (2000)

Figure 4. Crest movements during 2000.

The displacements of the quay wall measured at the traverse lines are illustrated on Figure 4. It can be seen that there was a noticeable effect upon outward wall displacements while the site investigation works were being undertaken in April 2000. Figure 4 also shows that the rate of outward movement also began to increase markedly in September of that year, and was accelerating. By September 2000 the worst affected area of the quay wall (Traverse Lines B and C on Figure 4) had recorded between 270 and 350mm of outward movement, relative to their

values in January of that year. At this time the analysis, design and procurement of the remedial works was still being progressed, but, based upon the evidence of the increased wall movements during the investigation work, contingency plans had already been put in place to deal with such a situation. Eleven dewatering wells were installed in a line behind the quay wall at approximately 10m centres, to lower the ground water level behind the wall. At that time the wall was moving forward by more than 10mm per day at the worst affected part, and was rocking measurably with the tide. The pumps were started as soon as the wells were connected, over a three day period, the first three being commissioned on 17 October and the balance by 19 October 2000.

As soon as the first pumps were started, the wall movement virtually ceased, as can be seen from Figure 4. Measurements eight days later showed that the amplitude of the rocking motion was less than half its magnitude prior to pumping. With the wall stabilised, work on installing permanent drainage and ground anchors could begin. The effects of the dewatering upon the groundwater levels behind the wall are illustrated on Figure 5.

A feature of Figure 5 is that a distinct 'plateau' can be seen in the levels recorded for the water immediately behind the quay wall. The level of the retained water is drawn down to 0.0mOD by the pumping wells as the tide falls. It does not fall below this level, however, giving the step-like feature in the graph. The 0.0mOD level coincides with the invert level of the lower access-ways through the quay wall, which were open to the sea. When the tide was above 0.0m, on a falling tide, the retained water was clearly draining through these accessways, as well as being removed by the pumping wells. Once the tide fell below this level, then the pumping wells alone were removing the retained water, and, on the evidence of these readings, could only maintain the retained water at about the 0.0mOD level against the fresh water flowing from the landward side of the quay wall.

Figure 5. Water levels and crest movements 27-28 Oct 2000.

## 4 OUTLINE OF INTERIM REMEDIAL MEASURES (2001 – 2002)

It was recognised from the outset that the efficiency of the wells was likely to deteriorate in the medium term due to bio-fouling. Hence, additional measures were designed to provide physical restraint to the worst affected section of the wall. These consisted of seventeen 1050kN permanent rock anchors installed through the face of the wall at an inclination of 43° to the vertical; twenty-four 525 or 626kN permanent anchors through the crest of the wall inclined to landward at 10° to the

vertical and approximately thirty near-vertical 63.5mm diameter shear keys into rock beneath the base of the wall.

In addition, a series of sub-horizontal drainage wells were installed through the quay wall at a level of +0.0m OD, to speed the drainage of the retained soils.

These works were completed in early 2002.

#### 5 WALL BEHAVIOUR 2002 – 2012

The dewatering wells were shut off in April 2002 and the wall behaviour was monitored.

The response of the wall in terms of its outward movement as measured by the inclinometers and the traverse line surveys is illustrated in Figure 6.

Figure 6. Wall displacements at crest level 2002 to 2012. (Toe displacements similar but generally smaller.)

Initial wall movements over the first 5-6 months were between 5 and 10mm at the crest and toe of the wall as the anchors took up further load. Load increases in the 43° anchors were typically between 50 and 200kN over this period.

By the end of 2002 the movements had stabilised at around 16 to 26mm at the crest, and 15 to 20mm at the toe. These data confirmed that the predominant mode of movement of the quay wall in the most active area was by sliding along a plane coincident with or close to the interface between the base of the wall and the underlying strata.

Over the next 3 years outward crest movements over the anchored section had increased to 30 to 40mm relative to the April 2002 readings and toe movements were between 35 and 40mm. Loads in the 43° anchors had increased by between 200 and 250kN. It had been planned to complete the main remediation works within this 3-year timeframe, but the monitoring works had demonstrated that movements were remaining controllable. The main works were put on hold, therefore and a watching brief was maintained on the wall. Based upon the previous readings, a movement criterion of 10mm/year had been adopted as a signal that further support works needed to be put in place.

By 2009 the loads in some 43° anchors were approaching or exceeding 1200kN – 15% above their design loads. Any anchors found to be in excess of this load level were being relaxed to avoid overstressing.

Outward wall movements over the anchored section generally continued at a rate of around 3 to 5mm per year.

By 2012, however, inclinometer and traverse line readings were indicating that outward wall movements were reaching 10 to 12mm per year, and the loads in the 43° anchors were increasing at an average of around 150 to 300kN per year. Additional interim measures were undertaken at the end of 2012, when a further six 1800kN capacity 43° anchors were installed through the face of the wall over the anchored section.

The aim of these works is to reduce outward movements back to acceptable levels.

These additional limited-scope works are intended to allow the continued limited working of the quay, consistent with the current requirements of the Port. As demand rises or operational needs change at the Port, then full remediation works will be implemented to upgrade the South Quay facilities to meet this demand.

For reference, the data from Figures 4 and 6 have been combined on Figure 7 to illustrate the relative degrees of movement measured at the crest of the quay wall over the worst affected section from 2000 to the present day. The figure clearly shows the rapid, and probably catastrophic, accelerating rates of movement in 2000, before the dewatering was switched on, followed by the relatively slow but continuing movements over the next 9-10 years, but increasing latterly.

Figure 7 Wall crest movements between February 2000 and June 2012

## 6 SUMMARY AND CONCLUSIONS

The long-term monitoring of this 19<sup>th</sup> Century harbour wall over the last twelve years in particular, (but with records extending back over thirty years) has given a unique opportunity to gain an insight into the behaviour and relative ‘flexibility’ of such structures. The data gained from this work highlight the importance of monitoring such structures once they are perceived to be ‘at risk’, and the need to establish ‘trigger values’ related not just to overall movements but to rates of movement, and, in particular where rates of movement are seen to be accelerating over time.

## 7 ACKNOWLEDGEMENTS

The authors acknowledge with thanks the permission and co-operation of the port owners and their engineers in gathering and collating the data obtained from these monitoring works and allowing their publication in this paper.

**ABSTRACT:** Reinforced soil structures have become an appropriate construction method for infrastructural buildings. Several types of facing are commonly used. Full height panels or segmental panels with a certain height are mainly used for flyover constructions and bridge abutments. The design of the constructions depends on the stiffness of the facing element. Large scale test with loads up to 450 kPa at laboratory conditions as well as on site test with one year of continuous measurement under weathering conditions are presented and compared to analytical design and calculations using commercial finite element software. The results indicate that this type of structure can be designed on the safe side using current design standards and benefits given by the interaction of stiff geogrid reinforcement and soil.

**RÉSUMÉ :** Les ouvrages en remblai renforcé sont devenus une méthode de construction adaptée aux projets d'infrastructures. Plusieurs types de parement sont couramment utilisés. Des panneaux de pleine hauteur, ou panneaux segmentaires avec une certaine hauteur, sont principalement utilisés pour les constructions surélevées et les culées de pont. La conception de ces ouvrages dépend de la rigidité de l'élément de parement. Cet article présente des essais réalisés à grande échelle avec des charges allant jusqu'à 450 kPa, en condition de laboratoire ainsi que sur site, avec une année de mesure en continu en condition de vieillissement. Les résultats sont comparés à la conception analytique et aux calculs réalisés à l'aide d'un logiciel commercial d'éléments finis. Les résultats montrent que ce type d'ouvrage peut être conçu de façon sécuritaire suivant les normes de conceptions actuelles et les avantages apportés par l'interaction d'une géogridde rigide avec le sol.

**KEYWORDS:** geosynthetic reinforced walls, concrete, design, testing, execution, DIN EN 14475, EBGEO, BS8006

## 1 INTRODUCTION

Creating robust and sustainable constructions in geotechnical engineering has become an upcoming topic in terms of reduction of carbon footprint as well as on cost reduction on PPP projects. Combining technologies for slim precast concrete panels with stiff geosynthetic reinforced walls allows for the use of local and in some cases even treated soils.

In the last years recent research has led to further understanding of reinforcing interaction, leading to design approaches published in EBGEO and allowing for a reduction of lateral stress on the facing constructions.

Design of precast panels in practice requires attention to the transport phase as well as on the construction steps during execution and serviceability limit state.

## 2 DESIGN OF REINFORCED STRUCTURES

DIN EN 14475, the British design code BS8006 as well as the German design recommendations EBGEO are state-of-the-art standards in order to safeguard the constructions.

Special attention has to be paid to the design of the facing, as these elements are directly exposed to the environment and deformations of the construction can be seen immediately. The mentioned design codes do not give a unique calculation of lateral stress acting on the facing elements. DIN EN 14475 already differentiates between several types of facing elements, depending on the stiffness:

- Rigid facings, e.g. full height panels

- Semi-flexible facings, e.g. concrete blocks without rigid connections, gabion baskets
- Flexible facings, e.g. wrap-around method

The lateral stress has to be different from the active earth pressure calculated according to Rankine's theory due to the geosynthetic reinforcing elements, "nailing" the fictive failure zone. As this becomes a hyper static system, the earth pressure distribution on the facing is indifferent.

Nevertheless, the design has to be proper and worked out on the safe side, so additional information has to be gained from sites and large scale tests, especially taking influence of water, subsoil settlements and installation conditions (compaction, construction steps, etc.) into consideration.

## 3 CURRENT DEVELOPMENT

### 3.1 *Lateral stress on facing*

Pachomow et al. (2007) collected several test-field data of executed walls in heights between 2.0 m and up to 30 m, with information concerning the lateral pressure on the facing given. It is interesting that the lateral stress gained by self-weight of the construction remained within a range of up to 50 kPa, although significant higher values would have been expected especially for high walls.

Normalising the height of all test field data, and recognising that nearly all data are linked to non-cohesive soils as well as to slope inclinations between 70° and 90°, the relationship between the vertical and lateral stress can be compared to the

active earth pressure coefficient, being expected in the range of 0.2 and 0.35, depending on the theory and boundary conditions. Figure 1 indicates that the normalised lateral stress on the facing is significantly less for reinforced structures. Furthermore, the data indicate that the absolute height might not have a decisive influence at all, but the normalised one.

Ruiken et al. (2010) have demonstrated the arching effects close to the facing of a geogrid-reinforced soil sample, using biaxial tests at plane strain conditions. The degree of arching and the absolute value of stress reduction depends on the lateral movement of the facing as well as on the degree of reinforcement, see also Bussert (2006).

Based on full scale tests using several commonly known reinforcing products varying in a small range of nominal strength from 40 kN/m up to 55 kN/m a clear tendency can be obtained concerning the stiffness, described by the secant modulus J of the products:

$$J \text{ [kN/m]} = \text{strength } F \text{ [kN/m]} / \text{strain } \varepsilon \text{ [%]} \quad (\text{eq. 1})$$

Figure 1. Compiled data of lateral stress to facing, presented at normalized height and relationship between normal load  $\sigma_h$  and lateral pressure  $\sigma_v$ .

Figure 2. Deformation of full scale walls with semi-flexible facing, depending on the product (Pachomow & Herold, 2009).

Figure 2 shows preliminary results of a 4.0 m high construction using a weak facing system and a load beam 1.0 m behind the wall surface, applying a top load of up to 350 kPa. The deformation varies significantly depending on the type of product. All products performed satisfactory in an acceptable

range, while some products allow for higher loads and show an enhanced performance in terms of serviceability.

#### 4 EUROPEAN DESIGN CODES

Exemplarily the mostly used design codes in Europe, BS 8006 and EBGEO 2010, dealing with reinforced earth will be discussed in the following.

Following the basic principles of designing reinforced soil, based on the results shown in Chapter 3, EBGEO allows further for a reduction of the lateral stress as compared to the Rankine's active earth pressure. The well-known coefficient for the lateral active earth pressure  $k_{ak}$  is just used as basic parameter (eq. 2), taking the inclination of the wall as well as the soil parameters (e.g. angle of internal friction  $\phi'$ ) into consideration. The correction factor  $\eta_G$  as per Figure 3 is then applied, knowing well that using the lateral active earth pressure  $k_{ak}$  as basic parameter is just an interim solution up to full understanding and modeling of reinforced earth. In the upper part of the construction respectively on the actual construction level, the earth pressure due to compaction (not shown in Figure 3, typically up to 25 kPa) becomes decisive, but is going to be superimposed by the earth pressure resulting from the self-weight of the construction.

$$E_{\text{Facing}} = (\eta_g * k_{a_{gh,k}} * \gamma_k * H_i * \gamma_G + \eta_q * k_{a_{qh,k}} * q * \gamma_Q) * l_v \quad (\text{eq. 2})$$

- with
- $E_{\text{Facing}}$  Earth pressure on facing [kN/m]
- $\eta_g, \eta_q$  Matching coefficient [-]
- $k_{a_{gh,k}}, k_{a_{qh,k}}$  Coefficient active earth pressure [-]
- $\gamma_k$  Weight of the soil [kN/m<sup>3</sup>]
- $H_i$  Covering [m]
- $q$  Traffic load [kN/m<sup>2</sup>]
- $\gamma_G, \gamma_Q$  Partial safety factor DIN 1054 [-]
- $l_v$  Vertical space between layers [m]

Figure 3. Correction factors applied to  $k_{ah}$  according to EBGEO, 2010.

In opposition to EBGEO, the earth pressure following BS 8006 is calculated using the active earth pressure coefficient  $k_{ah}$  for the structure, superimposed by  $k_0$  in the upper part. The reduced stress acting on the front of the construction depending on the stiffness of the wall-facings is considered by a reduction of the connection stress, e.g. by 25 % in the upper 60 % of wall height using wrap-around method.

The BS 8006 concept results in having the highest connection stress requirements at the footing of the construction, while research and lessons learned from failures indicate to have the highest stress levels at approx. 1/3 height starting from the bottom of the walls.

Nevertheless, the reduction of the lateral earth pressure of both concepts has a direct influence on the design of reinforced walls and allows for steep walls with a friction connection between e.g. blocks and reinforcement.

## 5 LARGE-SCALE TEST IN SITU

### 5.1 Design and set-up

In addition to the large scale tests on full height panel walls performed by Pachomow, a full scale trial has been performed by KWS Utrecht, Netherlands, supported by NAUE, Germany. While under laboratory conditions high loads up to 450 kPa could have been applied to the structure, in situ the influence on installation procedure, weathering (changes of moisture-content and temperature) and long term effects caused by the thermoplastic characteristics of the used high strength Polyester geogrid could be investigated. Figure 4 gives the cross section of the test set-up for the in-situ test with geometry comparable to the laboratory test.

Figure 4. Test setup full height panel wall, KWS Utrecht

To reduce the required amount of structural steel for the construction, the panel has not been designed using conventional design methods, but taking the results from laboratory test explained in Chapter 4 into consideration. Therefore, the design configuration has been optimized, assuming the load distribution given in EBGEO, applying an overall safety to the earth pressure distribution of 1.5 (assumption).

The load distribution has been applied to the panel design, testing several static systems and designs to optimize the amount of required structural steel. At the end, the system could be optimized for transport steel only.

To make the system as easy as possible, only 1.5 m long strips of the reinforcement have been precast to the concrete (Figures 4, 5a). The required length of the reinforcement to fit the overall safety according to EBGEO has been placed on site, just overlapped by friction. For the earth pressure distribution, satisfactory pull-out resistance of the strips from the reinforced backfill has to be ensured.

Several types of instrumentation have been used, taking the static principle of  $\Sigma H = 0$  into consideration. The sum of forces acting on the backside of the panel shall be equal to the forces

acting on the geogrids, the temporary prop, added by the friction on the toe of the panel.

Therefore, the toe of the panel has been designed as plain bearing, using geosynthetic components for sliding purposes with tested and well-known friction parameters for back-analysis of the forces acting at the toe. Temporary wooden wedges, applied during placing the panel, have been removed after the installation of the first 1.5 m of backfill material, so lateral movement of the panel toe was possible but has not been observed.

Further on, it had to be ensured that the material used is applicable to the use in concrete, as it is given here by independent testing and applying a partial reduction factor for environmental influences to the polyester material of 1.18 [-].

To predict stress, strain and lateral movement of the stage construction, finite element (FE) analysis have been worked out using PLAXIS 2D, 2011. These calculations are also usable for comparing the measurements and predictions for the reference times  $t_0 \dots t_5$  charged as indicator for significant changes in the static system with construction stage and time, Figure 5.

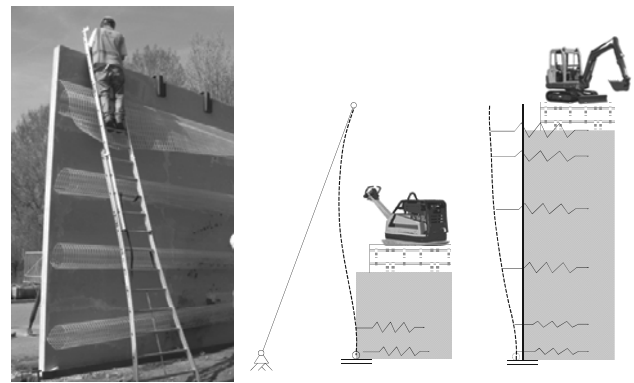

Figure 5a. Installation procedure and expected deformations of wall.

Figure 5b. Time schedule of construction.

### 5.2 Measuring strain and back-calculation of stress

For the back-analysis of horizontal forces from strain recordings, the corresponding stress has to be known. This can be read from isochronous stress-strain curves, as far as they are available. For the used material here, Secugrid<sup>®</sup> made from polyethylenterephthalat (PET), the curves are given. The back-analysis for representative times  $t_0$ ,  $t_1$  and  $t_2$  (see Figure 7) has been worked out using the isochronous curve for 1 hour, representative for the situation immediately after compaction of soil. As this gives conservative values of stress, no further differentiation is required.

For the time  $t_4$  and  $t_5$ , long term stiffness has been calculated using the isochronous curve for 1000 h, also giving

conservative values for stress, as  $t_4$  is approx. at 2880 h and  $t_5$  at 6500 h.

### 5.3 Main findings

Up to the date of printing, the construction is approximately one year in service. Data recording is available continuously during installation and in sequences during the service period. Within the service period, also 24h-measurements have been done to get an impression of temperature changes within the wall. Figure 6 gives the strain recording for the total time, indicating a very low level of strain of less than 1%, as it has to be expected. Nevertheless, only the three layers on the bottom get a significant loading. Two layers of geogrids on the top are up to now not taking any load. As these layers are mainly designed for a top-load of the construction not performed yet, the results fit with the expectations.

Removing the prop ( $t_1$  to  $t_2$ ) has been expected to increase the strain in the upper layers of the geogrids. Actually, this could not be found on site. The absolute values of strain (and therefore stress) at each layer remained stable.

For the sum of horizontal loads, compiled for the representative time  $t_0$  to  $t_5$ , measured forces as well as forces from FE-calculation and analytical approach by classical earth pressure theory can be compared. Friction at the toe of the wall, forces on the temporary prop as well as forces at the geogrids, measured right behind the wall, have to be compiled.

Figure 6. Entire strain recordings of the geogrids (DMS: strain gauge applied to geogrid).

For time  $t_0$  to  $t_4$ , the results gained by PLAXIS come quite close to the results gained from measurements in situ, Figure 7. Taking the rotation backwards due to settlements into consideration (time  $t_5$ ), PLAXIS gives a significant increase in stress, not be found on site.

In comparison to the measurements, results given by classical earth pressure have not been found to represent the reality for this combination of reinforcement and facing, neither the laboratory one nor the in-situ one. The difference is at least between 30% and 40% and therefore in line with the current status of research on reinforced soils. Compared to the design situation according to EBGEO, a reduction of lateral stress for the load case “unit weight of structure” and therefore a correction factor  $\eta_g \geq 0.7$  would be acceptable from the author’s point of view.

## 6 SUMMARY

Full scale laboratory tests have been performed for a full height panel wall, combined with a geogrid-reinforced soil structure. Tests are performed at loads up to 450 kPa according to bridge abutments as well as at dynamic loadings.

A comparable setup of a full scale panel wall has also been tested in situ. Monitoring of the reinforced wall allows for satisfactory back-analysis of the constructions steps.

The measured stress conditions fit with the expected low stress approach for the combined structure, given by FE-analysis. The findings combine the current results of international research and updated design approaches (EBGEO) also for full height panel walls. They allow for the consideration of a reduced earth pressure distribution in design as well as for simplified construction.

Due to limitations, the setup and results cannot be transferred to all combinations of reinforcement, soil and panel-systems, but allow for further analysis by FE calculations.

Universidad Politécnica de Madrid

**ABSTRACT:** This paper presents a brief analysis and comparison of different recommendations for a ground anchor fixed length design and a load transfer capacity at grout-ground interface, comparing it with the full scale test results recently carried out in Spain. Simple methodology for ground anchor routine design is proposed, incorporating efficiency factor as a conceptual control of anchor capacity, and fixed length criteria to determine range of application of conventional anchors, with single fixed length unit, or Single Bore Multiple Anchors (SBMA). Ground anchors discussed in this paper are cement pressure grouted, formed by pre-stressed strand tendons that are installed in soil or rock.

**RÉSUMÉ:** Cet article présente une brève analyse et la comparaison des différentes recommandations pour la conception de tirant d'ancrage de longueur fixe et la capacité de transfert de charge à l'interface coulis-sol, en le comparant avec les résultats d'essais à échelle réelle obtenus en Espagne au cours des dernières années. Une méthodologie simple pour la conception de tirant d'ancrage est proposée; elle intègre le facteur d'efficacité comme un contrôle conceptuel de la capacité de l'ancrage et les critères de longueur fixe pour déterminer le champ d'application des tirants d'ancrage conventionnels, d'unique longueur fixe, ou d'ancrages multiples en un unique forage (SBMA pour ses sigles en anglais). Les tirants d'ancrage décrits dans ce document sont injectés à pression au moyen d'un coulis de ciment et sont formés par un faisceau de câbles d'acier précontraints qui sont installés dans le sol ou la roche.

**KEYWORDS:** anchor, fixed length, bond stress, efficiency factor.

## 1 INTRODUCTION

Nowadays anchors represent a key medium to sustain and strengthen slopes formed by instable soils and fractured rocks, and to ensure the stability of various types of gravity structures.

Regarding bond stress and load transfer capacity at the grout-ground interface, most procedures for anchor design are empirical values or formulas derived by local experiences, very difficult to extrapolate for different locations or execution systems. The design procedure is often simplified, considering direct proportionality between fixed anchor length and its load capacity, as it is prevailing practice in Spain and South America.

However, since late 1960s numerous authors demonstrate bond stress or skin friction distribution to be highly non-uniform at all stages of loading, with high bond stress mobilization along reduced fixed length. In the following chapters, based on presented references and analysis of the field trial results recently performed in Spain, the methodology for anchor fixed length design is proposed.

## 2 DESIGN OF THE FIXED ANCHOR LENGTH

### 2.1 Current practice

Design assumption of uniform load distribution along the fixed anchor length is not only limited to usual methodology and standards in Spain and South America but is internationally generally adopted. Considering this hypothesis the ultimate or capacity of the anchor is commonly expressed as follows:

$$T_{ult} = \pi \cdot d \cdot L_{fix} \cdot \tau_{ult} \quad (1)$$

where:  $d$  = anchor diameter,  $L_{fix}$  = anchor fixed length and  $\tau_{ult}$  = ultimate bond stress.

This formula differs from experimental and theoretical evidence that corroborate that there is no linear dependency of ultimate capacity on fixed anchor length.

### 2.2 Non-uniform bond stress distribution

It is fully acknowledged by numerous researchers that the distribution of stress along the fixed anchor length is non-uniform, both at low stress levels and at failure. This phenomenon results from the general incompatibility between elastic modulus and corresponding deformation of the anchor strands, cement grout and ground.

Field tests on instrumented conventional anchors, reported by Muller (1966), Berrardi (1967), Ostermayer (1974), Ostermayer and Scheele (1977), Mastrantuono and Tomillo (1977), Barley (1995) and Briaud et al. (1998), showed that when applying the initial load the bond stress is concentrated over the proximal length of the fixed anchor, leaving a significant part of the fixed length towards distal end unstressed. By the evolution of the load the bond stress concentration zone is transferred along the fixed anchor as the bond stress along either the tendon/grout or grout/ground interface is exceeded.

Figure 1. Development of bond stress distribution along a fully bonded fixed anchor length (Barley 1995).

Simultaneously, due to progressive debonding, stress at the proximal end reduces to residual values. The bond stress concentration zone reaches distal end of the anchor just before the failure, as it can be seen in Figure 1.

The same mechanism of a non-linear load and bond distribution was confirmed by laboratory full-scale test accomplished by Weerasinghe (1993). It is also important to mention investigation done by Coates and Yu (1970), which studied stress distribution around a cylindrical anchorage in triaxial stress field using finite element methods. The results emphasize the non-uniform bond stress distribution for the ratio of the elastic modulus of the anchor material ( $E_A$ ) and the rock ( $E_R$ ) less than 10 ( $E_A/E_R < 10$ ), which is very common for wide range of rocks and soils in which anchors are usually constructed.

### 2.3 Efficiency factor

There have been a number of attempts to quantify the non-uniform load distribution and to introduce effects of progressive debonding into Formula 1. Casanovas (1989) recommended design based on definition of apparent fixed length ( $L_{ve}$ ) over which the ultimate bond stress can be mobilized:

$$L_{ve} = \left( \frac{L_{fix}}{L_0} \right)^{\frac{1}{\log(0.1 \cdot \frac{\tau_{ult}}{\tau_0})}} \cdot L_0 \quad (2)$$

where:  $L_{ve}$  = apparent fixed length over which  $\tau_{ult}$  (kN/m<sup>2</sup>) operates,  $L_0$  = reference length of 1 m,  $\tau_0$  = reference value of 1 kN/m<sup>2</sup>.

To understand better efficiency factor concept it is possible to analyze Figure 1 and to compare area  $A$ , that corresponds to the final and maximum load stage, with the total area below  $\tau_{ult}$ .

$$f_{eff} = \frac{Area.A}{Area.below.\tau_{ult}} \quad (3)$$

Then, ultimate anchor capacity can be expressed as follows:

$$T_{ult} = \pi \cdot d \cdot L_{fix} \cdot \tau_{fix} \cdot f_{eff} \quad (4)$$

Research based on over 60 full scale tests performed on different anchor fixed lengths, installed in wide range of soil (clays, silty clays, sandy clays, boulder clay and glacial till), permitted development of the concept of the efficiency factor (Barley 1995 and 1997, Barley and Windsor 2000). Figure 2 presents the distribution of the values of the efficiency factor ( $f_{eff}$ ) against anchor fixed length, and the best fit curve can be expressed by following expression:

$$f_{eff} = 1,6 \cdot \left( \frac{L_{fix}}{L_0} \right)^{-0,57} \quad (5)$$

It is important to emphasize that Barley's efficiency factor is quite consistent with Ostermayer (1974) diagrammatic presentation of the ultimate medium skin friction against fixed length for similar soil characteristics and anchor construction process, as it can be seen in Figure 2.

Figure 2. Ostermayer's (1974) boundary lines vs. Barley's (1995) efficiency factor.

Barley (1995) also suggested the efficiency factor for sands, correlating efficiency with the fixed length and the friction angle:

$$f_{eff} = (0,91) \frac{L_{fix} \cdot \tan \varphi}{L_0} \quad (6)$$

One of the most extensive attempts to model construction technique, characteristics and behaviour of anchors have been accomplished by Mecsi (1995), based on analysis of results from numerous installed and monitored anchors.

Analytical solution and simple graphical method based on the theory of expanded cylindrical cavity provide the possibility to define the approximate pull-out capacity. The Analysis of load distribution for the known anchor geometry and rigidity permits determination of the specific pull-out resistance of a 1 m anchor length ( $t_{ult}$ ) and the length of the fully mobilised bond stress ( $L_b$ ). Considering that only reduced percentage of maximum bond stress can be mobilised over the remaining fixed anchor length ( $L_{fix} - L_b$ ), the ultimate anchor capacity can be expressed by the following expression:

$$T_{ult} = \tau_{ult} \left[ L_0 + \frac{1}{k} \cdot \text{th} [k \cdot (L_{fix} - L_0)] \right] \quad (7)$$

$$k = \sqrt{\frac{\tau_{ult}}{E_{steel} \cdot A_{steel} \cdot \Delta_{ult}}} \quad (8)$$

where:  $k$  = rigidity index,  $E_{steel}$  = steel deformation modulus,  $A_{steel}$  = steel tendon area,  $\Delta_{ult}$  = elongation of the shear strength length ( $L_{fix} - L_0$ ).

Based on data from Ostermayer and Scheele (1997), Woods and Barkhordari (1997) proposed efficiency factor for its incorporation in the expression for ultimate capacity of low-pressured anchors in sand (Formula 10), recommended in BS 8081 (1989), which is a function both of fixed anchor length and friction angle:

$$f_{eff} = \exp(-0,05 \cdot \frac{L_{fix}}{L_0} \cdot \tan \varphi) \quad (9)$$

where:  $L_0$  = reference length of 1 m.

$$T_{ult} = f_{eff} \cdot L_{fix} \cdot n \cdot \tan(\varphi) \quad (10)$$

### 2.4 Single Bore Multiple Anchors - SBMA

This system involves the installation of a multiple unit anchors into a single borehole, with enough short unit lengths to reduce or even to avoid the progressive debonding. Each unit is formed by individual tendon and is loaded with the corresponding unit stressing jack, mobilizing its own capacity independently of other unit anchors.

Application of this system permits the unlimited theoretical total fixed length, while conventional anchors formed by only one unit do not provide beneficial effects in load capacity for fixed length superior to 10 m as is stated by numerous authors and design guidelines or codes.

Figure 3. Development of bond stress along a four unit single bore multiple anchor (Barley, 1997).

Total fixed lengths of 10 to 20 m are frequently used in all types of soils, achieving high anchor capacities (2000 to 5000 kN) that are almost three times greater than the normal conventional anchors capacity values (Barley 1997, Barley and Windsor 2000). A comparison of load distribution between conventional and SBMA anchor is presented in Figure 3.

N°/Type of Anc.	$L_{fix}$ m	$T_{ult}$ kN	$\tau_{ult}$ kN/m <sup>2</sup>	$f_{eff}$
8 SBMA (18 units)	2.5	450-540	322-386	1
2 Conventional	7.5	960-1080	230-254	0.59-0.79

### 3.4 Summary

An extensive series of field anchor tests performed in different soils showed that:

- there is no direct proportionality between fixed anchor length and its ultimate load capacity;
- obtained values of the average ultimate bond stresses in cohesive soils fit well with Ostermayer's (1974) diagrammatic presentation of skin friction against fixed length, while results obtained in gravelly sands fit well with Ostermayer and Scheele (1978) presentation of ultimate load capacity vs. anchor length;
- ranges of obtained efficiency factors are consistent with tendency of values proposed by Barley (1995);
- efficiency factor can be considered as a conceptual control of anchor ultimate capacity;
- fixed anchor lengths longer than 10 m do not contribute significant beneficial effects on capacity.
- SBMA anchors permits construction of high anchor capacities that approach more than two times that of the conventional anchors which utilize long inefficient fixed length.

## 4 PROPOSAL FOR DESIGN METHODOLOGY

Based on the information presented in previous chapters, proposal for design methodology for cement grouted anchors formed by steel tendons is presented below, considering most important parameters that define its capacity, like: soil characteristics, execution process, ultimate and average bond capacity, fixed length, type of anchors (conventional or SBMA), stress distribution and efficiency factor.

Emphasis is placed on the effects of progressive debonding that cause the non-uniform stress distribution along the fixed length, with efficiency factor as a conceptual control of anchor capacity. Due to the number of parameters that enter the analysis, recommended methodology has an iterative character, as it can be seen in Figure 6. Some of the most important steps of the flow chart are commented below.

Phase I: Evaluation of the site subsoil conditions and relevant properties of in situ soil and rock, as a factor that directly influence steps in the Phase II (construction system and skin friction estimation).

Phase II: For the skin friction estimation it is recommended to use at least two sources, taking into account the concept or formula that will be applied for the anchor design. If pre-design load tests are performed to evaluate ultimate anchor load capacity, construction process has to be exactly the same as planned for production anchors, and fixed lengths should be similar with test anchors. For the first iteration anchor length is calculated considering uniform bond stress distribution (Equation 1). If calculated fixed length is larger than 5 m, construction process can be reconsidered (Alternative A), varying anchor diameter or type of grouting, with objective to reduce fixed length up to 5 m. Other option (Alternative B) is to introduce directly the efficiency factor.

Phase III: If the fixed length obtained considering non-uniformity is in the range between 5 and 10 m, two alternatives are proposed. First alternative considers conventional type of anchor, with unique fixed length unit calculated taking into account efficiency factor ( $f_{eff}$ ) – Equation 2. Another alternative

is the application of SBMA. In this case fixed length of each unit that forms SBMA is calculated considering corresponding efficiency factor ( $f_{eff}$ ) – Equation 3.

If the fixed length, obtained considering non-uniformity is greater than 10 m it is recommended to apply SBMA anchors.

# The sustainability and assessment of drystone retaining walls

## Le développement durable et l'évaluation des murs de soutènement en pierres sèches

Warren L., McCombie P.

Donohue S.  
*Queens University Belfast*

**ABSTRACT:** The art of drystone walling is a highly sustainable traditional practise which uses local materials and craftsmen. As no mortar is used they have low embodied carbon, and much repair work or rebuilding can be carried out using very little if any new materials. However local practices developed to suit local materials, leading to a range of construction styles, making them difficult to assess. This paper examines a range of construction styles of drystone retaining walls in use across the United Kingdom. Understanding of the substantial variations of construction style is essential to enable proper assessment of these structures. Different frictional and weathering characteristics, and the naturally occurring shapes of stone found in an area, all affect the ways in which the stones have traditionally been assembled into walls. Ease of construction also plays a part, as the craftsman will naturally wish to achieve a robust construction in a way that is economical of time and effort. Aesthetics may be very important, for both client and craftsman. It is also shown that construction style is influenced by the location and function of the structures, with harbour walls particularly likely to have unique characteristics, and the reasons for this are explored.

**RÉSUMÉ :** L'art de la pierre sèche est une pratique hautement durable traditionnelle qui utilise des matériaux et des artisans locaux. En l'absence de mortier, elles ont une faible carbone incorporé, et les travaux de réparation ou de reconstruction bien peut exiger très peu ou pas de nouveaux matériaux. Cependant les pratiques locales développées pour répondre à des matériaux locaux, conduisant à une gamme de styles de construction, ce qui les rend difficiles à évaluer. Cet article examine une gamme de styles de construction de murs de soutènement en pierres sèches utilisées dans l'ensemble du Royaume-Uni. Compréhension des variations importantes du style de construction est essentielle pour permettre une évaluation adéquate de ces structures. Différentes caractéristiques de frottement et aux intempéries, et les formes naturelles de pierre trouvés, affectent la façon dont les pierres ont traditionnellement été assemblés. Facilité de construction joue également un rôle. L'esthétique peut être très important, à la fois pour le client et l'artisan. Il est également démontré que le style de construction est influencée par l'emplacement et la fonction des structures, avec des murs du port particulièrement susceptibles d'avoir des caractéristiques uniques, et les raisons de cette situation sont explorées.

**KEYWORDS:** Drystone, Construction styles, Assessment

## 1 INTRODUCTION.

Throughout the UK there are many different styles and types of walling to be found. Most styles can be categorised as horizontal construction, vertical construction or random construction (Figure 1). Each has its own unique features and is often associated with certain areas of the country and corresponding rock types. Horizontal construction is often found with more blocky types of stone such as limestones, which can be stacked in a more conventional fashion; the stones are also sometimes worked to give a better fit. Horizontal construction is probably the most common type of construction within the UK. Vertical construction is mainly associated with slate type stones that can be tightly packed and may be less successful in a horizontal configuration. Random construction is mainly associated with more granitic type rocks which are hard to work and are often irregular in shape. These styles are sometimes found in combination in a single wall with a single type of stone, and there are variations such as the herringbone construction, found in parts of Cornwall.

It could be argued that every drystone retaining wall works in essentially the same way, as every wall is essentially a gravity retaining wall that relies on the frictional forces between the stone for stability. However, each style is likely to use the mechanical properties of the stones in different ways to achieve the required coherence. The failure and movement of horizontally constructed walls is comparatively well documented and understood (Mundell, 2009) when compared to

the other construction styles. The mechanical differences between the styles are explored below.

Figure 1. Different wall styles found in the United Kingdom: horizontal construction, vertical construction, random construction.

### 1.1 Horizontal Construction

Experimental testing and numerical modelling (McCombie et al. 2012, Mundell et al. 2009, Colas et al. 2010, Villemus et al. 2007) have shown that the overturning moment due to the horizontal component of earth pressure is resisted in part by the vertical component acting in downwards shear on the back of the wall, with very small deformations for well-constructed walls in a normal condition. As walls become overloaded the deformations can become considerable, often showing the classic bulged profile as the walls adapt their shape to the higher applied load (Figure 2). Ultimately, the walls will typically overturn, though if a smooth stone is used the wall or a part of it may slide forwards first. If the wall is constructed in a well-bonded manner, with stones overlapping, then a tensile strength can develop along the length of the wall which greatly assists in

the redistribution of load, and helps give the wall substantial ductility. This behaviour is dependent upon a horizontal construction. A less beneficial consequence of horizontal construction is the reliance on through stones to connect coursed layers of stone at the front and back of the wall across an infill of rubble. These stones are necessarily larger than those used for the rest of the construction, and there may not be sufficient to ensure that the wall behaves monolithically, giving a greater chance of movement and hence failure.

Figure 2. 2.4m high test wall at the University of Bath showing a classic bulged profile in a limestone wall of horizontal construction.

### 1.2 Vertical Construction

There has been no notable published research into vertical or random forms of construction, but some indications of how they perform may be inferred from observations, in relation to the behaviour of horizontal constructions.

Figure 3. Model test showing concrete blocks partially rotated and wedged in against the sides of the test box.

Discussions with wallers who use the vertical form of construction, and detailed observations carried out in Somerset and Cornwall, suggest that vertical construction is reliant on compressional pre-stressing forces. In the majority of vertically constructed walls all stones either penetrate the full width of the wall, or are tightly packed throughout the wall depth creating an effectively continuous cross section. During construction pre-stressing is induced through the wedging of stones at regular

intervals which when combined with the overall confinement from the rest of the wall produces a compressional force. As the walls are backfilled, material will fill any remaining gaps at the back of the wall further strengthening the wedging. Evidence of this is shown in work carried out by Bailey (2008) in conjunction with Mundell (2009) (Figure 3). In Bailey's work during initial experiments using smaller individual blocks it was found that the backfill became wedged between the blocks making them virtually impossible to remove from the testing box. This was a nuisance for these tests, but gives useful information about the mechanical wedging of other wall types.

### 1.3 Random Construction

Random construction is likely to have features common to both the horizontal and vertical construction methods, however the variable morphology of the stones in random construction make it difficult to make generalised assumptions regarding any further mechanisms involved. However, it can be seen that an absence of bonding prevents the development of tensile strength along the wall face, whilst the lack of alignment of vertical stones prevents useful pre-stressing. Randomly constructed walls must rely much more on the size and weight of individual stones.

Table 1. Locations, principal stone types, and principal construction styles in this study.

Location	Geology	Wall Construction
Boscastle, Cornwall, UK	Slate	Vertical Herringbone
Mousehole, Cornwall, UK	Granite	Random
Dartmoor, Devon, UK	Igneous Intrusion	Random
Brompton Regis, Somerset, UK	Morte Slate	Vertical
Northleach, Gloucestershire, UK	Limestone Formations	Horizontal
Bath, Somerset, UK	Interbedded Limestone	Horizontal

The use of these different styles is often found to relate to the types of stone available in a given area. Horizontal construction is often found where stones are more block like in their nature, either naturally or by easy working to desired shapes. The stones used in horizontal construction are often stone types with more frictional surfaces, such as limestones, which help the stones to transfer loading more than any other mechanisms which might occur within the wall. Vertical construction seems more likely to be used with more slaty type materials. Due to its laminated nature slate is often found with a comparatively thin cross section that lends itself more to this style. This form of construction is likely to be beneficial for stones such as slate which have comparatively low surface friction because shear load from earth pressure is transmitted through contact between the rough edges of the stones rather than the smooth surfaces. Random construction is often found where stone is difficult to work e.g. granitic areas or where there is a variety of local stone types, which may all be used in conjunction within a wall. The geology of an area therefore has considerable influence on the locally dominant forms of construction, but it is still possible to see different styles within the same wall (Table 1).

## 2 SPECIFIC CONSTRUCTION STYLES – HARBOUR WALLS

Although wall construction style is often a reflection of locally available stone, sometimes the construction style reflects the purpose of the wall. Probably the best examples of this are the harbour walls found around the United Kingdom. Many of these walls are of significant age - parts of the quay in Mousehole are reported to date back to 1390 (Cornwall-online.co.uk) suggesting that they are well suited to their usage. Mousehole is also unusual when looking at harbour walls as much of it is uncut random rubble.

Figure 4. Wall at Mousehole, Cornwall, containing of large blocks.

It is typical when looking at harbour walls to find vertical construction as you would find with slate type materials, but they can be on a far larger scale to that found in a typical wall. Stones may also be shaped to suit vertical construction even if they are not usually built in the fashion, or are constructed from slate sheets far larger than you may expect to find in a typical vertically constructed wall. This is likely to be linked to the convenience of transport material by water, allowing larger stones to be transported. The vertical construction and larger stone sizes are both advantages in harbour construction. The verticality of the stone helps to prevent uplift by presenting a small bottom face for waves to act on, and provides better drainage for sea water, both during the changing tides and under wave penetration. Being drystone and hence free draining is better suited to harbour construction than most other wall types, in which any water which penetrated the wall under wave pressure may not flow out quickly under gravity alone, inducing extra pressures on the rear of the wall. Having a more massive construction provides better protection from wave action as a greater force is needed to move individual stones within the wall. The voided nature of drystone is also likely to help with wave energy dissipation as waves will break up into the wall on impact, as opposed to being reflected or running up and over an impermeable concrete wall.

Research has been carried out into the construction and tradition of drystone harbours by Richard Tufnell (2012) which he presented at the 13th International Dry Stone Walling Congress in September 2012

## 3 UNDERSTANDING CONSTRUCTION AND ASSESSMENT

Many of the current drystone retaining structures were constructed around 100 years ago with no records of how or exactly when they were constructed. Even many of the modern walls are constructed based on rules of thumb, with little or no input from engineers. Many of these walls have remained stable for a number of years and still continue to do so, retaining a significant proportion of various transport infrastructures throughout the United Kingdom, as well as being used in other applications such as harbour walls and domestic use.

Since the majority of these structures have been built, the loadings that they are subjected to have increased, particularly on the road networks. This combined with the increasing age of the walls and the need to be able to replace or repair walls before collapse means that improved assessment drystone retaining wall stability is increased. The assessment of these structures by engineers is often tricky due to the lack of formal engineering input during their design, as well as a lack of knowledge of failure mechanisms, unlike with more modern retaining structures. Assessing these structures in the same way as modern structures is inappropriate due to their un-mortared nature and inherent flexibility, which means that obvious deformation within the wall does not automatically mean that the wall is unsafe. Guidance on assessment can be found in work by O'Reilly and Perry (2009) and through the various publications by the dry stone walling association. However much of the guidance given is qualitative and relies on the judgement of the engineer assessing the wall as to whether it is safe or not. Where an engineer is familiar with drystone walls in general and the walls he is looking at in particular, then a reasonable assessment is likely to be made. However if an engineer has little to no experience of drystone walls they may take the walls' natural deformations and oddities to be signs of failure, and hence make an inaccurate or insecure judgement. This in turn may lead to walls unnecessarily being taken down and replaced with less sustainable modern alternatives which are out of keeping with their surroundings. It could also lead to a failure which should have been prevented

In order to improve assessment of these structures further engineering knowledge of them is required, both in terms of overall structural behaviour and the effects of properties of individual elements. This should include consideration of how these factors might change with time, such as the weathering of the stone. By understanding generic wall behaviour and how different factors affect this new assessment techniques can be developed that can enable the engineering judgement to be better informed.

It is also important to note the modifications that are often made to drystone retaining walls, often in good faith, which can be detrimental to the wall's health. For example, it is common practise for dry stone walls to be grouted or pointed either in an effort to prevent further movement, or to protect the base of a wall from salt spray, particularly in limestone areas. However in doing so the drainage paths through the wall are often blocked, thus taking away one of the main advantages of drystone retaining walls, which is that due to their un-mortared nature they are free draining. This can cause a build-up of water pressures behind the wall which did not exist before, and ultimately lead to collapse. The grouting of a wall will probably reduce its flexibility, which can be detrimental in two ways. If the wall is less ductile then it is unable to redistribute load concentrations, or distribute load away from weak areas, which could result in a local failure leading to a general collapse. On the other hand, a local crack which might allow a safe redistribution of load might give serious concern.

Unfortunately as with most retaining type walls a number of harbour walls are also being grouted. This is potentially understandable in harbour walls as over time wave action is likely to have caused some visible damage to the wall, and it

may be deemed necessary to protect the wall. However due to their voided nature these walls often need more grout than initially estimated and there is no guarantee that the grouting has been done sufficiently to fill all the voids in a wall. It is also difficult to know where the injected grout ends up. Grouting not only stops the draining of water that enters the wall through wave and sea action, but also most harbour walls retain land behind them so that the grouting will also prevent the drainage of groundwater, which as before exerts extra pressures on the wall and potentially causes failure.

Figure 5. Grouted wall of vertical construction at Port Gavern, Cornwall

A general difficulty of assessing walls which have failed is that due to their un-mortared nature, all that is usually left of a failed section of wall is a pile of rubble that is almost impossible to analyse, and it cannot be assumed that adjacent standing sections give a true indication of the form of a failed section. Some judgement may be able to be made about the foundations or conditions of the backfill but little can be said about the wall. Increasing the understanding of how these walls work as well as improving assessment it may make it easier for engineers to use drystone walling in new build projects or to replace existing damaged walls, rather than their more modern and less sustainable counterparts.

### 3.1 Appearance Vs. Wall Quality

When assessing a drystone wall much weight might be given to the appearance of the wall at its face. This can be deceiving, especially as the way in which walls are finished is likely to have changed over the years. It is likely that the majority of walls built a hundred years or more ago had greater emphasis on function, whereas aesthetics are likely to be an important factor in choice of drystone walling today. This means that quality of the aesthetics is easily taken as a proxy for quality of construction, but just because the wall face looks even and is cleanly finished does not mean that the wall behind will be to the same standard - and vice versa. For example, wallers cite cases where freestanding walls have appeared to be well constructed and have a good finish but have failed within months of being built, because instead of being constructed with properly packed filling they have been filled with pea shingle with no through stones, preventing the wall from performing as a monolith. In another case a waller was asked by a client to build a small retaining wall which was to have a hedge planted in front of it, so ultimately was not worried about the finished appearance of the wall. He also did not want any wastage of the stone, whereas normally a certain amount of stone is left at the end where stones have been shaped or just not used in the wall. However this wall was built to no less a standard than other walls he had built for the same client which had a very high quality of finish to them.

## 4 THE SUSTAINABILITY OF DRYSTONE WALLS

As with most constructions the sustainability of drystone walls must also be considered. When considering drystone structures this will also include the ecology impacts of the walls providing habitat and shelter for both animals and plants.

Drystone walls are naturally very sustainable structures and with the current imperative of low carbon structures are an almost ideal solution. Their main advantage is a lack of mortar, this not only means that the walls lack the embodied carbon associated with the mortar, but that when repair or rebuild is required very little if any new material is required. This does however depend on the stone type; for example a limestone wall is more likely to need some new material as limestone is prone to decay from water and frost. Traditionally walls have been built with materials local to where the wall was built, as with most vernacular structures, and this has continued through the generations of wall builders so that even today new materials are usually obtained from local quarries or sources well known to the waller. This means that there is minimal transport of materials, thus reducing the embodied carbon within a drystone wall. Drystone walls also provide an excellent habitat for a variety of animals and plants and various research has been carried out where drystone walls have been highlighted. (Hynes and Fairley 1978, Cody and Cody 1972,)

## 5 CONCLUSIONS

Drystone retaining walls of horizontal construction have dominated scientific work to date, but regional construction styles which have developed in response to the type of stone available or particular requirements may behave in significantly different ways. It is important that these differences are understood if the stability of walls is to be assessed correctly.

# Numerical modelling of groundwater flow around contiguous pile retaining walls

Modélisation numérique des écoulements des eaux souterraines autour d'écrans de soutènement de pieux contigus

Wiggan C. A., Richards D.J., Powrie W.

University of Southampton, Southampton SO17 1BJ, United Kingdom

**ABSTRACT:** Pore water pressure constitutes a significant proportion of the lateral load acting on a retaining wall. Consequently, guidelines often mandate that the worst case hydraulic conditions are applied in the design of retaining walls. This invariably dictates that retaining walls are treated as impermeable unless special consideration is given to the maintenance of drainage systems or to the prevention of infiltration. Contiguous pile retaining walls are, however, by their nature permeable unless considerable effort is expended to prevent seepage through gaps. If allowed, this seepage can result in reduced active side pore water pressures. Numerical simulations were conducted to determine the impact on pore water pressures of varying the pile gap ( $x$ ) to diameter ( $d$ ) ratio,  $x/d$ , in a contiguous pile retaining wall. A relationship between  $x/d$  and the effective bulk wall permeability,  $k_p$  was derived, and applied to two-dimensional simulations representing a contiguous pile wall. The results show that pore pressures behind the retaining wall reduced significantly with increased  $x/d$ .

**RÉSUMÉ:** La pression de l'eau interstitielle constitue une part importante des charges latérales agissant sur les parois d'un mur de soutènement. Par conséquent, les règles de l'art imposent que les pires conditions hydrauliques soient considérées dans la conception d'un mur de soutènement. Cela impose invariablement que les murs de soutènement soient considérés comme imperméables à moins que des considérations particulières soient données à l'entretien des systèmes de drainage ou à la prévention des infiltrations. Les murs de soutènement constitués de pieux contigus, sont cependant perméables (de par leur structure), à moins que des efforts considérables soient déployés pour empêcher les infiltrations à travers les intervalles. Ces infiltrations peuvent entraîner une réduction des pressions interstitielles effectives. Des simulations numériques ont été réalisées afin de déterminer l'impact des variations de l'espace entre palplanches ( $x$ ), de diamètre ( $d$ ), de ratio,  $x/d$ , sur les pressions interstitielles d'un mur de soutènement constitué de pieux contigus. Une relation entre le ratio  $x/d$  et la réelle perméabilité du mur,  $k_p$  a été déduite et appliquée à un modèle à deux dimensions représentant un mur en pieux contigus. Les résultats montrent que les pressions interstitielles derrière le mur de soutènement diminuent significativement lorsque le ratio  $x/d$  augmente.

**KEYWORDS:** Pore water pressure, numerical modelling, retaining wall, seepage forces, surface settlement

## 1 INTRODUCTION

Guidelines generally require that the most onerous tenable pore water pressure distribution is adopted for the design of subsurface retaining structures. For example, Eurocode 7 recommends that, unless reliable drainage can be provided or infiltration prevented, retaining walls should be designed with the water table at the ground surface (BSI, 2004). This can however cause over-conservative and unnecessarily expensive engineering solutions which go against the ethos of sustainable development. It would be advantageous if, based on the bulk permeability of the structure, the hydraulic loads on retaining walls could be treated as reduced.

There is however limited research into how the geometry influences hydraulic loads on retaining walls although, according to CIRIA 580, 'economic advantages' might be derived if through-wall seepage is allowed (Gaba et al. 2003). This is due mainly to the reduction in pore pressures because of through-wall seepage. Research into ways of facilitating through-wall seepage and quantifying its effect is necessary.

### 1.1 Research in hydraulic loads around retaining structures

Previous research has not generally sought to distinguish between the long-term pore water pressure distributions around different types of retaining walls. For example, Potts and Burland (1983) and Hubbard et al. (1984) showed that the long-term pore pressures behind a secant pile retaining wall recovered to near their pre-construction values as might be

expected of an impermeable wall in fine soils. Powrie et al. (1999) and Carder et al. (1999) observed a reduction in pore pressures following construction of a contiguous pile retaining wall at Woodford. The pore pressures at Woodford however, did not return to their pre-construction values in the long-term. This reduction was attributed at the time to under-drainage to the more permeable chalk layer and therefore no consideration was given to the possible contribution of through-wall seepage. However Clark (2006) and Richards et al. (2007) have shown that there was a reduction in long-term pore pressures measured at a contiguous pile retaining wall in over-consolidated clay at Ashford. The pore pressures have not returned to their pre-construction values. Although there is underdrainage to the more permeable Weald Clay at Ashford, there is evidence that the long-term reduction in pore pressure can be attributed to through-wall seepage.

In contrast to retaining walls, there has been significant research into methods of reducing pore water pressures acting on shallow tunnels and on tunnels acting as drains. Despite an earlier assumption by Atkinson and Mair (1983) that groundwater loadings do not change significantly in the presence of varying hydraulic conditions, it has been shown by numerical analyses that segmented tunnel linings do in fact allow seepage of groundwater which contributes to reduced pore water pressures around tunnels in fine grained soils. Pore pressures at segmented lined tunnels approach atmospheric values and increase with distance away from the tunnel (Shin et

al. (2002), Lee and Nam (2006), Bobet and Nam (2007) and Arjnoi et al. (2009)).

The corresponding reductions in axial forces and stresses on segmented tunnel linings in comparison with fully waterproofed linings are significant, although inconsistent. For example Arjnoi et al (2009) observed a 20% reduction, Lee and Nam (2001) 25%, Potts et al. (2002) up to 30% and Lee and Nam (2006) up to a 70% reduction.

1.1.1 Surface settlement

Notwithstanding the potential advantages of allowing through-structure seepage, some detrimental effects have been noted in the analyses of shallow tunnels which might be relevant to through-wall seepage. Significant settlements have been observed associated with segmented lined tunnels acting as drains in fine grained soils. For example, Yoo (2005) noted that settlement was proportional to the amount of drawdown in the groundwater levels around the tunnel. Consolidation settlement,  $\rho$  due to the drawdown of groundwater level may be estimated in a similar manner by considering the one dimensional stiffness modulus,  $E'_0$  of the soil as shown in equations 1 and 2 (Roberts et al. 2007).

$$E'_0 = 400 \sigma'_{v} \tag{1}$$

$$\rho = \frac{D_w \gamma_w S_{av}}{E'_{0av}} \tag{2}$$

where  $\sigma'_{v}$ ,  $D_w$ ,  $\gamma_w$  and  $S_{av}$  are the vertical effective stress, thickness of the soil layer, unit weight of water and average drawdown respectively.

In this paper, pore water pressure variations around contiguous pile retaining walls are investigated numerically. An expression for the resulting effective bulk wall permeability  $k_p$ , is derived. This is then applied to two dimensional analyses of contiguous and secant pile retaining walls to highlight the advantages of a semi-permeable structure.

2 NUMERICAL ANALYSES

Numerical simulations were conducted using the finite difference geotechnical application FLAC2D (ITASCA, 2012). The investigations were undertaken in two phases. Horizontal flow was simulated in phase 1 to determine how pore pressures and steady state flow vary with  $x/d$  in order to derive an expression for  $k_p/k_s$ . This relationship was then applied to a vertical plane flow in phase 2 and the pore pressures calculated.

Preliminary analysis, not included in this report, were carried out to establish i) suitable boundary locations, ii) the size of the numerical grid and iii) the limiting value of  $x/d$ . Grid boundaries were selected such that  $x/d$  did not influence the far-field conditions. It was determined that increasing  $x/d$  above 2 did not significantly impact the results.

2.1 Model soil and wall properties

An elastic constitutive soil model was used in all analyses. Elastic properties of bulk and shear moduli were used instead of Young's modulus and Poisson's ratios. The soil and model pile section and the model wall in phases 1 and 2 respectively were represented by grid elements attached directly to the soil grid without the use of interface elements so as to allow cross-boundary flow. Uncoupled groundwater flow analyses which ignored the impact of mechanically induced pore pressures were performed.

2.2 Derivation of bulk wall permeability,  $k_p$

The simulations started with a 'wished into place' model pile section and the water level at the surface. Pore pressures at the

discharge surface shown in figure 1 were lowered incrementally corresponding to pressure drops  $U_i$  for each step. Steady state discharge and pore pressures were measured and fluid flow-paths tracked for different pile gap to diameter ratios  $x/d$ .

Figure 1. Plan of typical numerical grid showing boundary conditions for phase 1 analyses.

2.2.1 Results and discussion

Darcy's equation for steady state flow (Eq. 3) was applied using the parameters  $\Delta l$ ,  $h_1$ , and  $h_2$  indicated in figure 2 and the values compared with the numerically derived flow rates ( $Q_i$ ) in figure 3 at pressure differences,  $U_i$ .

$$Q = A_p k_p \frac{h_1 - h_2}{\Delta l} \tag{3}$$

where  $(h_1 - h_2)/\Delta l$  is the hydraulic gradient between the distance of influence and the discharge surface (see Figure 2). (The distance of influence was selected as the point beyond which the hydraulic gradient was uniform).

Figure 2. Calculating bulk wall permeability,  $k_p$  and flow-paths.

Figure 3. Steady state flow-rates,  $Q_i$  at various pressure drops  $U_i$ .

The resulting bulk wall permeability was calculated for a soil permeability  $k_s = 2 \times 10^{-5}$  m/s and plotted for three values of  $U_i$  (see Figure 4). The empirical hyperbolic relationship between the pile gap to diameter ratios  $x/d$  and permeability ratios  $k_p/k_s$  derived in the phase 1 simulation is given in equation 4.

$$\frac{k_p}{k_s} = \frac{4 \frac{x}{d}}{1 + 4 \frac{x}{d}} \tag{4}$$

Figure 4. Calculated permeability from FLAC2D simulations.

2.3 Application of derived expression to 2D analyses

The aim of phase 2 simulations was to test the application of the permeability expression derived in phase 1.

2.3.1 Procedure

A continuous wall was used to represent the contiguous pile retaining wall. The model wall thickness (t) was calculated by equating the second moments of area (I) of the different cross-sections (A) as outlined by Powrie et al (1999) (Eq. 5). This gave a result similar to the stiffness approach adopted by Day and Potts (1993) (see Eq. 6 and 7).

$$I_p = I_m \tag{5}$$

$$tE_{eq} = EA \tag{6}$$

$$E_{eq} = EI \tag{7}$$

where  $E_{eq}$  and  $E$  are the equivalent model wall stiffness and material Young's modulus respectively.

The simulations commenced as before with a 'wished into place' model wall. Pore pressures were varied corresponding to  $U_i$  as before for different pile gap to diameter ratios,  $x/d$ .

2.3.2 Results and discussion

It was observed that flow patterns for the 'permeable' walls deviated from the classically accepted flow around an impermeable retaining wall especially at higher values of  $x/d$ . This seems to suggest that through-wall flow is taking place for  $x/d > 0.0$  as shown in figure 5.

Figure 5. Tracked flow-paths for  $x/d=0$  and  $x/d=0.1$ . Note these are not intended to be flownets, hence the flow elements are not "square".

2.3.3 Pore pressure distribution

Pore pressures ratios  $P_i/P_0$  are plotted against normalized distance (L/d) from the model wall in figure 6 for various values of  $x/d$ .

Figure 6. Normalised pore pressures for different  $x/d$  against distance (L/d) from the wall.

It was observed that pore pressures at each position behind the wall decreased with  $x/d$  as the equivalent permeability increased. Further analyses have shown that the pore pressures and hence hydraulic head reduce towards the wall (Figure 7).

Figure 7. Normalised pore pressure versus normalized depth below soil surface for different values of  $x/d$ .

2.3.4 The effect of seepage on surface settlement

Surface settlements increased as the bulk permeability of the wall increased (see Figure 8). The calculated settlement values were compared with an estimated solution which uses the one dimensional stiffness modulus (Roberts et al 2007). It was noted that the 1D stiffness modulus method over-predicted surface settlement at higher  $x/d$  as shown in Figure 9. This is unsurprising as in this approach all volume change is assumed to manifest as vertical settlement.

Figure 8. Normalised settlement increases with soil/structure permeability.

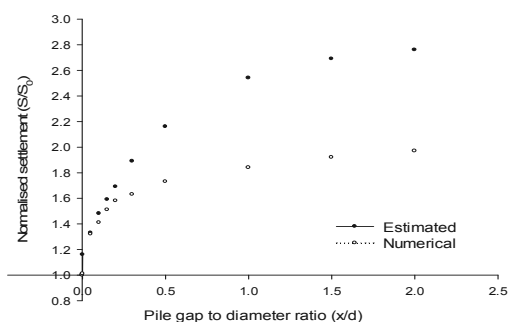

Figure 9. Comparison of analytical and numerical solutions for surface settlement variation with  $x/d$ .

### 2.5 Secant versus Contiguous Pile Retaining Walls

Comparisons were made between retaining walls formed of contiguous and secant piles 20m long with 10m excavation depth in homogeneous soil. Figure 10 shows that the pore pressure profiles are slightly less than hydrostatic for the secant and significantly less than hydrostatic for the contiguous pile wall.

Figure 10. Comparison of pore pressure profiles for secant and contiguous pile walls against hydrostatic pressure.

## 3 CONCLUSIONS

Limited research has previously been carried out on the influence of retaining wall geometry on the development of hydraulic loads on the active side. Numerical simulations presented in this paper have shown that the pore pressure magnitude behind bored pile retaining walls reduces with increasing pile gap to diameter ratio,  $x/d$ . This reduction in lateral loads however is accompanied by an increase surface settlement. However, the potential benefits of allowing through-wall seepage are likely to be greater than the drawbacks.

## 4 ACKNOWLEDGEMENTS

Funding for this research was provided by the Engineering and Physical Sciences Research Council, (EPSRC) grant number EP/F063482.

# Geosynthetic Reinforced Soil Wall Performance under Heavy Rainfall

## La performance du mur en sol renforcé par géosynthétiques sous de fortes pluies

Yoo C., Jang D.W.

*Dept. of Civil and Environmental Engineering, Sungkyunkwan University, Suwon, Korea*

**ABSTRACT:** Global warming is now considered to be one of the greatest threats to earth. The direct consequence of the temperature increase due to the global warming include a rise in sea levels and a change in the amount and pattern of precipitation. Since the amount pattern of precipitation have of paramount implications to short and long-term performance of geo-structures, geo-engineers should pay attention to the issue of global warming. In this paper, the results of laboratory investigation into the effect of rainfall on the performance of geosynthetic reinforced soil wall (GRSW) are presented. A series of model tests were performed using reduced scale model walls, which were reduced from a full-scale GRS wall according to the similitude law. The model GRSWs were subjected to cycles of wetting and drying process with different rainfall intensities but with a same amount. The results show that the cycles of wetting and drying associated with a heavy rainfall may induce additional wall displacement and reinforcement strains in GRSWs, and that such trends have significant implications to GRSW stability, especially for walls designed with marginal factor of safety in terms of long-term performance.

**RÉSUMÉ :** Le réchauffement climatique est aujourd'hui considéré comme l'une des plus grandes menaces pour la terre. Les conséquences directes de l'augmentation de température due au réchauffement climatique incluent notamment l'élévation du niveau des mers et un changement dans la quantité et le régime des précipitations. Ces paramètres ayant des implications primordiales sur les performances à court et à long terme de géo-structures, les géo-ingénieurs devraient prêter attention à la question du réchauffement climatique. Dans cet article, les résultats des études en laboratoire sur les effets de fortes précipitations pour la performance des murs en sol renforcé par géosynthétiques (GRSW) sont présentés. Une série d'essais sur modèles réduits a été réalisée avec des modèles réduits d'un mur à pleine échelle GRS suivant la loi de similitude. Les modèles GRSW ont été soumis à des cycles de mouillage et de séchage avec des intensités pluviométriques différentes. Les résultats montrent que les cycles de mouillage et de séchage associés à une forte pluie peuvent provoquer un déplacement supplémentaire du mur et les tensions dans le renforcement, et que ces tendances ont des implications importantes pour les GRSW conçus avec un faible facteur de sécurité en termes de performance à long terme

## 1 INTRODUCTION

Since the early 20<sup>th</sup> century, Earth's mean surface temperature has increased by about 0.8°C with about two-thirds of the increase occurring since 1980. A climate model projects that the global surface temperature will probably rise further 1.1 to 6.4°C during the twenty-first century (IPCC 2007). An increase in global temperature will cause sea levels to rise and will change amount and pattern of precipitation as well. Korea is no exception from the issue of global warming. The Korean Meteorological Administration (KMA) has made a report on climate change characteristics during the period of 1996–2005 that the mean temperature has increased by 0.6°C from the last 30 year mean temperature during the period between 1971 to 2000 (KMA 2008). The annual precipitation has also increased by 11%. It is projected that the temperature increase will be as great as 4°C with an annual precipitation increase of 17% by the end of 21<sup>st</sup> century. Since the increase in precipitation has of paramount implications to short and long-term performance of geo-structures, geo-engineers should pay attention to the issue of global warming.

In response to the need for addressing the effect of rainfall on geo-structures for design and construction, a number of studies have been undertaken. Most of the available studies are, however, focused more or less on the effect of rainfall on natural slopes (Gasmo et al. 2000, Tsaparas et al. 2002, Zhan and Ng 2004, Cai and Ugai 2004, Cheuk et al. 2005, Garcia et al. 2006, Rahardio et al. 2007, Rahimi et al. 2011) except Blake et al. (2003) and Yoo et al. (2008a, 2008b) in which the effect

of rainfall on retaining structures was investigated. More specifically, Yoo et al. (2008a, 2008b) investigated the effect of rainfall on GRSWs using a series of limit equilibrium analyses within the framework of unsaturated shear strength, coupled with transient infiltration analyses. Much still need to be studied on the subject of the effect of rainfall on geo-structures.

In this paper, the results of a laboratory investigation into the effect of rainfall on the performance of geosynthetic reinforced soil wall (GRSW) are presented. A series of model tests were performed using reduced scale model walls, which were reduced from a full-scale GRS wall according to the similitude law. The model GRSWs were subjected to cycles of wetting and drying process with different rainfall intensities but with the same total rainfall.

## 2 REDUCED SCALE MODEL TEST

A series of reduced scale model tests were performed with due consideration of the wetting and drying process. Details of the model tests and the results are given in the subsequent sections.

### 2.1 Model wall and backfill soil

The reduced scale model tests were performed using 0.5 m high reduced scale model GRSWs constructed in a test box, having dimensions of 0.9 m x 0.4 m in plan and 0.6 m in height, made of 2 cm thick Plexiglas as shown in Figure 1. The test box was made sufficiently rigid to maintain the plane-strain condition during test. The wall facing, made of 0.5 cm thick Plexiglas,

was hinged at the bottom of the test box so as to allow lateral displacement to occur during the wetting and drying process.

The backfill soil was a non-plastic poorly-graded sand, commonly known as decomposed granite soils (DCG) in Korea, classified as SP as per ASTM 2487 (ASTM 1992) with the effective size ( $D_{10}$ ), uniformity coefficient ( $C_u$ ), and coefficient of curvature ( $C_c$ ) of 0.36 mm, 5.3 and 1.1, respectively. The soil was compacted to 70% of its maximum unit weight ( $19kN/m^3$ ) to create reinforced as well as retained zones. The estimated effective internal friction angle ( $\phi'$ ) using a series of consolidated-undrained (CU) triaxial compression tests with pore pressure measurements at a density corresponding to the as-compacted state was determined as approximately  $35^\circ$  with a shear stress intercept of 8 kPa.

Figure 1. Test box and model GRSW

A non-woven geotextile was used as reinforcement. Note however that the tensile strength of the non-woven geotextile was intentionally reduced by creating 5 mm x 5 mm square holes (Figure 2) to have an ultimate tensile strength of  $3.8 \times 10^{-2} kN/m$ . Six layers of reinforcement, 35 cm in length each, were placed at a vertical spacing of 6 cm (Figure 3). The reinforcement layers were firmly connected to the wall facing by bolting.

Figure 2. Model geotextile reinforcement

Figure 3. Schematic sectional view of model GRSW

### 2.2 Rainfall simulation

Three cycles of wetting and drying were applied to the model walls to simulate the natural weather condition. Two rainfall intensities ( $I_r$ ) were considered, i.e., 18.7 mm/h and 56.2 mm/h

for a given total precipitation of 450 mm. The duration of the rainfall for the case with  $I_r = 18.7 mm/h$  was therefore 24 hours while 8 hour duration was used for the case with  $I_r = 56.2 mm/h$ . Note that these rainfall conditions were based on the actual rainfall occurred in 2011 in Kyoung-Gi province, Korea. Followed after each wetting process was a 24 hour drying period prior to the ensuing wetting to observe the wall behavior during the repeated wetting and drying.

The rainfall was simulated by spraying water at the top of the backfill using spray guns with 15HP compressor and a 20W water motor (Figure 4).

Figure 4. Schematic diagram of rainfall simulator

### 2.3 Instrumentation

The performance of the model GRSW under a series of wetting and drying cycles was evaluated in terms of wall facing displacements, pore water pressures, and reinforcement strains. The layout of instrumentation program is shown in Figure 5.

As shown, the horizontal displacements of the wall facing were measured by using three LVDTs having gauge length of 100 mm, placed at locations along a vertical row. In addition, the wetting and drying cycle induced reinforcement strains were measured using high-elongation strain gauges, manufactured by Tokyo Sokki Kenyujo Company (Model YFLA-5-5L) which were mounted directly onto the selected reinforcement layers in one array. Also installed at the back of the reinforced zone were two pore pressure cells (Model BPR-A-200 kPa) at the bottom (0 mm) and 250 mm above the wall base. The volumetric water content of the backfill soil during the wetting and the drying process was also measured using a tensiometer (Model EC-5).

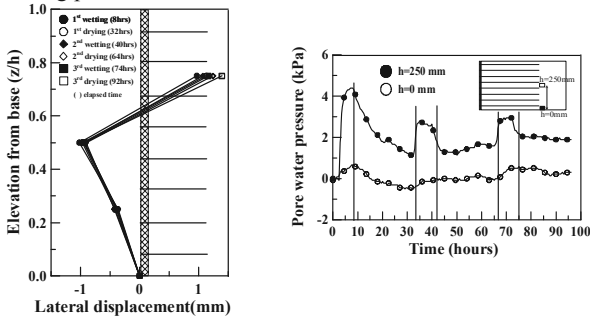

Figure 5. Instrumentation layout

## 3 RESULTS AND DISCUSSION

### 3.1 General behavior

Figure 6 show the measured data for the rainfall intensity of  $I_r = 56.2 mm/h$ . As mentioned, the 56.2 mm/h intensity rainfall

lasted for 8 hours for wetting. As shown in Figure 6(a), the wall displacement increased about 1 mm during the 1<sup>st</sup> cycle of wetting after which no significant increase was recorded. The pore water pressures measured at the bottom and the mid-height at the back of reinforced zone tended to increase during the first wetting period as great as 4 kPa, followed by gradual decreases during the ensuing 24 hour drying period as shown in Figure 6(b). As observed in the wall displacement, the largest increase in the pore water pressure was measured during in the first wetting period.

(a) wall displacement (b) pore pressure  
Figure 6. Wall displacement and pore pressure ( $I_r = 56.2 \text{ mm/h}$ )

Shown in Figure 7 are the measured reinforcement strains in the selected reinforcement layers. Of salient features are twofold. First, the reinforcement strains tended to steadily increase over the repeated wetting and drying cycles unlike the wall displacements and the pore water pressures which showed cycles of fluctuation during the wetting and drying process. Second, larger strains, as great as 0.015%, are measured in the upper reinforcement layers than in the lower layers due possibly to the downward movement of wetting front caused by the rainfall infiltration.

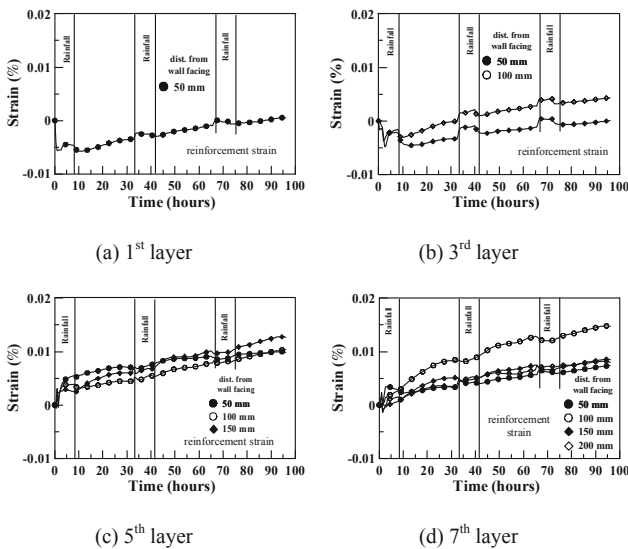

Figure 7. Reinforcement strains ( $I_r = 56.2 \text{ mm/h}$ )

Figure 8 shows the time variation of volumetric water content ( $\theta$ ) measured at 160 mm above the wall base at the back of the reinforced zone. As shown, the initial volumetric water content of 0.05 at the measuring point sharply increased to 0.35 after which it remained constant over the remaining wetting period. During the drying period,  $\theta$  then sharply decreased to 0.2 and remained constant during the entire drying period. A similar trend can be observed in the following cycles suggesting that the cycles of the wetting and drying with the rainfall intensity and duration considered in this study may increase the water content of the backfill soil.

The results shown here indicate that the repeated cycles of wetting and drying associated with a heavy rainfall may induce additional wall displacement and reinforcement strains in GRSWs. Such results suggest that the weather induced wetting drying has significant implications to GRSWs designed with marginal factor of safety in terms of long-term stability.

Figure 8. Time variation of volumetric water content ( $\theta$ )

### 3.2 Effect of rainfall intensity

Figures 9 and 10 show the measured wall displacements and the reinforcement strains for the case with a rainfall intensity of 18.7 mm/h. Note that the total rainfall was kept same at 450 mm as in the case of  $I_r = 56.2 \text{ mm/h}$  but with a longer wetting period of 24 hours. The discrepancies in the wall performance between the two cases can therefore be thought to stem from the rainfall intensity.

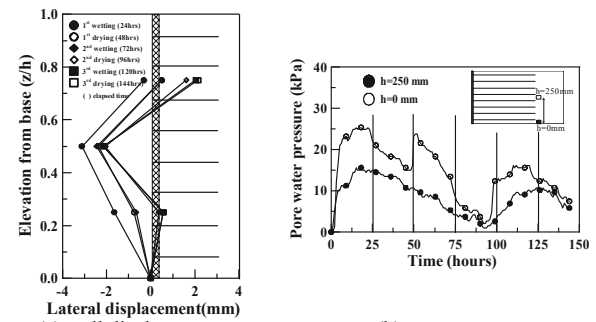

Figure 9. Wall displacement and pore pressure ( $I_r = 18.7 \text{ mm/h}$ )

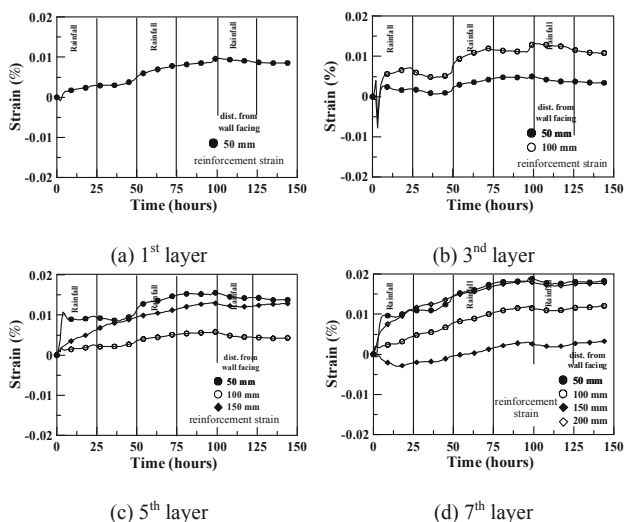

Figure 10. Reinforcement strains ( $I_r = 18.7 \text{ mm/h}$ )

The direct comparison between the two cases reveals that the case with the smaller rainfall intensity but with the longer duration generally induces larger wall displacements and reinforcement strains except for the pore water pressure measured at the back of reinforced zone. Considering the backfill soil being a high permeability soil, these results

contradict those reported by Cai and Ugai (2005) as well as Rahardjo et al. (2007) which were based on a numerical study. A further study is therefore warranted to confirm the effect of rainfall intensity. It can however be stated that the rainfall intensity is a controlling factor for the performance of a GRSW during rainfall infiltration as reported by Rahardjo et al. (2007) in their study concerning natural slopes.

#### 4 CONCLUSIONS

In this study, the results of laboratory investigation into the effect of rainfall on the performance of a geosynthetic reinforced soil wall (GRSW) using reduced scale model tests are presented. The model GRSWs were subjected to cycles of wetting and drying process with different rainfall intensities but with the same total rainfall. The results show that the cycles of wetting and drying associated with a heavy rainfall may induce additional wall displacement and reinforcement strains in GRSWs, and that such trends have significant implications to GRSWs with marginal factor of safety in terms of long-term performance. The effect of rainfall intensity for a given total rainfall is such that the case with a smaller rainfall intensity but with a longer duration generally induces larger wall displacements and reinforcement strains except for the pore water pressure measured at the back of reinforced zone. Although a further study is required to confirm the effect of rainfall intensity, it can be concluded that the rainfall intensity is a governing factor for the performance of a GRSW during rainfall infiltration.

# General Report of TC 208 Slope Stability in Engineering Practice

Rapport général du TC 208  
La stabilité des talus dans la pratique de l'ingénieur

Bowman E.T.  
University of Sheffield

Fannin R.J.  
University of British Columbia

**ABSTRACT:** This General Report reviews 37 papers from 21 countries or provinces that were submitted to the conference on the topic of slope stability in engineering practice. These papers serve either to advance the state-of-the-art, else to inform the state-of-practice. Further, by developing new knowledge, else refining existing knowledge, the observations reported in the papers and the conclusions that are drawn from them provide for improved decision-making in the face of risk and uncertainty.

**RÉSUMÉ :** Le présent rapport général passe en revue les 37 communications provenant de 21 pays et provinces qui ont été soumis au Congrès sur le sujet traitant de la stabilité des talus dans la pratique de l'ingénieur. Les communications ont comme objectif soit de faire évoluer l'état des connaissances, soit de rendre compte de la pratique actuelle. Par le développement de nouvelles connaissances ou par l'affinement de connaissances existantes, les observations relatées dans ces communications et les conclusions qui en sont tirées permettent d'améliorer les processus décisionnels face aux risques et aux incertitudes.

**KEYWORDS:** Slope stability, landslide, debris flow

## 1 INTRODUCTION

Slope stability in engineering practice is considered by many to be a broad-ranging subject, and this viewpoint is perhaps supported by the diversity of papers submitted to the conference. Yet, in reality, studies of slope stability in engineering practice are unified by the common objective of a better understanding of (i) the spatial and temporal variation of demand and capacity at the point of origin and (ii) the magnitude and travel distance of the event along its path of movement downslope. All of the papers submitted to the conference address these objectives in one form or another. In this regard, the findings of the papers serve either to advance the state-of-the-art, else to inform the state-of-practice. More importantly, by developing new knowledge, else refining existing knowledge, the observations reported in the papers and the conclusions that are drawn from them provide for improved decision-making in the face of risk and uncertainty.

This General Report reviews 37 papers from 21 countries or provinces that were submitted to the conference on the topic of slope stability in engineering practice.

### 1.1 Focus / approach of papers

Table 1 indicates that there is overlap in the focus of many of the papers, with 24 of them sharing two or more approaches or topics. This is particularly evident for papers that have a case study element with 14 of these linking to a numerical model, detailed field study and/or risk assessment. It is encouraging to see that such case studies are being increasingly presented with a critical and quantitative assessment of the factors that may have contributed to a slope failure occurring. A further 4 of the case study papers directly link to implementation of mitigation measures (*Şengör et al.*; *Coutinho and da Silva*; *Bozo and Allkja*; *Chang and Huang*), although with the exception of the paper by *Şengör et al.*, other than qualitatively showing the utility of such measures, the outcomes are neither analysed nor presented in detail.

Table 1. Number of papers by approach or focus.

Approach / focus	Papers
Case study	21
Numerical - deterministic	9
Numerical - probabilistic	6
Field study / instrumentation	6
Experimental / physical model	6
Risk assessment	6
Mitigation measures	6

In contrast, it is interesting to note that 4 of the 9 papers that use deterministic numerical models do not attempt to validate against any particular field situation. In these cases, the models in question may be still at the development stage (*Saha*; *Nonoyama et al.*; *Law et al.*) else the authors intend to illustrate a potentially general mechanism of failure (*Dey et al.*).

A total of 6 papers present a detailed study of a particular area via field instrumentation or discuss the development of instrumentation for monitoring of slope instability, while a further 6 papers present an experimental analysis of soil behavior or a detailed physical model of a particular scenario. These approaches are important to enable an understanding of fundamental mechanisms of slope instability and can be very important to determining the details of complex interactions between, for example, groundwater and precipitation on rainfall-induced landslides, or sediment supply and frequency of debris flows.

Six papers take a risk assessment approach – either for a defined area for site-specific purposes related to risk assessment or for a more regional approach that is more appropriate to concern of risk management.

### 1.2 Type of instability investigated

Table 2 shows the types of landslide failures that are discussed in the papers. Approximately 30% of the papers are on rainfall-induced landslides, 8% on earthquake-induced landslides (solely) and nearly 30% on debris flows or flow-

slides, with multi-hazard landslides (mostly earthquake coupled with debris flow) accounting for 10%. The remaining papers address progressive slides (4%) or the triggering / landslide type is unspecified (19%).

The fact that there are 10 papers on debris flows or flow slides is a marked increase on previous years. For the 16<sup>th</sup> International Conference on Soil Mechanics and Geotechnical Engineering, Chau (2005) noted that only two papers dealt with debris flows. While as Chau (2005) has pointed out, there are dedicated conferences on debris flows elsewhere, the inclusion of these papers in a broader geotechnical forum is promising in terms of applying geotechnical rigor to a problematic subject of global concern.

The recognition of landslides within a multi-hazard causal framework is also extremely important, although the number of papers presented is still relatively small. As determined by Lin et al. (2004), amongst others, earthquakes can lead to worsening conditions for landslides and debris flows, while landslides can be the precursor of debris flows particularly where the landslide meets a body of water or ice. A thorough understanding of the complexity of such scenarios is believed warranted, because the state-of-the-art must continue to inform the state-of-practice and, on occasion, the cutting-edge of practice is challenged to address some very challenging realities of risk management.

Table 2. Number of papers by instability type

Type of failure	Papers
Rainfall / pore pressure induced	11 (14)
Earthquake induced	3 (7)
Debris flow / flow slide	10 (11)
Multi-hazard	4
Progressive	2
Unspecified	7

(Parentheses indicate numbers that include multi-hazard papers)

### 1.3 Breakdown of research papers by country

Table 3 presents the number of papers from different countries and indicates an important reality with respect to where research activity is currently concentrated by region. As has been previously noted by Petley (2012), much of the work on landslides is carried out by researchers in developed economies, where the focus has moved from life impacts (which have been reduced over time due to the development of a relatively good understanding of catastrophic landslide behavior in these countries) to economic impacts (which may be more influenced by slower movements and low-magnitude, albeit high- frequency events). However, in emerging and developing economies, which have large numbers of landslides per annum, there is relatively little research on-going, the threat to life remains unacceptably large.

Table 1. Number of papers in session by country / province

Country	Papers	Country	Papers
Norway	6	India	1
Japan	4	Korea	1
Taiwan / Chinese Taipei	4	Lebanon	1
USA	4	New Zealand	1
Hong Kong, China	3	Russia	1
Albania	2	Sweden	1
Brazil	1	Turkey	1
Canada	1	United Kingdom	1
Mainland China	1	Vietnam	1
Greece	1		

To illustrate this, Figure 1 after Petley (2012) presents the total number of publications on landslides found in ISI journals for each country (taken from provenience of the lead author's

institution) against the recorded number of fatalities in those countries in the period from 2004 to 2010. He has divided the figure into three zones – termed research intensive, research active, and research inactive. The results clearly show that many countries which are least research active have some of the highest incidences of landslide fatalities.

Figure 1. Total number of publications on landslides / slope stability by country in ISI journals from 2006-2010, reproduced from Petley (2012).

Using China as an example, Petley (2012) also showed that increasing the research intensity within a country prone to landslide activity can reduce the rate of fatalities experienced. Two decades of data from 1990 to 2013 are reproduced in Figure 2.

Figure 2. Example of the effect of increasing annual research on landslides on the rate of fatalities in China over 20 years, after Petley (2012). Note that a single landslide that occurred in 2010 in Gansu province killed over 1700 people, which distorts the overall dataset.

In the following section, papers are grouped by type of instability (Table 2).

## 2 RAINFALL / PORE PRESSURE INDUCED SLOPE INSTABILITY

3 This section discusses the major findings of the 11 papers on rainfall or elevated pore pressure induced landslides.

Two papers by Wang et al. and Uchimura et al. discuss the use of a tilt-sensor to detect the onset of instability in slopes that are experiencing creep movements. Wang et al. covers details of innovative sensor development and field installation. Uchimura et al. elaborates further on the use of the device coupled with volumetric water sensors within an experimental arrangement of artificial rainfall on natural ground. The experiments show that instability can be detected by an increase in the rate of change of the tilt angle, while the volumetric water content is related to

the deformation, and is independent of the rainfall period. Some interesting observations are made regarding the influence of the soil water characteristic curve (SWCC) on the deformation behavior of an unsaturated slope undergoing infiltration – in particular, that a temporary reduction in deformation rate may not be indicative of increased stabilization, but rather an effect of the reduced rate of change of suction loss with infiltration. The finding is an excellent illustration of the potential for the state-of-the-art to influence the state-of-the-practice.

*Nakata et al.* examines the influence of pore pressure cycles on the collapse behavior of a slope in a study combining element testing of a standard sand with field monitoring of a natural slope. Plane strain compression tests carried out on Toyoura sand showed that cycles of pore pressure always led to soil hardening rather than increasing the likelihood of failure. In the field, it was found that the slope's behavior was a function of both the recent and antecedent rainfall, yielding a recommendation to monitor the groundwater level as well as the use of rainfall data to understand the fundamentals of collapse behavior.

*Rahhal et al.* presents a study on two landslides that occurred in Lebanon for which geotechnical parameters were obtained via laboratory testing. Slope stability analysis of one slide showed that a loss of cohesion in the clay, at the interface of the clay and underlying stiffer material, due to seasonal moisture infiltration, resulted in the instabilities that were reported. For the second study area, weakening and loss of cohesion in clay schist due to prolonged water contact was thought to be largely responsible for the instabilities recorded, with a minor contribution from cracks that were opened allowing water infiltration.

*Jeng et al.* present a study on the effects of heavy rainfall on a slope in northeastern Taiwan that is covered with a 10-20m depth of colluvium and instrumented with a surface monitoring system. The results from 295 locations of settlement and displacement monitoring locations are evaluated, together with the significance of rainfall on initiating ground movements. Figure 3 shows annual surface settlements of up to 20mm in the study area. From the analysis of the influence of typhoon rainfall on the ground displacements in different parts of the site, a threshold value curve of risk for rainfall was proposed for the area and a slope stabilization programme subsequently recommended by the authors. Once again, a careful series of field observations serve to influence the state-of-the-practice.

*Kavvadas et al.* presents the management of a mine site in Greece in which significant ground displacements are seen to occur with rainfall. Figure 4 shows a generally good correlation between surface velocities as determined at monitoring prisms (top) and rainfall records taken approximately 6km away (bottom). The data indicates a stick – slip mechanism and a regressive movement in which the velocity does not increase or decrease at a constant rate but undergoes abrupt changes. The authors posit that, during and after heavy precipitation, the water-filled tension cracks provide an increasing driving force. As displacement continues, the width of the cracks increases and the water level drops with a resulting dissipation of water pressure. This is a different mechanism to that of tertiary creep in which an increase in velocity of slope movement may be the precursor to imminent failure (Rose and Hungr, 2007).

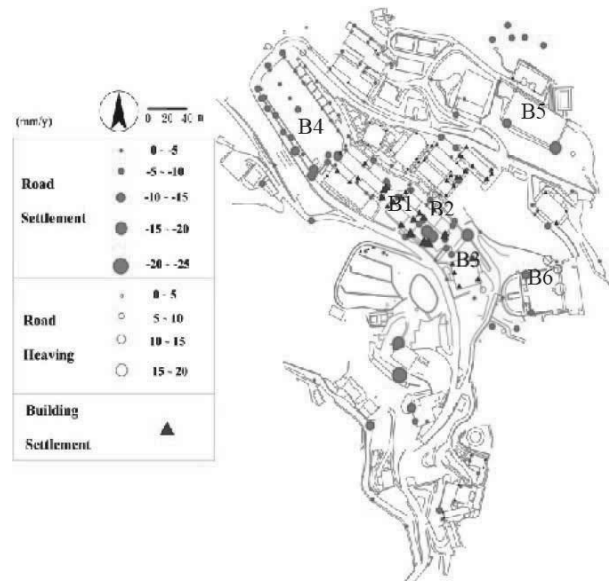

Figure 3. Jeng et al. Annual surface settlement distribution

*Kavvadas et al.* highlights the importance of understanding the underlying mechanism of slope deformation and, in doing so, shows that high mine slopes can operate under large rates of displacement, as long as the type of sliding mechanism is identified and continuously monitored. Finally, the paper shows that remedial measures can be incorporated in a mine plan in order to reduce movements, if not to arrest them entirely.

Figure 4. Kavvadas et al. Correspondence of slope velocity change with precipitation.

*Coutinho and da Silva* present a paper on the characterization, analysis and stabilization of a landslide located in a township in Brazil. The soil formation is characterised as sandy clay to silty sand (Barreiras formation) and residual granitic soil. The landslide was analysed as a two-part process during a precipitation event (Figure 5). The analysis suggested that the upper part of the slide zone failed first, due to a lower

permeability zone, leading to elevated pore pressures in that zone during heavy rainfall. The upper slope failure then resulted in an additional surcharge loading and failure in the lower slide mass. This paper highlights the importance of local geological conditions on the triggering of slope instability and that localized heterogeneity can play a major role in the distribution of groundwater flow.

Figure 5. Coutinho and da Silva. Upper and lower slope failure models.

*Son et al.* present a study on landslide susceptibility zonation for an area in the south central coast of Vietnam developed using a Bayesian conditional probability model. Surveyed landslides from one year's rainy season were used as inputs to the model which was examined to develop suitable weighting factors on elements such as elevation, slope angle, drainage distance, geology etc. and was integrated with GIS analytical tools to produce the map. The reliability of the model can be improved as new landslide occurrences are updated annually in the landslide inventory.

*Tremblay et al.* discuss the influence of climate change on the risk of landslides and its assessment for a valley in Sweden. Notable effects of climate change are increases in annual precipitation and temperature and potential reduction in water levels in the river through dry summer periods (although controlled by the authorities) and increased river flows in winter (Figure 6). Each of these scenarios may lead to a decrease in slope stability around the river valley. Readers are referred to detailed risk assessment and reports available from SGI.

*Li et al.* discusses the detailed instrumentation and full-scale field monitoring programme for a study on the mechanisms of rainfall-induced sliding slope, through a study conducted for a new development in Hainan, China. Large variations of volumetric water content and matric suction at shallow depth in decomposed granitic soils, during the rainy season, may explain why so many slope failures have occurred in this region at times of heavy rainstorm activity. The paper also highlights the inherent difficulties associated with the protection of delicate monitoring instruments on an active construction site.

*Harris et al.* describes the implementation of an early warning system (EWS) for a highway embankment subject to rainfall induced landsliding. Volumetric water content sensors were installed at a cross section of the site. A 2D finite element model was then used to replicate the response of the sensors to rainfall, using monitored rainfall events as an input. Next, a limit equilibrium analysis was carried out and an artificial neural network was trained to predict the factor of safety obtained using the sensor readings as inputs. Data from rainfall forecasts are then used to establish a predicted factor of safety for the slope in real time, allowing road-users to be advised accordingly.

Figure 6. Tremblay et al. Percentage increase in precipitation with year from 16 climate scenarios after Bergstrom et al. (2011)

### 3 DEBRIS FLOWS AND FLOW SLIDES

In total 10 papers are presented on debris flow or flow slide initiation, and aspects of runout or travel distance if the specifics of entrainment of debris along the path of movement as taken into account (see Fannin and Bowman, 2010)

Several studies are presented that use statistical data to derive debris flow hazard potential in particular areas based on local topography and associated hydro-geological behavior. Some of these studies follow statistical-empirical methodologies that do not require precipitation inputs, and may be used for a general assessment of debris flow potential, while other studies include a temporal element by taking account of precipitation records. *Yune et al.* present a paper on debris flows that occurred in the Umyeon Mountain area of Seoul, Korea during the rainy season of 2011, determining that most were initiated from small slope failures induced by high-intensity rainfall. The paper discusses the application of a statistical landslide hazard map which has been developed on parameters such as slope angle and direction, strength of soil, hazard record, rainfall condition and plantation type. This map has demonstrated the ability to highlight areas that are vulnerable to heavy-rainfall-induced slope failure and resulting debris flow disasters.

*Lin and Lin* present a study on the analysis of debris flow torrents in Nantou County, Taiwan, using discriminant analysis based on 199 known debris flow torrents and 175 non-debris flow torrents. The influence factors included: watershed area, stream length, form factor, hypsometric integral, stream mean slope, slope distribution, slope aspect, and geological formation. In order to examine the feasibility of the model, the data sets of debris flow torrents and non-debris flow torrents not used in developing the estimation models were used for validation and prediction.

*Cepeda et al.* presents a probabilistic procedure based on a Monte Carlo simulation for run-out modeling of debris flows, in order to analyse the effect of uncertainties in the input parameters. The framework is based on a dynamic model, which is combined with an explicit representation of the different parameter uncertainties. The main goal is to present a framework to obtain potentially expected run-outs and intensities in areas where it is not possible to determine the rheological parameters on the basis of back analyses.

Two papers are presented that use experimental techniques to examine debris flow behavior. *Katzenbach and Bergmann* present a paper to understand some fundamental flow properties of saturated soil in a large-scale experimental apparatus. The study is designed to examine the influence of parameters such as grain size, grain shape and grain size distribution, water content and pressures on the flow behaviour. This paper focuses on coarse grained water-saturated soils, which excludes the

complexities of cohesive internal forces. Initial results indicate the importance of particle size on the flow velocity of the granular mixture. Results are intended to supplement numerical work that is on-going.

*Choi et al.* present a paper on a series of flume tests that examine the influence of baffle row number on reduction of debris frontal velocity. The average frontal velocity of the debris flow downstream of the array of baffles was measured. Results show one row to be ineffective in reducing the debris frontal velocity, however, two to three rows of baffles exhibit notable frontal velocity reduction.

*Law et al.* present a related paper to that of *Choi et al.* on the dynamic interaction between a granular surge flow and baffles. In contrast however, *Law et al.* use the three-dimensional discrete element method with the granular flow medium modeled as spherical discrete elements and the baffles as rigid square objects. The location, velocity and forces acting on the individual elements during the impact and interaction process are presented. Assessment of the numerical results indicates that a single row of baffles is effective in reducing the kinetic energy and discharge of the granular flow. Interestingly, this actually runs counter to the findings of *Choi et al.* One possibility for this may be a difference in the relative size of largest particles to the baffle spacing used in the experiments by *Law et al.* and *Choi et al.* although data on this are not available from *Choi et al.*

Figure 7. Buscarnera and Whittle. MIT-S1 constitutive model predictions for a sand in undrained shear at different initial void ratios.

*Buscarnera and Whittle* present a framework for evaluating the triggering of flow slides in infinite slopes using the anisotropic MIT-S1 model. The selected soil model is able to simulate realistic transitions in the contractive/dilatative response of sands and enables the prediction of the shear perturbations able to induce instability (Figure 7), as well as the location of potentially unstable zones within the soil mass. In order to show the capabilities of the proposed approach, the methodology has been applied to the well-known case of slope failures in the Nerlerk berm: results suggest that static liquefaction is likely to have contributed to the failures. The analyses illustrate a unified methodology that combines the theory of material stability, the critical state framework for sands and data from in situ tests. The authors state that the methodology offers a simple, consistent and complete geomechanical framework for interpreting and predicting the triggering of flow slides that can be easily applied to other similar engineering cases.

*Thakur et al.* propose a new approach to assess the potential for flow slides via a new laboratory test procedure referred to as the quickness test. The test focuses on remoulded behaviour of sensitive clays in terms of a numerical value referred as quickness ( $Q$ ). Based on their study, it is found that a  $Q < 15\%$  or remoulded undrained shear strength  $c_{ur} > 1$  kPa seems to be the threshold limit above which the extent of retrogression of a landslide is limited to the initial slide. This criterion has been supported using data available from several Norwegian landslides in sensitive clays.

*Winter et al.* present fragility curves as a means of describing the vulnerability of elements at risk to impact by a debris flow. The specific category of element considered in the paper is a road. Expert engineering judgment was used to develop preliminary fragility curves, from a compilation of responses to a questionnaire. Analysis and interpretation of the collected data is made with reference to two events, in an attempt to relate event volume to the probability of a state of damage.

#### 4 EARTHQUAKE INDUCED SLOPE INSTABILITY

Consideration of seismic slope stability occurs in several papers, two of which are considered here and five of which are more rationally addressed within the context of multi-hazard considerations in the section that follows this one.

*Strenk and Wartmen* present the findings of a sensitivity analysis conducted on an idealized slope, to examine uncertainty in seismic deformations established using the Newmark rigid-block method, given variability in ground motion. The effect was found to be most pronounced at low acceleration ratios, and little influence of frequency content and waveform was observed. The findings suggest that use of spectral matching to create variability in both intensity and frequency may be “of limited utility”.

*Paçi et al.* presents a study on the stability of a new road located in a very disturbed tectonic zone where the rock quality is extremely poor. Active surface slides are very unstable due to water ingress especially during seismic events. Geotechnical parameters of the intact flysch / clay and limestone rock are determined from laboratory tests and empirical methods, while for residual parameters, a back-analysis is carried out using Plaxis 2D software. Hence, slope stability problems resulting from seismic loading are examined in two stages. The first model determines a critical sliding plane (if any) under an artificial accelerogram that takes account of near-source effects and then the second uses residual parameters for the soil strength mobilized within the sliding plane. The second model is used to define and design the engineering measures (walls, piles, anchored wires, nails, etc.). This two-step process, is a pragmatic approach for designing mitigation measures for prefailed slopes, and may also be used for pore-pressure induced instabilities (e.g. Tatarniuk and Bowman, 2012).

#### 5 MULTI-HAZARD INSTABILITY OF SLOPES

*Nadim and Liu* present on the use of Bayesian networks to inform reasoning when there is uncertainty and reliance on expert judgment, such as is done in many branches of civil engineering (for example, avalanche risk assessment, dam risk analysis etc.). They built a network for consideration of earthquake-triggered landslides using the open-source MATLAB package BNT, and used it to conduct a sensitivity analysis. The method is believed to have merit in deciding where to take no action, versus installing a warning system, else opting for active countermeasures.

*Chang and Huang* present an interesting case study on the influence of the Chi-Chi earthquake in 1999 on a road above slope that had been stable. Although no obvious damages to the road were observed at the time of shaking, during Typhoon Nari in 2001, several parallel cracks developed along the road alignment – suggestive of underlying instability. Remedial work

was initiated. Nonetheless, a loss of road base during the monsoon season the next year imposed a stop on the work. The remedial plan was revised and implemented, but failed again due to typhoons in 2005. The current repair works have been completed and generally show no major signs of slope distress. However, data from subsurface exploration and in-situ monitoring have shown signs of slope instability.

Figure 8 indicates potential slip surfaces in the upslope that would have impact on the road section. The downhill side slope also was not improved during the remedial works and its surface was bared with remains of previous slides. The upslope mitigation works are not useful for the stability of the downslope area and do not remove the concerns regarding the long-term stability of the road section and slopes at the site. Discussion addresses the potential for further remedial works, but it is pointed out that the cost of these may make a rerouting of the road desirable in the long term.

Figure 8. Chang and Huang. Instabilities detected by borehole investigation

*Long and Tjok* present a paper on submarine slope instability due to earthquake excitation leading to mass gravity flow which may pose risk for the integrity of offshore structures along the flow path. This paper demonstrates the ability of using a fully coupled nonlinear effective stress analysis to simulate the development of liquefaction and the instability of a liquefied slope. A prediction of run-out distance of subsequent debris flows is also made. The authors use a 1D model and parameters correlated with liquidity index in the absence of other data, although they also point out that estimation of run-out distance should be tested and calibrated to the case in question.

*Quan Luna et al.* present a study on the effects of earthquakes on subsequent slope stability, undertaken in an explicitly multi-hazard framework. The developed model is designed to give a rough spatial and temporal prediction of expected change in landslide hazard in an area following an earthquake. The model is able to describe the reduced impact of earthquakes with distance from the epicenter as well as how the soil loses strength due to shaking and gradually regains it with time. These reductions are then applied to an equilibrium stability analysis in order to compute new factors of safety on stability. The model is demonstrated by using a virtual region, and while further work is required to calibrate and validate the model with respect to real situations, it provides a mechanism whereby prospective outcomes from future hazards can be investigated in a conceptual manner.

*Cohen-Waeber et al.* presents data from a project combining GPS and InSAR time series analyses for the detailed characterization of spatial and temporal landslide deformation as a result of static and dynamic forces. A review of three independent InSAR time series analyses of the Berkeley Hills from 1992-2011 shows remarkable consistency. They reveal accelerated landslide surface deformation as a consequence of precipitation, though not in relation to seismic activity. Further, after a mild wet season in early 2012, the GPS instrumentation of several landslides in the Berkeley Hills has recorded well-defined precipitation triggered slope movement. In contrast, the occurrence of a nearby Mw = 4 earthquake did not appear to

have produced a measurable effect (Figure 9). Both InSAR and GPS studies confirm strong correlation and sensitivity to periods of precipitation, and downslope sliding velocities of around 30 mm/year. These observations, taken over longer time periods will enable important insight on the triggering mechanisms and internal landslide behavior of this area.

Figure 9. Cohen-Waeber et al. North (circles) and east (triangles) components of relative displacement with respect to reference site P224 shown together with cumulative precipitation (solid line) and time of Mw = 4 earthquake (dashed line).

## 6 PROGRESSIVE FAILURE OF SLOPES

Two contrasting papers on progressive failure are included – the first presents retrogressive failures in tuff over an existing landslide area, and the second investigates the strain softening behavior of sensitive clays leading to river bank erosion.

*Sengör et al.* present a paper on a landslide that occurred during foundation excavation of an industrial plant in Turkey. The instability occurred in a natural slope with a slope angle of 9°-13°. The sliding mass grew progressively backward into the slope as multistage rupture surfaces from the toe of the landslide developed. Back-analyses and laboratory tests were performed for the determination of shear strength parameters at the sliding surface. Mitigation measures included: two rows of stabilizing piles which were analyzed by FE independently for geotechnical and structural performance, permanent ground anchors, and surface drainage. The deformations of the system were measured by 12 inclinometers (8 in the soil, 4 in the piles) at each stage of the construction works and there have been no displacements in three years since completion.

*Dey et al.* present a study on upward progressive failure due to river bank erosion in sensitive Canadian clay which is numerically modeled using nonlinear post-peak strain softening behavior. Three cases are analyzed. In Case-I, the ground surface is horizontal and there is a 15m thick layer of sensitive clay below a 5m crust. The Case-II is same as Case-I but the ground surface is inclined upward at 4°. In Case-III only a 1.0 m thick sensitive clay layer parallel to the horizontal ground surface from the toe of the slope is assumed, with the crust the same as for Case I. In Cases I and II global failure was found to occur. However, for Case-III, although global failure did not occur, the shear band propagation reduced the shear strength in the potential failure plane significantly over a large distance and the slope might be marginally stable for further loading. Hence it is shown that the pattern of propagation of shear band varies with soil type and slope geometry.

## 7 UNCLASSIFIED

This last group of papers includes some highly theoretical contributions and some highly pragmatic ones – both ends of which help to advance the state of knowledge or practice within the profession.

Saha develops a global population-based search procedure (APMA) and applies this to a classic slope-stability problem as originally defined by Spencer (1967). It does not require problem-specific knowledge in searching the critical slip-surface of a soil slope but rather is a heuristic technique based on the 'generate-and-test' strategy. The results show that a lower factor of safety may be obtained with this technique than is found by Methods-of-Slices that are commonly used.

Bogomolov *et al.* suggest a method for calculating the stability of a loaded slope, based on the combined use of the finite element method, complex function theory and the principle of virtual displacements, as formalized in a computer program by the authors. The method ensures that a minimal condition of the factor of safety  $K$  value at each point is obtained without simplifying assumptions.

Nonoyama *et al.* apply the SPH (Smoothed Particle Hydrodynamics) method to a series of slope stability problems. This numerical method, in which continuum-based constitutive relations are input, can handle large deformation problems because it is based on a free mesh system. This means it has the potential to describe the deformation of geomaterials from the initial state to subsequent large deformation and can be used to estimate deformation and failure conditions simultaneously. Using two example constitutive models, the authors present analysis of both simple slopes and those with countermeasures (piles) included and compare results to those obtained by the Fellenius method.

In their extremely practical contribution, Yeh *et al.* introduce the currently most adopted ground anchoring inspection system used in Taiwan for anchoring slopes. The paper also proposes a new method of ground anchoring assessment, in order to establish a standardized quantitative analysis procedure for professional reference. They find that four categories of assessment should be made: inspecting the exterior of the anchor, the anchor head, an endoscopy inspection and conducting lift-off tests. They also examine the most common shortcomings of anchor installation and suggest remedies.

Bozo and Allkja present a study on the cuttings constructed for the Vlora road in Albania. A description of the geological setting of the site and of the rock and soil profiles is provided. Using in situ and laboratory tests they have determined the type of cuts and their geometrical forms in a manner designed to protect both the environment and the stability of slopes. Correlations between in situ test results and soil types are given as well as classification data and strength data for the soils encountered. They have also carried out some classifications of cuts for the road taking into account the conditions of the terrain.

The paper by Lo and Lam highlights some key lessons learnt and observations made from selected landslide investigations by the Geotechnical Engineering Office (GEO) of the of the Civil Engineering and Development Department (CEDD) of Hong Kong. On average, about 300 landslides are reported to GEO in Hong Kong each year. The paper discusses the use of robust stabilization measures for cut slopes, improved rock slope engineering practices, enhanced practices in the monitoring and maintenance of water-carrying services affecting slopes and improvement to drainage detailing.

Du *et al.* propose a quantitative model for estimating the vulnerability of elements at risk from impact by a slope failure, where vulnerability is defined as a function of landslide intensity and of susceptibility of the element. A conceptual framework is described for the model, and commentary provided on parametric inputs to it, together with suggested values for those parameters. The authors acknowledge the limitations of the model in its current form, which arise from a need to calibrate some of the input parameters.

Lacasse *et al.* summarize the findings of a European Commission project, SafeLand and its related 'toolbox' that is web-based, which includes nearly 75 mitigation measures for different types of landslide. Features of the toolbox are

described, which extend to estimates of cost-benefit factors and likely effectiveness, all of which are predicated on a ranking of the most appropriate mitigation measures. In this regard, the toolbox takes the form of a decision-support tool.

## 8 SUMMARY REMARKS

In engineering, like many other subjects of professional practice, it is important that the state-of-the-art continue to inform the state-of-the-practice. In reality, the state-of-the-practice involves risk management, whether it is done implicitly or explicitly. It is by developing new knowledge, else refining existing knowledge, that the findings of research enable improved decision-making in the face of risk and uncertainty. A total of 37 papers were submitted to the conference on the topic of slope stability in engineering practice.

Although they are broad-ranging in subject matter, they are unified by a common thematic objective of better understanding the spatial and temporal variation of demand and capacity at the point of slope instability, together with the magnitude and likely run-out or travel distance of the ensuing event. In many respects the findings of these studies are a timely reminder of the observations of Karl Terzaghi that "In soil mechanics the accuracy of computed results never exceeds that of a crude estimate, and the principal function of theory consists in teaching us what and how to observe in the field" (Goodman, 1999).

# Calculation of slopes stability based on the energy approach

## Calcul de la stabilité des pentes sur la base de l'approche énergétique

Bogomolov A.N., Ushakov A.N., Bogomolova O.A.

*Volgograd State University of Architecture and Civil Engineering, Volgograd, Russia*

**ABSTRACT:** For quantitative evaluation of slope's stability value safety factor coefficient  $K$  is used, defined by various known methods. However, the results ensued in this way for identical objects may substantially differ. The reason for this are numerous assumptions and simplifications adopted in the calculations. Approach based on the analysis of the stress fields and displacement of soil mass points and principle of virtual displacements allows to get adequate results while solving the corresponding task. The used method of sliding surface constructing ensures realization of minimal condition of  $K$  value at each point. Analysis of the stress-strain state of homogeneous and heterogeneous slopes is accomplished by using finite element method (FEM), and the boundary conditions imposed on the design scheme FEM are processed based on the analytical solutions of the first basic boundary value problem of elasticity theory for homogeneous weight simply connected domain, get by the authors.

**RÉSUMÉ :** Pour l'évaluation quantitative de la stabilité des pentes on utilise la valeur du facteur de sécurité  $K$ , définie par diverses méthodes connues. Cependant, les résultats obtenus de cette manière pour des objets identiques peuvent différer substantiellement. Les raisons de cette situation sont de nombreuses hypothèses et simplifications adoptées dans les calculs. Obtenir des résultats satisfaisants lors de la résolution du problème correspondant devient possible grâce à l'approche basée sur l'analyse des champs de tensions et de déplacements des points du massif de sol et aussi sur le principe des déplacements virtuels. La méthode utilisée de la construction de la surface de glissement assure l'accomplissement d'une condition de minimalité pour la valeur  $K$  dans chaque son point. L'analyse de l'état précontraint et déformé des pentes homogènes et hétérogènes est réalisée en utilisant la méthode des éléments finis (FEM), tandis que les conditions aux limites, imposées au schéma de calcul FEM, sont traitées sur la base des solutions analytiques du premier problème aux limites faisant partie de la théorie de l'élasticité pour une domaine homogène simplement connexe, obtenues par les auteurs.

**KEYWORDS:** slope, safety factor, stresses, displacements, work, restraining and moving forces

### 1. QUESTION STATUS

Principle of virtual displacements - one of the basic principles of mechanics, evaluating general condition of equilibrium of the mechanical system. It is widely used in static studies of material systems, with the effect imposed on the system connections, considered by adding appropriate reactions. This principle has been used previously in the stability of slopes calculation (Goldstein 1969, Dorfman 1975, Magdeev 1973, etc.), however, movements of the points lied on the most probable slip surface, are not appointed on the basis of the stress-strain state analysis of near the slope area and arbitrarily vary in magnitude until the condition  $K=K_{min}$  is achieved.

In addition the following quite not correct assumptions can be provided:

- sliding prism splits into separate blocks, the interaction force and the friction between them is rarely taken into account; orientation of this forces and the position of the points of their application does not settle, and set arbitrarily to make a statically indeterminate task about equilibrium of blocks, statically determinate;

- the form and position of the fracture surface are taken in advance, in the process of problem solving their direct link with physical and mechanical properties of soils, slope geometry, surface loads is not established;

- almost always only one (and approximately in the form of bay weight) vertical  $\sigma_z$  component of the stress at near the slope area is taken into account;

- semi-infinite slope is considered (the fact of stress concentration in the transition region of the slope into the base is left out of the account); well-known calculation methods

doesn't allow to take into account mutual influence of embankment's slopes and excavations on their stability, as in the design scheme base of the slope is not considered, and the daily surface of the slope is infinite, etc. and so on;

- in stability calculation such important value as the coefficient of lateral earth pressure  $\xi_0$  is not considered and etc.

All this makes it necessary to look for new solutions of the slope's stability problem, in particular, based on the analysis of the stress-strain state.

Known method (Potapova 2001), when the value of  $K$  is defined as algebraic sum of work of restraining and shearing forces acting at the points of most likely slip line

$$K = \frac{\sum A_i y_{\partial}}{\sum A_i c_{\partial}} = \frac{\sum (F_i y_{\partial} \delta_i \cos \alpha_i y_{\partial})}{\sum (F_i c_{\partial} \delta_i \cos \alpha_i c_{\partial})}, \quad (1)$$

where  $F_i y_{\partial}; F_i c_{\partial}$  - restraining and shearing forces agreeably;

$\delta_i$  - complete movement;  $\alpha_i y_{\partial}; \alpha_i c_{\partial}$  - angles between positive directions of the restraining and shearing forces and direction of the total displacement vector, respectively, in the  $i$ -th point of the sliding surface. Equation (1), in our opinion, is not quite correct, because in this equation full displacements of the points made of movements of the external load and dead weight of the soil are taken into account. Movements from dead weight of soil are formed during all period of the soil mass existence, and therefore their true values cannot be reliably

determined using the theory of elasticity, which may affect the validity of the getting result. Ignoring of this fact can lead to getting while calculation overstated or, conversely, understated safety factors that may result in additional costs of material resources, or emergency initiation.

2. PROPOSED APPROACH

The following algorithm for calculating the value of the slope safety factor K of loaded soil slope, based on the joint application of the finite element method (FEM) and methods of complex function theory (Kolosoov 1934, Muskhelishvili, 1966):

a) design scheme of FEM is made up provided with maximum possible degree of homogeneity of the finite element mesh observance, which provides the minimum width of the stiffness matrix of the system;

b) based on an analytical solution of the first fundamental boundary value problem of elasticity theory for a homogeneous isotropic half-plane with a curvilinear boundary (Bogomolov 1996) data handling of boundary conditions applied to uniform FEM scheme so that the stress values  $\sigma_x; \sigma_z; \tau_{zx}$  at the corresponding points of the investigating region, found by FEM and analytical solution, coincided with the maximum degree of accuracy;

c) in the case of heterogeneous geological structure of the slope, therein geological elements endowing with corresponding physical and mechanical properties (solid weight  $\gamma$ , specific cohesion C; angle of internal friction  $\varphi$ , coefficient of elasticity E; coefficient of lateral pressure  $\xi_0$  (Poisson's ratio  $\mu$ )) are extracted;

d) to the study area  $n$  external loads are applied, which according to all parameters coincide with loads specified in problem specification, but the values of their intensities  $q_n \rightarrow 0$ . If in the near the slope area plastic deformation regions are absent, the construction of most likely slip surface is performed by the method (Tsvetkov 1979), ensuring fulfillment of the condition of minimum value of K at each point. At the same time the safety factor value  $K_i$  in the  $i$ -th point of the soil mass is determined by the following expression

$$K_i = \frac{[0,5(\sigma_{iz} - \sigma_{ix}) \cos 2\alpha_i + 0,5(\sigma_{ix} - \sigma_{iz})]tg\varphi}{0,5(\sigma_{ix} - \sigma_{iz}) \sin \alpha_i + \tau_{ixz} \cos 2\alpha_i} + \rightarrow$$

$$\rightarrow + \frac{[\tau_{ixz} \sin 2\alpha_i + 2\sigma_{cb}]tg\varphi}{0,5(\sigma_{ix} - \sigma_{iz}) \sin \alpha_i + \tau_{ixz} \cos 2\alpha_i} \quad (2)$$

where:  $\sigma_{cb}=C/tg\varphi$  - cohesion pressure, numerator and denominator of the formula (2) determine, respectively, the numerical values of restraining  $F_{\text{voi}}$  and shearing  $F_{\text{coi}}$  forces acting in the  $i$ -th point of the slip surface along the most likely site of shift. Analysis of formula (2) shows that the value of  $K_i$  depends on the components of the stress and angle  $\alpha_i$  most likely site shift at each point of sliding surface, as well as physical properties of soil.

The value of  $\alpha_i$  is defined by formulas (4), which arise from the boundary condition (3)

$$\left. \begin{aligned} \frac{\partial K}{\partial \alpha} &= 0; \\ \frac{\partial^2 K}{\partial \alpha^2} &> 0. \end{aligned} \right\} \quad (3)$$

$$\sin 2\alpha_i = 2N\tau_{ixy} + (\sigma_{iy} - \sigma_{ix}) \sqrt{\frac{1}{L} - N^2} \quad (4)$$

where:

$$L = (\sigma_{ix} - \sigma_{iy})^2 + 4\tau_{ixy}^2; N = (\sigma_{iy} + \sigma_{ix} + 2\sigma_{cb})^{-1}$$

If the plastic deformation regions have been developed, but their sizes are small, then the construction of the most probable slip surface is carried out by a method built on the basis of approximate solutions of the mixed problem of elasticity theory and plasticity theory of soil (Bogomolov 1996). In this case, the stress at the plastic region (marked by a prime) are given by

$$\left. \begin{aligned} \sigma'_{iz} &= \sigma_{iz}; \\ \sigma'_{ix} &= \frac{\sigma_{iz}(l - \sin \varphi) - 2\sigma_{cb} \sin \varphi}{l + \sin \varphi}; \\ \tau'_{ixz} &= \frac{(\sigma_{iz} + \sigma_{cb})b \sin \varphi}{l + \sin \varphi}, \end{aligned} \right\} \quad (5)$$

where  $b = tg 2\alpha_i^*; l = (1 + b^2)^{0,5}; \alpha_i^* = \alpha_i - (\pi/4 + \varphi/2)$ .

The value of the safety factor coefficient  $K_i'$  at the point of the slope, which is in the plastic area (obviously  $K_i' = 1$ ) is given by

$$K_i' = \frac{(\sigma_{iz} + \sigma_{cb}) \sin \varphi (\cos 2\alpha_i^* + b \sin 2\alpha_i^*) + \sigma_{iz} l + \sigma_{cb} b}{(\sigma_{iz} + \sigma_{cb})(b \cos 2\alpha_i^* - 2) \cos \varphi} \quad (6)$$

The numerator and denominator of formula (6) determine values of appropriate restraining and shearing forces. In  $m$  points of sliding surface with the help of FEM total displacements from the gravity forces and the external load are calculated. Note that construction of the most probable slip surface is carried out with such a step, that the difference between the horizontal coordinates of neighboring points on it is  $x_{k+1} - x_k = \dots \dots x_{m+1} - x_m = 0,01H$  (where  $H$  - the height of the slope).

e) the value of the intensity of the external load is increased to the calculated value. Once again we construct the most probable slip surface and the calculation of the total displacements in its  $m$  points.

f) the principle of virtual displacements is used, at the same time the role of the possible movements is carried out by differences of movements in corresponding  $m$  points of the sliding surface, obtained under the use of two previous steps of the algorithm. The role of active forces is played by restraining and shearing forces acting at the same  $m$  points of slip surface. The formula for calculating the safety factor value of the slope, provided that the plastic deformation is absent, has the form

$$K = \frac{\sum A_i y \delta}{\sum A_i c \delta} = \frac{\sum (F_i y \delta (\Delta_i - \delta_i) \cos \alpha_i y \delta)}{\sum (F_i c \delta (\Delta_i - \delta_i) \cos \alpha_i c \delta)} \quad (7)$$

where:  $\delta_i$  and  $\Delta_i$  - respectively the total displacement of  $i$ -th point of the most probable slip surface, calculated from the action of its own weight of soil, provided that  $q_n \rightarrow 0$ , and taking into account dead weight of soil, provided that the value of the intensity of the external loads are equal to calculated values, i.e.  $q_n = q_p$ .

The value of the safety factor coefficient of the slope in the case of plastic regions in the near the slope area is determined by the formula

$$K = \frac{S'_{y\partial} + S_{y\partial}}{S'_{c\partial} + S_{c\partial}} \quad (8)$$

where:  $S'_{y\partial}$  and  $S'_{c\partial}$  - squares of restraining and shearing force's diagrams, built along a section of the most probable slip surface that is in the region of plastic deformation,  $S_{y\partial}$  and

$S_{c\partial}$  - squares of restraining and shearing force's diagrams, built for the area most likely slip surface, which is outside the boundaries of the plastic deformation regions. In that way, if in a soil mass there are no plastic deformation regions or their sizes are small, then the proposed procedure excludes from examination of displacement from dead weight of the soil, which, as noted above, it is impossible to determine exactly what increases the reliability of the getting results.

### 3. PROCEDURE FORMALIZATION

Described above procedure is formalized in a computer program (Bogomolov and others, 2010), which allows to calculate stability of homogeneous slopes and slopes of complex geological structure with any configuration of the outer boundary. At the same time all strength and deformation characteristics of the soil are taken into account, to the surface of the slope can be applied almost any number of point and distributed loads of any orientation, length and intensity. It is possible inside the design schemes automatically generate fields of various shapes, endowed with certain properties, including the voids. Figures 1 and 2 show the most probable slip surfaces in the absence of the plastic deformation areas and while their development. Here

Figure 1. Fragment of a design scheme and work diagrams of restraining and shearing forces (plastic deformation areas are not presented)

Figure 2. Work diagrams of restraining and shearing forces provided formation of plastic deformation areas

built in the computer program shell developed by the authors work diagrams of restraining and shearing forces acting at the points of the sliding surfaces are shown. Areas of diagrams are calculated automatically and are used in calculations of the safety factor value (see equation (8)).

Note one more circumstance. If the slope is uniform, then safety factor value calculated by the proposed method is independent from the value of deformation modulus of soil  $E_o$ , as in this case, displacements linearly depend on the numerical value. If the slope is not uniform, then the stresses at the points of soil mass will depend on size of the deformation modules and coefficient of lateral earth pressure of the nearby geological engineering elements. Consequently, the safety factor value will also be a function of these variables. This fact cannot be accounted by any of these methods, during the implementation of which analysis of the stress-strain state of the soil mass is not conducted.

### 4. COMPARISON OF NUMERICAL RESULTS WITH EXPERIMENTAL DATA AND FIELD OBSERVATIONS

We (Bogomolov & Vereshchagin, 1990) conducted experiments on the destruction of loaded slopes, made on the models from equivalent materials, as a basis for which were used: a) a mixture of river sand (97%) and motor oil (3%) having the following physical properties:  $\gamma=1,55 \text{ t/m}^3$ ;  $C=0,49 \text{ MPa}$ ;  $\varphi=24^\circ$ ; b) gelatinegel XC having the following characteristics: mass concentration of gelatine 30% -  $\gamma=1,15 \text{ t/m}^3$ ;  $C=72 \text{ MPa}$ ;  $\varphi=25,5^\circ$ , and at 15% -  $\gamma=1,078 \text{ t/m}^3$ ;  $C=34,8 \text{ MPa}$ ;  $\varphi=13,5^\circ$ . Value  $\xi_o$  for sand-oil mixture is set by pulling steel strips in a tray filled with the material which is under study (Terzaghi 1961), equal  $\xi_o=0,75$ .

Models from sand and oil mixture have height  $H=0,3 \text{ m}$ , width  $L=0,6 \text{ m}$ ,  $\beta=75^\circ$ . They were loaded with uniformly distributed load over the stamp which has the following dimensions in plan  $0,6 \times 0,5 \text{ m}$ , consistently placed at a distance  $b=0,25H; 0,5H$  from the edge of the escarpment. When  $b=0$  the average value (based on 10 experiments) of the intensity of the breaking load  $q_p=1,84 \text{ kPa}$ , when  $b=0,25H$  -  $q_p=0,78 \text{ kPa}$ , and when  $b=0,5H$  -  $q_p=1,39 \text{ kPa}$ . Calculated safety factor values for each of the three variants were found to be  $K_1=1,11$ ;  $K_2=0,99$ ;  $K_3=1,02$ . Evidently these values differs from limit value  $K=1$  for no more than 11%.

Models from gelatinegel XC formed in dismountable container made of organic glass, in the same forms loading of models up to failure was conducted, and at this moment loading size was fixed. Safety factor values, calculated on the basis of our proposals for the moment of destruction, were found to be  $K_{30\%}=1,08$  and  $K_{15\%}=1,1$ , i.e. differ from the limiting value of  $K=1$ , on 8% and 10%.

Figure 3 show the most probable surface of failure obtained theoretically (1 and 2) and in experiments (1' and 2'), which are almost identical to the corresponding models.

Figure 3. Theoretical and experimental slip lines in model made of equivalent materials

A case (Mochak 1964) of landslides formation in the quarry in Tsinzendorf (Germany) in the excavator ledge with the angle  $\beta=36^\circ$  was described. Soils - ribbon clay with the following content 42,9-58,5 of silt and 30,6-43,5% of clay, consistency – flexibly soft, with  $\varphi=21^\circ$ ,  $C=17,2$  kPa. The intensity of the load created by the excavator, which was at the edge of the slope ( $d=0$ ),  $q=4,4$  kPa, its width  $b=7$  m.

Author (Mochak 1964) calculated the slope stability by the method of K. Tercagi, resulting in safety factor value determined to be  $KT=1,19$ . The calculation by the proposed method results in  $K=0,97$ , which is only 3% different from the limit.

## 5 CONCLUSIONS

Method for calculating of loaded slope's stability, based on the combined use of the finite element method, complex function theory and the principle of virtual displacements, which is formalized in a computer program was suggested. The results of calculations with the help of the program that was announced with sufficient accuracy for engineering practice with the experimental data and behavior of landslide danger objects specifically.

**ABSTRACT:**The development of the tourism in Albania is a very profitable branch of the economy. For this reason we have request to construct much new roads. One of them is the road to Jonian sea side which is with rarely beautiful nature. In this zone has constructed much restaurants, hotels, touristic resorts, but the access to them is difficult because the low quality of the existing roads. In these conditions is decided construction of the by-pass Vlora, and we have accomplished the geological and geotechnical study along the track of the new road. By this study we have in evidence : a) all dangerous phenomena's which can appear during the construction of the road, b) the sites where the road will passes by viaducts and bridges, c) the zones where the road will passes by cuts, d) the zones where the road will passes by embankments. In this paper we would like to present our study about the road's section which passes by cuts in hills terrain. By in situ tests and laboratory tests we have determined the kind of cuts, their geometrical forms in manner to protect environment and stability of slopes. Also we have take some classifications of cuts in this road regarding real conditions of the terrain.

**RESUME:** Le tourisme en Albanie est l'une des activités les plus profitable pour l'économie du pays. Afin d'en accélérer le développement, le pays à souhaiter construire un grand nombre de nouvelles routes. L'une d'entre elle est la route qui conduit au littoral de Jonian, site naturel d'une grande beauté. Dans cette zone ont été construits beaucoup d'hôtels, de restaurants et des stations touristiques. Malheureusement, l'accès au site de Jonian est difficile à cause des routes de qualité médiocres. Aussi, a été décidé la construction du contournement de "Vlora" et à cette occasion, de nombreuses études géologique et géotechnique ont été effectué. Grace à ces études in-situ, nous avons pu a) détecter les phénomènes dangereux qui sont susceptibles d'apparaître pendant de la construction de la route, b) identifier les sites où la construction de la route Allait induire la construction de viaducs et de ponts, c) les zones des excavations seraient nécessaires, d) les zones où des remblais devraient être édifier. Dans cet article, nous souhaitons présenter notre étude sur la portion de route pour laquelle des excavations ont été réalisées. Par le biais d'essais in-situ et d'essais de laboratoire, nous avons pu dimensionner les excavations à effectuer en tenant compte de la problématique de la stabilité des talus.

## 1. INTRODUCTION

The new road "By-pass Vlora" passes in the hill's and mountain's zones, which intersects several small streams and rivers. In the 29 km of their length 80% of the road passes in cutting and 20% in embankment. The hills of east part of the city Vlora are longitudinal of the direction of the Vlora By-pass. These hills are built from sedimentary rocks and they form steep rocky slopes. The soft slopes of these hills are transformed into agricultural lands, while the deep slopes are covertures with small trees. The intention of the study is the determination of the physical and mechanical properties of the soils and rocks encountered in the area where will passes the new road. The data taken from field and laboratory works will be useful to made the detailed road project for embankments, cutting, new bridges, or viaducts etc. Also from geological and geotechnical study can judge for the dangerous phenomena's which can appear during the construction and exploitation of road and for the selection of the construction material. These properties are determined by specimens from bore-holes, trial pits, refraction seismic tests, field tests, and laboratory tests. We want to present in our study the following problems: The evidence of the dangerous phenomena's for the road and environment. Determination of the physical and mechanical properties of the soils and rocks in this zone.

The evidence of the zones where the road passes in cutting and their calculation.

Classification of the different cutting's types.

Engineering measures for the protection of the equilibrium of the slopes and environment in the zone of the new road.

## 2. PHYSICAL GEOLOGICAL AND GEODYNAMICAL PHENOMENA'S

By Albanian geological map, existing investigations and new information from our study, in the zone where will passes the new road, we have evidenced or observed the following geological phenomena's:[1]

### 2.1. Erosion Phenomenon

This phenomenon is visible in all hilly part of the road's axis. The heavy rainfall, the current of the surface water, the inclination of the slopes, the type of the soils and weathered part of core formation are causes of this phenomenon. The body of road is at the middle part of the valley and it is exposed to this phenomenon and negative action of the erosion. For this we recommended not only remove the water by means of ditches, but during excavation, the road must protected in the upper and bottom part, to not allow erode of the slope's material, small surface slides and detaching of the mass rock.

2.2. Weathering Phenomenon

This phenomenon is visible at the rock formation that are composed by sedimentary rocks( mudstone, sandstone, conglomerates), which are new deposits with weak clay cementation. Under the action of the atmospheric agents they are transformed from weak rock to soils. When the road passes in cutting in the zone with clay rocks we will be attention and we will take the engineering measures to protect the stability of the environment.

2.3. The movement and sliding of the weathered mass rocks

From the beginning of the new road we have identified some zones with limited area landslide. The kind of the instability are:

- Slide of the colluviums
- Slide of the upper part of the weathered rocks
- Rock landslides
- Debris flow

We thing that , the design of this road to show maximal care for the stability of the slopes during and after the construction of the road and a special attention must to paid for the protection of the foundations of the bridges that are on the slopes prone to slide.

2.4. Activity of the tectonic movements(tectonic faults )

In Albania there are a developed regional tectonics, which is mainly horizontal with a ,low angle over thrust and others secondary tectonic movement.[5] The eastern areas have moved with a low angle over thrust towards west. This phenomenon has caused a total destruction of the rock mass in 7 km length of the road, and it is associated with a lot of other local tectonics. These zones are founded in the contact between different rocks, or inside the same rock. As result of this phenomenon in the hills side many rocky mass have moved toward the relieve fall and have created a rocky bent relieve. We must be very attention to not destruct the existing brittle, or frail equilibrium.

2.5 Seismic Hazard

After Albanian Seismic Code [4] the zone to be studied is classify ( by MKS-64) with intensity 8 ball and the soils in the second category [ ]. For calculation of the slope stability, by [ 2 ] we can use  $a_{max} = 0,2g$ , and the deep of epicentrum 25-30 km. For these conditions some of the observed slides can to reactivate caused the destruction of the road.

3. GEOLOGY AND HYDROGEOLOGY

The geological structure of the studied area[1] is composed by sedimentary deposits, limestone rocks, and granular rocks as below:

3.1 Limestone rock (Pg<sub>2</sub>, Cr<sub>2</sub>, Cr<sub>1</sub>, J<sub>1</sub>, J<sub>2-3</sub> up T<sub>3</sub>).

They have white to grey color, little cracks, in some part karst phenomenon, very resistible against atmospheric agents, very good characteristics for the foundations of the bridges, stabilized slopes and for the embankment.

3.2 Paleogene's deposits (Pg<sub>1</sub>, Pg<sub>3</sub><sup>1</sup>).

They are flysch deposits, brown to beige color, medium to weak cementation, in superficial part weathered, they form unstable slopes and at Radhima is very active sliding zone.

3.3. Neogene's deposits ( N<sub>1</sub><sup>2h</sup>, N<sub>1</sub><sup>2t</sup>, N<sub>1</sub><sup>3</sup> ).

They are composed by mudstone, sandstone and rare conglomerates, conglobreccias, brown to beige color, good to weak cementation with superficial part weathered. In the mudstone layer and colluviums dposites can observed landslide.

3.4. Quaternary deposits ( Q<sub>4</sub> ),

Are alluvial, torrent and colluviums deposits. Alluviums of the Dukati and Shushica rivers are consolidated gravel, sands, silty- sands, silty- clay, with 20-25m thickness. Elluviums or torrent deposits are moderate consolidate silty- clay, silty- sands with 8-15 m thickness. Colluviums are presented by silty- clays and gravely-silty-clays, moderate consolidated, unstable and with 2-4,5m thickness.

The level of the underground water is deep and the water is not aggressive to concrete and steel.

4. FIELD AND LABORATORY INVESTIGATIONS

For the part of the road that passes in cutting or over embankments, we have made trial pits which passes by viaducts and bridges, we have made bore-holes until 10-40m depth. At the same time we have realized SPT-tests and laboratory tests in ALTEA laboratory from samples taken by BH. From laboratory test[1] we have determined physical and mechanical properties for the soils, some characteristics for the rocks, and LA, soundnes, Proctor, CBR etc for the disturbed soils and rocks which will be serve as building material for the road and embankment.

4.1. Results of the site investigations.

From BH we have discover some different layers and we have compile the geological profile.

Fig. 1 Geological Profile

4.1.1 By description of layers and SPT-tests we have evidence six layers (Table 1)

Table 1. Description of the different layers

Nr.of layer	Description	Thickness(m)	Classification	N <sub>SP</sub>
1	soft brown	silty-clay	3-4	CL 9-12
2	medium dense	silty-clay-gravel	3,5-4	GC 24-28
3	clayey's elluvium	6-8	ML-CL	60-80
4	sand's elluvium	4-6	SM	50-60
5	gravel and sandy-silty-gravel	7-14	GM	35-50
6	moderately weak mudstone	7-30	- 80-12	and sandston

4.2. Results of laboratory investigations

From laboratory tests we have determined the following parameters :

Grain size distribution

Moisture content  $W = (5-29)\%$  mean 15%  
 Specific gravity  $\gamma_0 = (26-27,2) \text{ kN/m}^3$  mean 26,5  $\text{kN/m}^3$   
 Bulk density  $\gamma = (18,8-23) \text{ kN/m}^3$  mean 19,5  $\text{kN/m}^3$   
 Limits of plasticity ( liquid)  $LL = (18-50)\%$  ( plastic)  
 $PL = (13-28)\%$  mean 34% and 25%  
 Void ratio  $e = 0,355-0,743$  mean 0,62  
 Resistive parameters of soils by direct shear test :  
 $C = 22-25 \text{ kPa}$  mean 23  $\text{kPa}$   $\phi = 22^\circ-24^\circ$   
 mean  $23^\circ$   
 Bearing capacity  $R = 150-300 \text{ Kpa}$  mean 200kpa  
 Modulus of deformation  $E = (0,4-0,7) \cdot 10^4 \text{ kPa}$  mean  $0,55 \cdot 10^4 \text{ kPa}$  etc.

4.3. Correlation between different soil parameters.

After elaboration of the results from laboratory tests and in situ tests we have take the following correlations :  
 Correlation between bearing capacity of each layer “R” and percentage of gravel.

Fig.2 Correlation between R and percentage of gravel

Correlation between bearing capacity “R” and percentage of silty grains

Fig.3 Correlation between R and percentage of silty grains

Correlation between bearing capacity “R” and modulus of deformation “E”( fig.4)

Fig.4 Correlation between R and E

Correlation between  $N_{SPT}$  and void ratio “e”

Fig.5 Correlation  $N_{SPT}$ -e

Correlation between  $N_{SPT}$  and percentage of gravel grains

Fig.6 Correlation  $N_{SPT}$  and percentage of gravel grains

By the results of the test in direct shear apparatus we have the following values :

In the upper layers ( 3-5 m depth), which are “UCS” classification are silty-clay, maximum shear strength is 0,88, that to say the soils are with low sensibility.

The “pic” value and the “residual” value of the resistive parameters of this layer are :  $\phi_p = 23^\circ-24^\circ$   
 $\phi_{res} = 20^\circ$ ;  $C_p = 20-25 \text{ KPa}$ ,  $C_{res} = 10 \text{ KPa}$

From static loading test, for the upper layer ( 3m depth) they are suitable for the construction of the road because they have  $R > 150 \text{ KPa}$  and  $E > 40 \text{ MPa}$ .

5. THE CHOICE OF THE CUTTING’S TYPE

The choice we base in our calculations about the stability of the cohesive slopes that have :

$\gamma = 19-20 \text{ KN/m}^3$ ,  $\phi = 23^\circ-24^\circ$ ,  $C = 20-25 \text{ KPa}$ . In the zones where are visible slides we have determined the depth of the sliding surface ( 4-5 )m and residual resistive parameters of the soil  $\phi = 20^\circ$ ,  $C = 10 \text{ Kpa}$ . For the seismic zone with magnitude  $M = 5,5$ , depth of epicentrum of the earthquake 25- 30 km, second category of soils and  $a_{max} = 0,2g$ , by [ 3 ] we have take the coefficient  $K_s = 0,07$  for the calculation of the supplement earth inertial force. The factor of safety “FS”, in general, is  $FS = 1,5-1,8$  but we have the cases when  $FS, 1,3$ . The types of cutting choice by us satisfied three conditions:

- Preservation of existing equilibrium of natural slopes
- Unloading of the part of the slopes when they are in limit state (  $FS, 1,3$ ).
- Harmonization of the cuttings with environment to create beautiful landscape.

5.1 Classification of the cuttings

For the road with length 29 km, where 80% passes in cutting, by our study we have made some classification:

5.1.1 Classification by relief

The hills when passes the new road have the slopes with inclination 10°-35° and more.

Regarding this relief we have use four categories of cuttings

Table 2 Classification by relief

Category	Slope inclination	Nr.of escalations	Schema H <sub>1</sub> H <sub>2</sub>
1	(8-14)°	1 and 2	3-8 2-4
2	(15-22)°	2 and 3	8-15 1,5-3
3	(23-30)°	2 and 3 in	8-14 3-14
4	(31-35)°	5 and 6	18-24 10-28

5.1.2 Classification by geological conditions

In the unstable slopes we have choice two categories of cuttings:

Construction of the cuttings by excavation of the part of the sliding mass

Fig7 Cutting by excavation in the sliding mass

Construction of the cuttings based in the stable rock mass and preservation of slopes by nails protection mesh and concrete slab.

5.1.3 Classification by geotechnical properties of the slope's soils

Regarding the resistive soils parameters of the slopes and characteristics of the rock mass of the slopes also the inclination and fault direction of the layers in slopes, we have design three categories of slopes ( Table 3 )

5.1.4. Classification by geotechnical properties

Table 3

Geotechnical characteristics)	High(H),width(b),inclination( $\alpha$ )
Rock mas $R_c = (50- 60)Mpa$	$H = ( 3-6 ) m$ $b = ( 2-3 ) m$ $\alpha = 60^{\circ}-65^{\circ} m = 2:1$
Medium cemented soils $\phi = 25^{\circ} C = 50KPa$	$\alpha = ( 60-65 )^{\circ} m = 2:1$ $H = ( 3-5 ) m b = ( 2-3 ) m \alpha = 45^{\circ}$ $m = 1:1$
Silty-clay soils $\phi = (20-23)^{\circ}$ $C = 20KPa$	$H = ( 3-5 ) m$ $b = ( 2-3 ) m \alpha = (33-35)^{\circ}$ $m = 1:1,5$

5.1.5. Classification by dangerous phenomena's.

Regarding the more dangerous phenomena's which can appear during the construction and exploitation period of the new road, we have made the following classification. In the colluviums zones ,which are in limit state of equilibrium, we can predict the protective geotechnical structures as piles, sheet piles and retaining walls

In more weathering zones we have predict protective geo-synthetic covertures combined with different vegetable

In the rock zones with intensive erosion phenomena's or weathering phenomena's we can use protective metallic mesh combined with metallic construction

6. CONCLUSIONS

For the new road "By-pass Vlora" that passes in cutting we have take the following conclusions:

By geometry we have classify three types of cuttings:

With big cut in left side

With big cut in right side

With two big cuts in both sides

By cutting's height we have three classifications:

Shallow cutting  $H = 5m - 6m$

Middle cutting  $H = 6m - 15m$

Deep cutting  $H > 15m$

By intersect layers the cuttings are classify:

Cutting which intersects 1 layer

Cutting which intersects two or more layers

Regarding the dangerous zones we have classify:

Cutting without the sliding plane

Cutting with presence of the sliding plane

Regarding the base of the road in cutting we have classify:

Cutting based completely in the same layer

Cutting based in two layers

Cutting based in core formation

partially in embankment

Escalations we have made regarding the inclination of the terrain to secure esthetical harmonization with environment, not damage of the environment and security for the road.

In the sliding zones we must undertake ( predict) the following engineering measures:

Excavation of the soils over sliding surface to unload the slope

Construction of the retaining walls, anchorage walls etc

Enforcement of the slopes by piles, micro-piles etc

In the zones that have evidence the rolling rock mass must take the following engineering measures:

Horizontal drainage

Enforcement by metallic nyle mesh combined with metallic profiles

Use vegetable revetment

Enforcement by geo-synthetics, concrete revetment etc

# A Methodology for Evaluating Liquefaction Susceptibility in Shallow Sandy Slopes

Une méthodologie pour l'évaluation de susceptibilité à la liquéfaction dans les pentes sableuses

Buscarnera G.  
Northwestern University

Whittle A.J.  
Massachusetts Institute of Technology

**ABSTRACT:** The paper illustrates a modeling approach for evaluating the liquefaction susceptibility of shallow sandy slopes. The proposed methodology consists of two main components: (i) a theoretical framework for undrained stability and (ii) the MIT-S1 constitutive model for simulating the response of sands. In the first part of the paper, the use of a stability index able to capture the onset of undrained failure in infinite slopes is illustrated. In the second part, the practical significance of the method is discussed by back-analyzing the series of flow failures in an underwater berm at the Nerlerk site. The reinterpretation of these events in the light of the theory of material stability confirmed that liquefaction was a plausible mechanism for the failures. In addition, the analyses have provided a prediction of the spatial distribution of the unstable masses which is compatible with what was observed through bathimetric surveys conducted after the events. This particular application of the theory supports the idea that realistic constitutive modeling is crucial for achieving consistent predictions of liquefaction potential under field conditions.

**RÉSUMÉ:** L'article illustre une approche de modélisation pour évaluer la susceptibilité à la liquéfaction des pentes sablonneuses peu profondes. La méthodologie proposée se compose de deux éléments principaux: (i) un cadre théorique pour la stabilité non drainée et (ii) MIT-S1, le modèle de comportement pour la simulation de la réponse des sables. La première partie du document illustre l'utilisation d'un indice de stabilité capable de saisir le début de la rupture dans des pentes infinies dans des conditions non drainées. Dans la deuxième partie, les implications pratiques de la méthode sont évaluées par rétro-analyse d'une série de ruptures par écoulement dans une risberme sous-marine sur le site de Nerlerk. La réinterprétation de ces événements, à la lumière de la théorie de la stabilité des matériaux, a confirmé que la liquéfaction est un mécanisme plausible pour expliquer ces défaillances. En outre, les analyses ont fourni une prédiction de la distribution spatiale des masses instables, qui est compatible avec ce qui a été observé par des mesures bathimétriques menées après les défaillances. Cette application de la théorie soutient l'idée qu'une modélisation réaliste du comportement est essentielle pour faire des prédictions cohérentes de potentiel de liquéfaction dans des conditions de terrain réalistes.

**KEYWORDS:** sands, static liquefaction, flow slides, material stability, theoretical analyses, constitutive modeling.

## 1 INTRODUCTION.

Landslides and slope failures are widely recognized as one of the major natural hazards affecting both the development of densely populated areas in rugged terrain and the design of artificial earthworks [Terzaghi 1957, Sladen et al. 1985b]. Within the general class of slope failures, runaway instabilities or flow slides represent impressive phenomena that still raise several open questions.

Even though various studies have been carried out on the subject [Sladen et al. 1985a, Lade 1993], there is still need for advanced tools of analysis that can explain catastrophic failures, evaluate hazard levels in landslide prone areas and define geotechnical design criteria. The purpose of this work is to propose a predictive modeling methodology to study flow slide phenomena. The proposed methodology aims to evaluate (i) the shear perturbations that can trigger a flow slide, (ii) the spatial distribution of soil masses prone to liquefaction and (iii) the characteristics of the post-failure response of the slope.

## 2 MODELING FLOW SLIDE TRIGGERING.

The evaluation of liquefaction conditions based on geotechnical criteria typically relies on the combined use of the critical state theory and empirical observations from laboratory experiments and in situ tests [Poulos et al. 1985]. Although these methods provide guidance to assist engineering judgement, they lack appropriate geomechanical foundations that can be applied to general cases.

Indeed, the application of stability criteria to field conditions requires accurate consideration of the realistic static-kinematic characteristics of the problem at stake. An important example is represented by shallow slopes, in which initial stress conditions and kinematics are highly anisotropic and cannot be appropriately represented through classical triaxial testing. One of the first approaches to consider the role of soil behavior through a comprehensive constitutive model was suggested by di Prisco et al. (1995). In order to study the onset of a flow slide, these authors considered the geometry of an infinite slope (Figure 1) and modeled sand behavior through simple shear simulations.

Figure 1. Reference system for a submerged infinite slope and initial stress conditions.

The present paper discusses a methodology which is inspired by this original idea, but tries to link it directly to the critical

state of sands and in situ observations. The key contribution is the incorporation of a constitutive model with predictive capabilities for describing transitions from contractive to dilative volumetric behavior upon shearing. As a result, the approach is able to distinguish among different types of sand response induced by an undrained perturbation (e.g., complete liquefaction, partial liquefaction, etc.), which is an essential aspect to define the expected post-failure behavior of a sliding mass.

In order to define in appropriate mathematical terms the onset of failure in a shallow infinite slope, our methodology frames static liquefaction within the theory of material stability [Hill, 1958, Buscarnera et al. 2011, Buscarnera and Whittle 2013]. In particular, we introduce an index for undrained simple shear failure:

$$\Lambda_{LSS} = H - H_{LSS} \quad (1)$$

where  $H$  is the hardening modulus of the sand considered as an elastoplastic medium, while  $H_{LSS}$  is a kinematic correction factor that depends on the mode of deformation. Vanishing values of (1) indicate the onset of unstable conditions. In other words,  $H_{LSS}$  represents a critical value of the hardening modulus at which undrained simple shear perturbations are no longer admissible. More details about the derivation of the index (1) are given by Buscarnera and Whittle (2012). For the purpose of the current paper, it is sufficient to note that positive values of (1) at a given state of stress and density reflect a stable undrained response of the infinite slope, while vanishing/negative values indicate the loss of undrained strength capacity. In this way, the values of  $\Lambda_{LSS}$  (as well as its increment,  $\Delta\Lambda_{LSS}$ ) can be used to assess both the initial stability conditions prior to shearing and the critical triggering perturbations. More specifically, the simple shear response predicted by a constitutive model can be interpreted by means of (1), identifying the stresses at the initiation of a flow failure and the residual margin of safety. For example, Figure 2 illustrates two MIT-S1 simulations of undrained simple shear response at the same level of initial vertical effective stress but with different values of initial shear stresses (representing different slope angles).

Figure 2. Example of simple shear simulations (loose Toyoura Sand simulated with the MIT-S1 model).

The results illustrate that the initial state of stress affects the magnitude of the shear perturbation required to induce instability ( $\Delta\tau_1$  vs  $\Delta\tau_2$ ). The onset of an instability coincides with the peak in the shear stress, and can be readily interpreted through the stability index (1).

As is well known, the undrained behavior of sands is also influenced by changes in the effective stress and density. For example, even very loose sands can exhibit a tendency to dilate at low effective stress levels, but will collapse for undrained shearing at high levels of effective stress. Hence, the prediction of liquefaction potential requires a constitutive framework that can simulate realistically the stress-strain properties as functions of stress level and density. To illustrate this aspect, Figure 3 shows MIT-S1 simulations for a pre-shear void ratio ranging from 0.87 to 0.94, with the model predicting a sharp transition from a stable behavior to complete collapse.

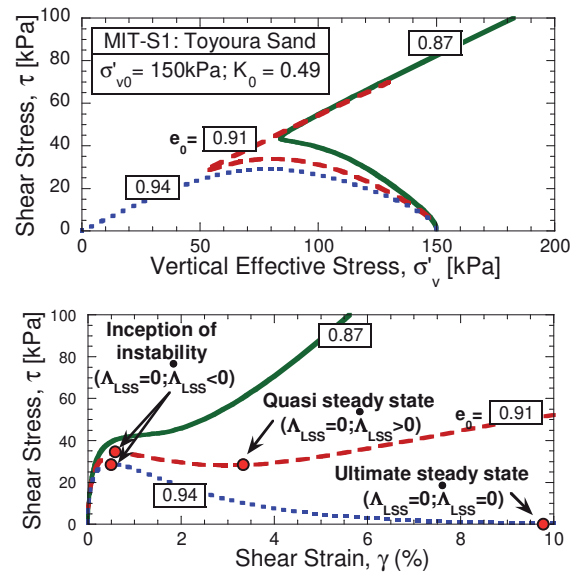

Figure 3. MIT-S1 predictions: effect of void ratio on undrained simple shear response of Toyoura Sand: a) stress path; b) stress-strain behavior.

The effect of confining pressure and density on the undrained response of sands implies that the perturbation shear stress ratio,  $\Delta\tau/\sigma'_{v0}$ , associated with the initiation of liquefaction is not only a function of the slope angle, but must be evaluated at the depth of interest. This information can be encapsulated in appropriate stability charts of the triggering perturbations. Figure 4 gives an example of such charts, and uses MIT-S1 simulations for a constant value of the initial void ratio to show the effect of the stress level on the predicted triggering perturbations.

In general, such charts should be evaluated at any depth of interest, being they a function of the values of density and stress state at that specific location. Once the stability charts expressing the shear resistance potential have been obtained, it is possible to define the variation of the triggering perturbation at any depth. These capabilities are illustrated in the next section by applying the theory for a case study involving flow failures in a sandy deposit.

Figure 4. Effect of effective stress level on the stability charts (all points in the chart are characterized by  $\Lambda_{LSS}=0$ ).

### 3 EXAMPLE OF APPLICATION: THE NERLERK CASE.

The Nerlerk berm case history refers to an impressive series of slope failures that took place in 1983 during construction of an artificial island in the Canadian Beaufort Sea (Sladen et al., 1985b). We have used the MIT-S1 model to investigate potential static liquefaction mechanisms in the Nerlerk berm. In order to apply the theory to the Nerlerk case, it is assumed that the local behavior of the sides of the berm can be approximated

by considering stress conditions in an infinite slope. Although this choice represents an important simplification of the real geometry, this assumption allows an immediate mechanical evaluation of possible incipient instabilities within the fill and provides an insight on the type of expected undrained phenomena.

The application of the methodology is based on the calibration of the MIT-S1 model parameters for the site-specific properties of the Nerlerk sands. Given the lack of data, the calibration procedure required a number of approximations. Here only some key aspects of the calibration process are described, while more details are available in Buscarnera and Whittle (2012). First, the parameters governing the critical state of the Nerlerk sands have been evaluated on the basis of the available literature data (Sladen et al., 1985a). Then, the critical state properties of the Nerlerk sands have been compared with those of similar Arctic sands (Figure 5), for which one-dimensional compression data were available.

Figure 5. Comparison of Critical State Lines (CSL) and Limit Compression Curves (LCC; dotted lines) for Erksak and Nerlerk sands (while fines content affects the CSL of Nerlerk sand, no influence on the LCC is assumed given the lack of data).

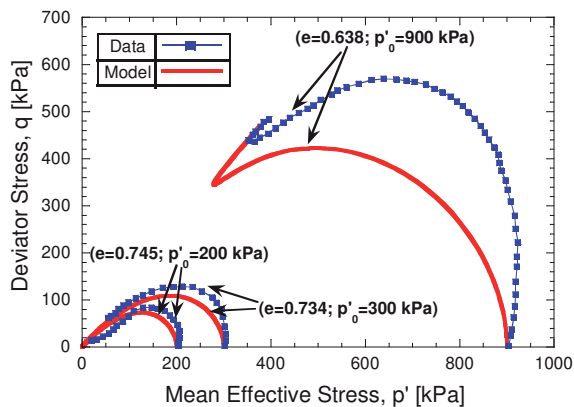

Figure 6. Comparison of computed and measured undrained shear behavior for Nerlerk Sand with 12% fines.

Such comparisons, together with empirical considerations compiled for a broad set of sands (Pestana and Whittle, 1995), allowed the definition of a set of parameters for the compression response of Nerlerk sands. The remaining model constants were calibrated using data on the undrained response (Figure 6).

In order to use the calibrated MIT-S1 model for the Nerlerk berms it is finally necessary to define the in situ void ratios along the slope profile and evaluate the stability charts of the Nerlerk berm for several depths within the slope. The first step is largely dependent on a reliable interpretation of the available in situ tests. Several CPT tests were performed on the hydraulic

fills at Nerlerk, with the aim of estimating the in situ density. For consistency with prior studies (Sladen et al. 1985b; Lade 1993), the current analyses assume that relative density ( $D_r$ ) can be estimated using the CPT correlation proposed by Baldi et al. (1982). It is clear that the choice of a specific interpretation method for CPT test results will affect the estimation of relative density (and, in turn, the model predictions). This uncertainty, however, is probably unavoidable in any method of interpretation. Figure 7 shows that the estimated values for  $D_r$  range from 30 to 55 %, while Figure 8 illustrates the distribution of these initial states relative to the CSL of Nerlerk sands with 12% fines content.

Figure 7. In situ relative density from CPT tests (Baldi et al. 1982)

Figure 8. Relative location of in situ and critical states for Nerlerk sands

Figure 9 shows the computed stability charts at selected depths for infinite slopes in Nerlerk sand, while Figure 10 illustrates the undrained response predicted by the MIT-S1 model at various depths for a slope made of the same material and characterized by a slope angle  $\alpha=13^\circ$ .

The results show that the magnitude of the shear perturbation needed to cause instability can be significantly affected by the selected depth within the slope profile. More specifically, the analyses define the initial state of stability within the Nerlerk berm slopes in a proper mechanical sense, allowing a prediction of the critical inclination for incipient instability. Since the Nerlerk berm was constructed at slope angles in the range  $\alpha=10^\circ-13^\circ$ , these results suggest that the Nerlerk slopes were likely not in an incipient state of instability, and additional shear stresses were required to trigger flow failures. In other locations where steeper slopes were recorded, however, only very small perturbations in shear stress could have triggered failure. This result suggests that an undrained collapse triggered by rapid deposition can be considered as a mechanically feasible failure mechanism for the berm.

Figure 9. Stability charts for the Nerlerk berm.

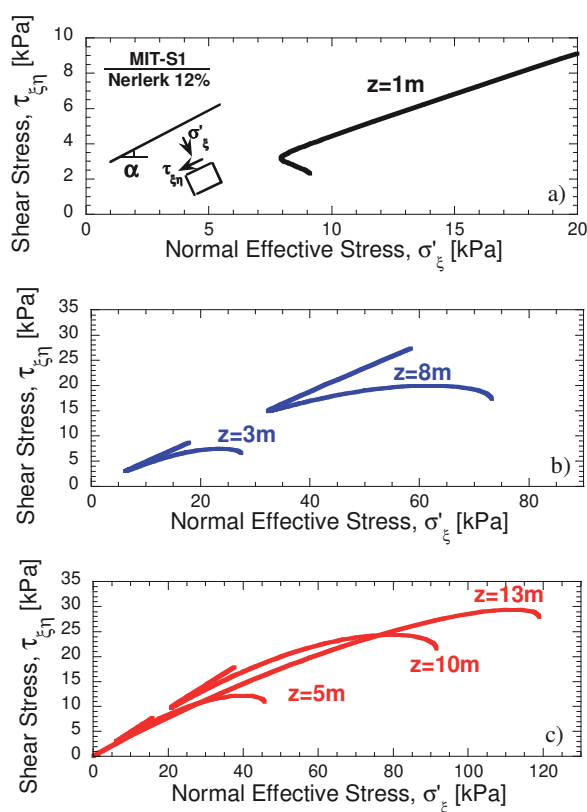

Figure 10. Predictions of undrained response across the Nerlerk berm section ( $\alpha=13^\circ$ ): a) no potential for liquefaction; b) limited potential for liquefaction; c) high potential for liquefaction.

#### 4 CONCLUSIONS

This paper has presented a framework for evaluating the triggering of flow slides in infinite slopes by modeling the undrained shear behavior using the anisotropic MIT-S1 model. The selected soil model is able to simulate realistic transitions in the contractive/dilatative response of sands and enables the prediction of the shear perturbations able to induce instability, as well as the location of potentially unstable zones within the soil mass. In this paper, these features have been used to derive stability charts of triggering perturbations for different combinations of initial density and stress state.

In practice the model needs to be calibrated for the site specific properties of the soil, and requires reliable data on in situ density in order to make predictions of liquefaction

potential. In order to show the capabilities of the proposed approach, the methodology has been applied to the well-known case of slope failures in the Nerlerk berm. A general picture of the distribution of liquefaction susceptibility on the Nerlerk slope profile has been obtained. The analyses have been based on the calibration of model input parameters against published laboratory test results, while empirical correlations for CPT data have been used to define the initial density conditions prior to shearing. The results show that there were two zones within the slope that were vulnerable to flow failure. Although some sections of the berm were oversteepened, most were deposited with a slope angle  $\alpha=10^\circ-13^\circ$ . For these slope angles, the current analyses show that instability could have been triggered by the undrained perturbations possibly induced by the rapid deposition of hydraulic fill. Thus, static liquefaction is likely to have contributed to the observed failures, confirming earlier hypotheses by Sladen et al. (1985b).

The analyses presented in this work illustrate a unified methodology that combines the theory of material stability, the critical state framework for sands and data from in situ tests. As a result, the proposed methodology offers a simple, consistent and complete geomechanical framework for interpreting and predicting the triggering of flow slides that can be easily applied to other similar engineering cases.

# Assessment of landslide run-out by Monte Carlo simulations

## Évaluation de la dynamique des glissements de terrain par des simulations de Monte-Carlo

Cepeda J., Quan Luna B., Nadim F.

*Norwegian Geotechnical Institute – NGI and International Centre for Geohazards - ICG, Oslo, Norway.*

**ABSTRACT:** Landslides run-out models are based on theoretical descriptions of mass motion which attempt to model the complex behaviour of the actual flow phenomenon. To reproduce the general features of the mass motion, these models simplify the problem by using parameters that account for complex aspects, which are not explicitly included. This simplification results in model parameters that cannot be related to a specific physical process, and therefore cannot be directly measured. In order to analyse the effect of uncertainties in the input parameters, a probabilistic procedure based on a Monte Carlo simulation for run-out modelling was considered. The framework is based on a dynamic model (MassMov2D), which is combined with an explicit representation of the different parameter uncertainties. The main goal with the proposed methodology is to present a framework to obtain potentially expected run-out extents and intensities in areas where it is not possible to determine the rheological parameters on the basis of back-analyses. The outlined procedure provides a useful approach for experts to produce hazard or risk maps in cases where historical records are either poorly documented or completely lacking, as well as to derive confidence limits on the proposed zoning.

**RÉSUMÉ :** Les modèles de la dynamique des glissements de terrain sont basés sur des formulations mathématiques qui tentent de théorétiser les phénomènes d'écoulement réels, par nature très complexes. Afin de simuler les caractéristiques générales du mouvement, ces modèles utilisent des paramètres qui représentent et simplifient les aspects complexes du problème, sans pour autant les prendre en compte explicitement. Il en résulte une simplification des paramètres du modèle: ceux-ci ne sont donc plus liés à un processus physique réel, et ne peuvent par conséquent pas être mesurés directement. Afin d'analyser l'effet des incertitudes entourant ces paramètres, une approche probabiliste, basée sur la méthode de Monte Carlo, a été employée. Celle-ci se base sur un modèle dynamique (MassMov2D) ainsi que sur une représentation explicite des incertitudes des différents paramètres. L'objectif principal de cette méthode est de proposer une approche générale dans le but de prédire la taille et l'amplitude des glissements de terrain dans des zones où il n'est normalement pas possible de déterminer les paramètres rhéologiques par méthode arrière. La méthode décrite ici propose une approche pratique afin d'établir des cartes de risque dans les cas où la documentation est limitée, voire inexistante, ainsi que pour estimer les limites de confiance des zonages proposés.

**KEYWORDS:** Landslides, run-out, Monte Carlo, Bingham rheology, Voellmy rheology, quantitative risk assessment.

## 1 INTRODUCTION

Dynamic run-out models for landslides are able to simulate the spatial distribution of depth and velocity of the moving mass, which is essential for a quantitative evaluation of hazard and risk at a specific site. Another advantage of the application of dynamic models is that they can simulate the effect of variations in the release volume as well as in the rheological parameters for different scenarios including ones that have no historical evidences.

In practice, a substantial degree of uncertainty characterizes the definition of the deterministic model parameters. This is due to the lack of experimental data and the poor knowledge of the mechanical behaviour of the moving flows. Consequently all models, either those widely used in practical applications or those more recently developed, are based on simplified theoretical descriptions of mass motion which try to capture the complex rheology of the flow phenomenon. This results in a generalization of all models to attempt to reproduce the general features of the moving mass through the use of parameters (mostly for evaluating base shear) which account for aspects not explicitly described or oversimplified. The outcome is that the model parameters cannot be related to a specific physical process, and therefore directly measured, but need to be calibrated. At the moment, a relatively complete and well-established calibration for most of the run-out models is still lacking or not reliable enough to be applied in practical applications. This is connected with one of the basic limitations with the use of dynamic run-out models, which are significantly sensitive to the parameters controlling the base shear (Revellino et al. 2004, Hurlimann et al. 2007, Hungr & McDougall 2009). Inherent uncertainties in the specification of the input data for models are well acknowledged but usually not explicitly

incorporated into the analyses. Such uncertainties are normally addressed through conservative estimate of parameters, or in some cases, by a sensitivity analysis. These approaches do not integrate objectively the estimation of uncertainties, and thus may be impractical and lead to either conservative or underestimated hazard levels.

In order to analyze the effect of the uncertainty of input parameters, a probabilistic framework based on a Monte Carlo simulation for run-out modelling is considered as an alternative approach. Monte Carlo analysis is a method that uses statistical sampling techniques of input parameters to derive the probability distributions of solutions for mathematical equations or models. The Monte Carlo analysis was initially developed in the 1940's and it has been applied to a wide variety of problems for addressing the uncertainty of data and models (Metropolis 1987).

## 2 METHODOLOGY

The dynamic model used in this study was MassMov2D (Beguiria et al. 2009), which solves the equations of conservation of mass and momentum averaged over the depth of the landslide mass using an Eulerian scheme scripted in PCRaster, a GIS modelling environment (Karszenberg et al. 2001). In the equation of conservation of momentum, the shear stress at the bed contact (base of the analysed differential column) is calculated using a rheological model (a relation coupling stresses and strain rates) that should be physically consistent with the overall behaviour of the landslide. In this particular case, two models are used for describing frictional and cohesive-like dominated behaviours, namely the Voellmy and the Bingham models. Simplified formulations of these models are presented in Equations (1) and (2), respectively:

$$\tau = \sigma \tan \phi_{app} + \frac{\rho g v^2}{\xi} \quad (1)$$

$$\tau = \tau_y + \mu \dot{\gamma} \quad (2)$$

where,  $\tau$  is the shear stress at the base of a differential column of landslide mass,  $\sigma$  is the normal stress at the base,  $\phi_{app}$  is an apparent friction angle,  $\rho$  is the bulk density of the landslide mass,  $g$  is the acceleration of gravity,  $v$  is the velocity,  $\xi$  is the turbulent coefficient,  $\tau_y$  is the yield strength,  $\mu$  is the viscosity, and  $\dot{\gamma}$  is the shear strain rate. The apparent friction angle and the turbulent coefficient are material parameters of the Voellmy rheology. The yield strength and the viscosity are the corresponding parameters for the Bingham model.

The main objective of the present application of the Monte Carlo analysis is to examine the effect of uncertainty associated to the variability of the rheological parameters of the Voellmy and Bingham models on the estimation of debris flow run-out. This method allows evaluating the probability distribution of the relevant output parameters (intensity parameters) for a hazard assessment once the proper probability distributions for the parameters of both rheologies have been defined. In other words, it is possible to account explicitly and objectively for the effect of uncertainties in the model. For the application of the Monte Carlo analysis, each of the input parameters was assigned a distribution. The output from the model is calculated several times for a set of randomly selected input parameters. This produces a probability distribution for the output values, such that the uncertainty for the exceedance of any particular value can be estimated. Figure 1 presents a simplified flowchart of this procedure.

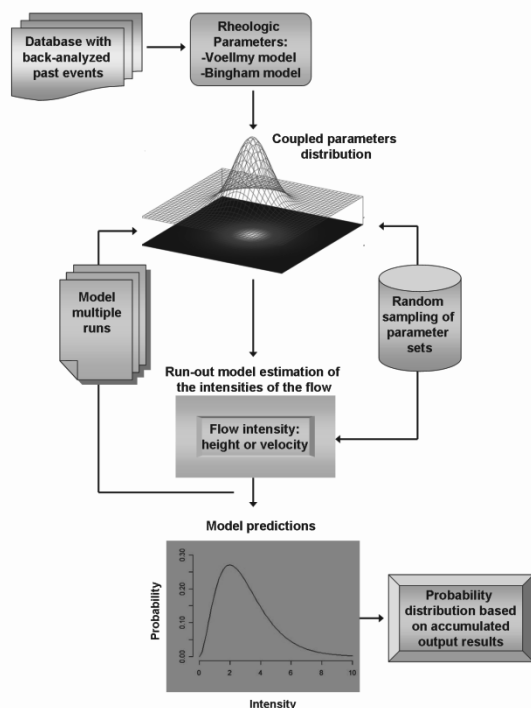

Figure 1. Flow chart of the application of a Monte Carlo method for a probabilistic assessment of landslide run-out.

The uncertainty resulting from the physical process (variability inherent to the phenomenon) is expressed inside the probability density functions of the parameters characterizing the base shear. An extensive literature study was carried out for collecting a database of past back-analyzed landslides, including the calibrated rheological parameters for each event. The

relationships between the parameters of the Voellmy and Bingham rheologies were modelled as a “Gaussian Copula” to define the probability density function for both rheological models (Fig. 2)

Figure 2. Fitted “Gaussian copula” distribution function to the Bingham rheology (left) and Voellmy rheology (right).

Each distribution was randomly sampled to obtain a set of 5000 pairs of rheological parameters. In the next step, a routine was coded to repeatedly run the simulations for each pair of parameters. At the end of each simulation, the output values of peak intensity parameters (maximum depth and velocity) were saved for selected points on the area of interest. Finally, the output values were fitted to a theoretical probability density function. The parameters for each probability distribution were reported. In addition, the probability that the output exceeds a particular value or will fall within a certain range was calculated.

The dynamic run-out model MassMov2D (Beguiria et al. 2009) was selected because it allows the use of scripts which can be modified to include output reports in the form of maps or text files. A batch file was built-in and incorporated inside MassMov2D which selects the randomly generated sets of parameters to produce multiple simulations. The results of each simulation regarding the maximum flow depth and maximum velocity at each control point were reported in a text file form for being fitted to a theoretical probability density function.

### 3 STUDY CASES

#### 3.1 The Faucon catchment in the Barcelonnette Basin

Inside the Barcelonnette Basin, the Faucon torrent was selected as a test site. The Faucon catchment is a steep forested watershed with an area of approximately 10.5 km<sup>2</sup> which rises to 2984 m a.s.l. Most slopes are steeper than 25°, reaching 80° at the highest elevations. Many of the slopes in the Faucon catchment are covered by various types of Quaternary deposits: thick taluses of poorly sorted debris; moraine deposits; screes and landslide debris. These deposits have a sandy-silty matrix, may include boulders up to 1–2 m in size and are between 3 and 15 m thick (Remaître 2006). The main incised channel has an average slope of about 20°, ranging from 80° in the headwater basin to 4° on the alluvial fan, and is approximately 5500 m in length. Channel morphology is characterized by a V-shaped profile with a steep channel in the upper part, and a flat-floored cross-profile between steep slopes. The Faucon torrent has formed a 2 km<sup>2</sup> debris-fan that spreads across the Ubaye valley floor. It has a slope gradient ranging from 4 to 9°. The fan consists mostly of cohesionless and highly permeable debris (debris-flows strata and/or torrent deposits) (Remaître et al 2005). Two points within the area of interest (in terms of exposed elements) were selected on the accumulation area to calculate the maximum flow height and the maximum velocity (Fig. 3).

### 3.2 Tresenda village in the Valtellina Valley

Valtellina is an important Italian alpine valley located in Central Italian Alps (Northern Italy, Sondrio Province). The valley starts near Bormio (1,225 m a.s.l.) and it runs for about 100 km to Colico (218 m a.s.l.) near Como Lake. The axis of the valley is formed by the Adda River, originating from small lakes in the Rhaetian Alps at 2,335 m a.s.l. The Adda River flows through the entire valley in a flat alluvial plain up to 3 km wide and it joins the Po River in the Lombardy Plain. Valtellina has a U-shaped valley profile derived from Quaternary glacial activity. The lower part of the valley flanks are covered with glacial, fluvio-glacial, and colluvial deposits of variable thickness (Crosta et al. 2003) The Tresenda village is located in the Valtellina area and is located in the municipality of Teglio in the Valtellina Valley. Spatial information of past damage derived from historical records, local chronicles, and interviews with local people confirmed that the village of Tresenda was affected by debris flows events which caused significant losses in 1983, 2000 and 2002. Soil slips, resulting in debris flows were triggered on the steep slopes above Tresenda, where the soil thickness varies from 0.7 to 2.5 m.

Figure 3. Digital elevation model of the Faucon catchment with the location of the two points used for reporting the results (A and B).

The documented past events crossed minor roads and impacted buildings in the Tresenda village, while running along main drainage lines (Cancelli & Nova 1985, Guzzetti et al. 1992). Major events in future may produce casualties and serious property damages as well as the obstruction of a main road. In the Tresenda case study two location points were also located within the area having the highest concentration of exposed elements.

## 4 RESULTS

### 4.1 Application of the methodology to the Faucon catchment

The release volume chosen in the Faucon study was 50,000 m<sup>3</sup> and was set as constant in the simulations. Past events in the Faucon area have had final volumes between 55,000 m<sup>3</sup> – 80,000 m<sup>3</sup>. The unit weight of the debris flow was set to a constant value of 19 kN/m<sup>3</sup>. The time step was set at 1 s and the total duration of each simulation was 500 s. The Monte Carlo method applied in the Faucon catchment was modelled with the Bingham model. This model was selected because of the geo-environmental setting of the area where past events are described to have viscoplastic behaviour (Remaître et al. 2005). In total, 5,000 runs were completed corresponding to the input parameters obtained from randomly sampling the fitted Gaussian copula. For each of the 5,000 runs, the maximum flow

heights and maximum velocities were reported for each of the two points. The results of each point were used to populate a probability density function of each intensity parameter. A Gamma distribution was the distribution that best fitted the maximum flow height and velocities measured in points A and B (Fig. 5 & 6).

Figure 4. Digital elevation model of the Tresenda village with the location of the two points used for reporting the results (A and B) and three different release areas (1, 2 and 3).

Figure 5. Gamma distribution fitted to the maximum height (left) and velocities (right) values obtained in point A.

Figure 6. Gamma distribution fitted to the maximum height (left) and velocities (right) values obtained in point B

The obtained results of the mean values of height and velocity computed with the Monte Carlo method were compared with the events that took place in 1996 and 2003 (Remaître et al. 2008, Remaître et al. 2009). In both cases, the mean value of the distribution overestimates the flow height and the flow velocities. In the results, point A which is located higher up in the catchment than point B (apex of the fan) reports higher values for both intensity parameters (height and velocity).

### 4.2 Application of the methodology to the Tresenda village

In the Tresenda case, the main purpose of the study was to observe the response of the model when using more than one release area. In the Tresenda case, three simultaneous release

areas with different volumes were considered (Table 1). The initiation of the debris flow is assumed to be caused by soil slips and the flows are unchanneled along most of the path. The unit weight of debris flow was set to the same value as in the case of Faucon. The total duration for each simulation was 500 s. The Voellmy model was used in the run-out analysis.

In total, 5,000 simulations were carried out associated to the corresponding set of input parameters sampled from the Gaussian copula. For each simulation

Table 1 Release volume used for the Monte Carlo simulation for the three different release areas in the Tresenda village

Release Volume (m <sup>3</sup> )	
Release area 1	1424
Release area 2	1410
Release area 3	1518
Total released volume	4352

the maximum flow heights and maximum velocities were reported for each point. Also in the Tresenda case, a Gamma distribution had the best fit to the output parameters. Figures 7 and 8 show the results for the maximum flow height and velocities calculated in points A and B.

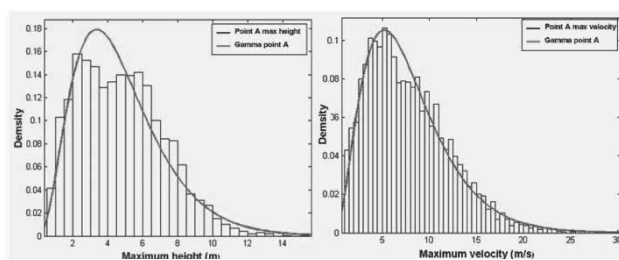

Figure 7. Gamma distribution fitted to the maximum height (left) and velocities (right) values obtained in point A.

Figure 8. Gamma distribution fitted to the maximum height (left) and velocities (right) values obtained in point B.

The results for the Tresenda case study were compared with events in 1983 and 2002. In these incidents, only information regarding the flow heights was available (no velocities were estimated for these events). In the Tresenda case, the mean value of the flow height in point A is overestimated compared to the actual event while point B has a lower mean value than the observed event. In the Tresenda case the simulated values are closer to the actual events than in the Faucon case. This can be possibly attributed to the potential of the Voellmy rheology to model consistently these types of events.

## 5 CONCLUSIONS

The Monte Carlo method offers the advantage of modelling the probability distributions of the intensity parameters from run-out simulations. Of course, the reliability of the fitted probability density functions for the input parameters strongly depends on the completeness and accuracy of the original back-analyses included in the collected database. Another limitation of this study is that the estimated probabilities do not explicitly

account for the temporality of the phenomena. For future assessments it is recommended that run-out simulations using a stochastic approach become a routine practice in order to produce adequate future hazard scenarios and quantify the uncertainty due to the input parameters. This will result in intensity maps that are easier to interpret for end users, especially within a probabilistic framework for landslide mitigation.

## 6 ACKNOWLEDGEMENTS

The authors would like to thank Jean Philippe Malet and Alexandre Remaître from the University of Strasbourg for the data of the Faucon catchment.

# The Challenge of the Slope Failure Problem and Its Remedial Considerations at Mileage 39km, Mt. Ali Road, Taiwan

Le défi du problème du glissement de pente et des dispositions correctives apportées, au kilomètre 39, de la route Mt. Ali Road, à Taïwan

Chang M., Huang R.  
*National Yunlin University of Sci. & Tech., Taiwan*

**ABSTRACT:** Mt. Ali Road is a main scenic route to Alishan National Scenic Area and Yushan National Park in the middle of Taiwan. At Mileage 39Km, the downslope side of the road consists of a 200m deep 60° angle bare cliff with a creek passing around the slope's toe. Despite complex geologic conditions, the underlying slope materials appeared competent for about 20 years after the road opening. In 1999, however, a severe earthquake (Chi-Chi,  $M_w = 7.6$ ) hit central Taiwan and caused numerous landslips in the mountain range of the island. Although no obvious damages to the road were observed after the time of shaking, the geologic setting of the site was deteriorating. During the attack of Typhoon Nari in 2001, the first serious effect on the road appeared and caused several parallel cracks along the alignment. Remedial work was initiated. Nonetheless, a loss of road base during the monsoon season next year had called for a stop of the work. The remedial plan was revised and implemented, but failed again due to Typhoons Talim and Longwang in 2005. The current repair works have been completed and generally show no major signs of slope distress. In view of repair histories and the geologic setting, this paper discusses the concerns and challenges for long-term stability of slopes at the site.

**RÉSUMÉ :** Mt. Ali Road est une route principale pittoresque qui mène à l'Alishan National Scenic Area et au parc national de Yushan, au centre de Taïwan. Au kilomètre 39, le côté aval de la route est formé d'une falaise nue de 200m de haut, inclinée à 60° avec un ruisseau la bordant en pied de pente. En dépit des conditions géologiques complexes, les matériaux de la pente se sont bien comportés au cours des 20 années l'ouverture de la route. Cependant, un violent tremblement de terre (Chi-Chi,  $M_w = 7,6$ ) a frappé le centre de Taïwan en 1999, et a causé de nombreux glissements de terrain dans la partie montagneuse de l'île. Bien qu'aucun dommage apparent n'ait été détecté après la secousse, la situation géologique du site s'est détériorée. Les premiers effets conséquents ont pu être observés lors du typhon Nari en 2001, plusieurs fissures parallèles étant apparues le long du tracé. Un projet de confortement fut entrepris. Malgré cela, une rupture de la couche de fondation, de la route l'année suivante pendant la saison des moussons a nécessité un arrêt temporaire des travaux. Le projet fut révisé et remis en œuvre, mais a dû être à nouveau arrêté en raison des typhons Talim et Longwang en 2005. Les réparations sont aujourd'hui terminées, et la pente ne montre en général aucun signe de désordre. Compte tenu de l'historique des réparations et de la situation géologique, ce document aborde les préoccupations et les défis concernant la stabilité à long terme des pentes du site.

**KEYWORDS:** slope failure, repair works, landslide prevention and mitigation, slope stability, case histories, Mt. Ali Road.

## 1 GENERAL

Mt. Ali Road is a main scenic route to Alishan National Scenic Area and Yushan National Park in the middle of Taiwan. As entering into the hilly terrain of central mountain range of the island, the road starts climbing up along the side of slopes for a distance of about 5Km until it reaches a hill top with an elevation of 460m MSL at the mileage of 39Km, where the road levels off and makes a loop around the hill. The downslope side of the road at this location consists of a 200m deep 60° angle bare cliff with a creek passing around the slope's toe.

Although both regional and local geology generally show a complex geologic structure at the site, the subgrade materials and underlying rock appeared competent for about 20 years since the road's opening. Figure 1 shows the regional geology of the area, and Figure 2 illustrates the geologic profile of the road section and its adjacent slopes.

On September 21, 1999, a severe earthquake (Chi-Chi,  $M_w = 7.6$ ) hit central Taiwan and caused numerous landslips or slope failures in the mountain range of the island, as indicated in Figure 3. Based on studies by National Center for Researches on Earthquake Engineering (NCREE 2000), approximately 1500-2000 landslides were directly induced by the earthquake. Although the shaking did not have immediate impacts at the site, the condition of the road and its adjacent side slopes appears to be deteriorating.

Figure 1. Regional geology of the area (Liu & Tseng 2000).

The monsoon season normally starts from early April to the end of September in the island. Annual precipitation is around 2150mm (Sinica 1999). Figure 4 shows accumulated rainfalls of the site in 2001 & 2005 were 4700mm & 4600mm, respectively. As will be discussed later, the abundance of rainfalls appeared to have contributed to the failures of slopes along the Mileage 39Km in 2001 & 2005.

Figure 2. Geologic cross-section at the 39Km project site (CECI 2005).

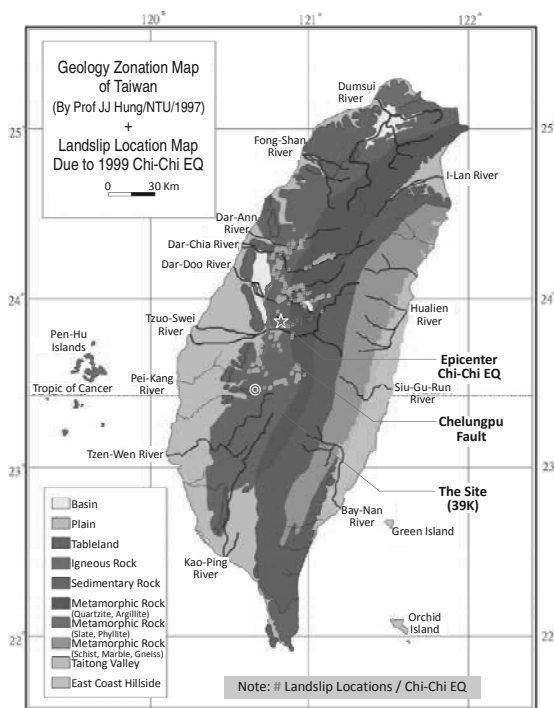

Figure 3. Locations of landslides due to Chi-Chi EQ (NCKU 2000).

Figure 4. Monthly and accumulated rainfalls at the site (Peng 2009).

## 2 SLOPE FAILURE & ROAD REPAIR HISTORIES

Prior to failures of the subject slopes, a severe typhoon (Herb) with a rainfall of about 2000mm attacked Taiwan in 1996 and resulted in significant damages in central region of the island. Based on an official investigation report, the event had caused 91 landslides and 57 losses of road base along the entire length of

Mt. Ali Road (DOT 1996). However, the subject road and its slopes were only experienced very minor effects due to this typhoon and had no influence on the slope stability. Three years after the severe typhoon incident, a damaging earthquake (Chi-Chi, 1999) occurred. As mentioned previously, the earthquake had resulted in numerous landslips in central Taiwan. Although the site and its adjacent slopes appeared to be competent during the shaking, the in-situ earthen materials were apparently weakened and deteriorating due to the earthquake. In subsequent years, signs of slope distress and movement became obvious, and some key events and associated repair histories are discussed in the following sections.

### 2.1 2001 Typhoon Nari

Typhoon Nari swiped Taiwan in September, 2001, and brought about 1400mm precipitation to the site, 4700mm for the entire year. This had been the largest rainfall event since the attack of Typhoon Herb in 1996. The site had experienced a series of parallel cracks of 10~80cm in width along the road alignment which called for a temporary shutdown for one lane of the road. A remedial action was subsequently taken by District V of Directorate General of Highways (DGH), Taiwan, that included the repair of surface cracks by a new AC paving and a planning on reconstruction of the road section by conventional retaining structure on the downhill side of the road.

### 2.2 2002 monsoon rainfalls

As the reconstruction work for the retaining structure was about to start in 8 months after Typhoon Nari, a failure in downslope of the road occurred (Figure 5). The failure was apparently due to the intense rainfall during the monsoon season. Recorded accumulated precipitation was greater than 1000mm within the two months prior to the failure.

Figure 5. Slope failure at Mileage 39Km due to 2002 monsoon rainfalls.

The original construction work had to be terminated and re-planned. In view of steep downslope and insufficient road width, DGH had once considered remedying the problem by cutting back and flattening the upslope. However, the plan was turned down due to unsuccessful negotiations with local ownerships of lands adjacent to the road.

The remedial plan was finally decided to limit within the extent of the road owned by DGH. Considerations of the road redesign had included a section of box-type concrete structure, as shown in Figure 6, which would provide a design with enough road width, structure rigidity, and relatively light-weight. The box structure was secured to the native ground by two rows of ground anchors, each of which with a total length of 35m, a horizontal spacing of 20m, and an anchor force of 45T. The

base of the box structure was also fixed to the ground by a series of mini piles of 16m in length.  
Figure 7 shows the rebuilt road section after completion of the remedial works.

Figure 6. Box-type structure design for road section at Mileage 39Km.

Figure 7. Completion of box-type structure at Mileage 39Km.

### 2.3 2005 Typhoons Talim & Longwang

The new road section appeared to be in good shape for the next 1-1/2 years until mid of 2005 when the precipitation started to reach another historic peak.

Figure 8. Failure of box-structure road section due to Typhoon Talim.

In late August of 2005, a severe Typhoon Talim slammed Taiwan. By considering a series of heavy rainfalls in the previous two months, the accumulated precipitation of the year at the site had exceeded 4000mm. As a result, the box-type structure finally gave up and the entire road section of about 100m in length fell into the valley (Figure 8).

Post-failure investigation had revealed that the loss of entire road section was due to the downslope movement of the uphill slope mass which pushed the box-type structure, tore down the ground anchor tendons, and sheared off the mini piles.

Emergency action was implemented right after the failure by constructing a temporary road to the uphill side and installing I-beams for the downhill support (Figure 9) in order to maintain the local traffic (DGH 2005).

Figure 9. Emergency repair of the road section due to Typhoon Talim.

In late September, 2005, the emergency measure failed again one month after the attack of Typhoon Longwang. The temporary road lost 5m of its road width. Site reconnaissance showed significant tension cracks at the crest of uphill slope.

District V of DGH had to launch another remedial measure to mitigate potential impacts on the road section in the future. The plan had considered mostly the upslope protections that included filling of tension cracks, rechanneling surface drainage, installing subsurface horizontal drains, and surface vegetation, etc. Figure 10 shows the completion of upslope remedial works after Typhoon Longwang.

Figure 10. Completion of upslope remedial works at Mileage 39Km.

### 3 FIELD MONITORING & STABILITY ANALYSIS

In the following few years after Typhoon Longwang, the annual precipitation of the site was decreasing. To date the road section and its adjacent slopes appear competent for maintaining local traffic. However, data from subsurface exploration and in-situ monitoring during the previous remedial works showed signs of slope instability at the site (LEC 2006). Figure 11 indicates potential sliding masses (slip surfaces) in the upslope that would have impact on the Mileage 39Km road section. The downhill side slope was not improved during the remedial works and its surface was bared with remains of previous slides, as shown in Figure 12.

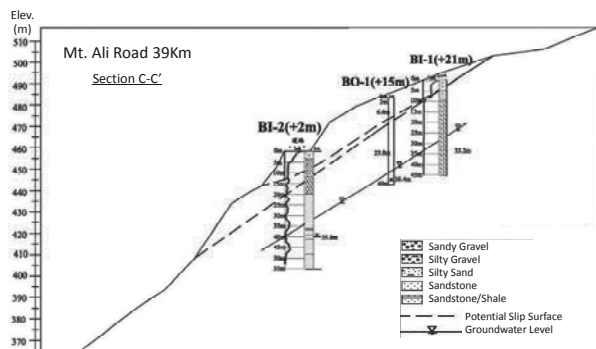

Figure 11. Material strata and potential slip surfaces at Mileage 39Km.

Figure 12. Downhill slope of Mt. Ali road section at Mileage 39Km.

### 4 CONCLUSIONS

In view of past failure incidents and associated remedial works, the road section at Mileage 39Km and the alongside slopes are still at perceivable risks of a potential slide. The signs of slope instability appeared to be pronounced since the attack of 1999 Chi-Chi Earthquake, which was believed that the shaking had weakened the underlying geologic units and thus accelerated the weathering process of materials at the site.

Conclusions on causes of slope instability and measures of slope mitigation for this site can be drawn and discussed below.

#### 4.1 Potential & triggering factors

From a retrospective stand point, the factors that had caused instabilities of slopes at Mileage 39Km road section could be attributed to the following:

- A complex geologic structure at the site (Figure 1) where the underlying geologic units are generally fractured.
- The 1999 earthquake shaking that had weakened underlying geologic structure and enhanced deterioration process of the materials.
- The steep downhill slope geometry (60° angle & 200m deep).

- The potential uphill sliding masses (Figure 11).
- The unprotected downhill slope surface that enhanced rainfall infiltration and surface runoff erosion.
- A long-term erosion of slope toe by Do-Tzuo Creek (Figure 12).
- The abundance of groundwater that was observed seeping out of the surface of downhill slope.
- The prolonged and intense rainfalls that infiltrated, saturated and softened the slope materials, increased the perched water level, and directly triggered the slips.

#### 4.2 Long-term stability considerations

The previous remedial works at site after Typhoon Longwang has been successful to date. However, the work details were mainly for improvements on surface protection of the upslope. From the analysis above on causes of slope failure, the current remedial activities would be helpful to mitigate the infiltration of rainfall and possibly prevent the triggering of a slide in the upslope. It would not be useful, however, for the stability of downslope, and would not either remove the concerns (i.e., potential factors) above that could be detrimental to the long-term stability of the road section and slopes at the site.

In accordance, more stability considerations and measures need to be taken to ensure the safety of the road section, and to maintain the transportation function of Mt. Ali Road as well. The considerations might include:

- Removal of potential sliding masses or reducing slope angle in the uphill.
  - Downhill slope protection including vegetation and drainage installations.
  - Road base and adjacent slopes strengthening by piling and anchoring.
  - Subsurface drainage installations in uphill & downhill slopes.
  - In-situ monitoring and warning system installation.
- The above measures appear to be sound from an engineering standpoint. However, the total cost and time for all of the above works would be extremely high, in view of difficulties in access for construction and generally incompetent subsurface materials at the site. Another option would appear more favorable as to reroute the Mt. Ali Road away from this difficult section.

### 5 ACKNOWLEDGEMENTS

The authors would like to thank District V, Directorate General of Highways, Taiwan, for providing documents for this study.

# Downstream Frontal Velocity Reduction Resulting from Baffles

Effets des déflecteurs dans la réduction des vitesses frontales dans un écoulement descendant.

Choi C.E., Ng C.W.W.

**ABSTRACT:** Debris flows occur in mountainous regions during rainfall and can result in disastrous consequences to downstream facilities if appropriate mitigation measures are not taken. Common mitigation measures include flow impeding structures within the flow path. An array of baffles is a type of flow impeding structure used primarily to reduce the mobility of landslide debris. However, they are usually designed on an empirical and prescriptive basis and the degree of impedance resulting from an array of debris flow baffles is not well understood. This paper presents a series of systematic flume tests examining the influence of baffle row number on reduction of debris frontal velocity. Photoconductive sensors installed at the base of the flume channel have been used to measure the average frontal velocity of the debris flow downstream of the array of baffles. Results show that one row is ineffective in reducing the debris frontal velocity. Two to three rows of baffles exhibit notable frontal velocity reduction.

**RÉSUMÉ :** Les coulées de granulaires représentent un risque majeur en régions montagneuses en période de fortes pluies et peuvent avoir des conséquences désastreuses pour les installations en aval si des mesures appropriées ne sont prises. De telles mesures comprennent la construction de déflecteurs à matériaux sur le parcours des coulées avec pour objectif principal est de réduire la mobilité de la masse granulaire en mouvement. Cependant, la construction de ces déflecteurs repose sur des hypothèses empiriques. La contribution exacte des déflecteur est mal comprise à l'heure actuelle et elle est difficile à évaluer précisément. Cet article présente une série de tests expérimentaux ayant pour objectif d'évaluer l'influence de l'augmentation du nombre de déflecteurs sur la réduction de la vitesse frontale de la coulée granulaire. Des capteurs photoconducteurs placés dans le fond du canal de test ont été utilisés pour mesurer la vitesse frontale moyenne des grains en aval des déflecteurs installées. Les résultats révèlent qu'au moins deux à trois rangées de déflecteurs sont nécessaires pour avoir une réduction significative de la vitesse frontale de l'écoulement.

**KEYWORDS:** physical modelling; flume; debris flow; baffles; landslide mitigation measures

## 1 INTRODUCTION

Ground mass detached from landslide source travels down hillside under gravitational actions. Landslide debris can have high mobility and can result in serious consequences to downstream facilities. Velocity of debris fronts can reach up to 30 m/s (Costa 1984; Rickenmann 1999) with peak discharges several times greater than floods occurring in the same catchment (Hung et al. 1984). In order to mitigate this hazardous phenomenon, debris-resisting structures are often used as defence measures to retain landslide debris and impede debris mobility (Mizuyama 2008). Defence measures may include the rigid and flexible barriers (Wendeler et al. 2007), levees, slit dams (Watanabe et al. 1980), and arrays of baffles.

The primary function of baffles is to impede the flow pattern such that flow slows down after it passes through the baffles (USFHA 2006). Baffles can be installed upstream of barriers to reduce the impact resistance required by the barriers and to promote lateral dispersion of flow in deposition basins (Cosenza et al. 2006). Figure 1 shows rectangular gabion baffles installed in front of a rigid barrier in Lantau Island, Hong Kong. Baffles are usually designed by empirical and prescriptive methods and their fundamental impedance capacity is not well understood.

Similar studies on snow avalanche impeding obstacles report that an individual row of obstacles can dissipate energy by 20% and an additional row contributes to 10% extra energy dissipation (Hakanordottir et al. 2001). Salm (1987) reports that the degree of impedance can be estimated based on the consideration of the cross-sectional blockage over the channel area. However, the above criteria are applicable only for snow avalanches because the flow regimes characterising avalanche and debris flow are quite different (see Sect. 2.1 for further

details). This study aims to examine the reduction of downstream debris frontal velocity resulting from an array of baffles. The influence of the number of staggered rows of baffles on downstream debris frontal velocity is investigated.

## 2 METHODOLOGY

### 2.1 Scaling

Three types of similitude are required for modelling debris flow-baffle interaction; they are (i) geometric similarity, (ii) kinematic similarity, and (iii) dynamic similarity. For simplicity, geometric similarity is achieved by normalising

model dimension by the flume channel width and debris flow depth (more details presented in Sect. 3). Kinematic similarity describes the impedance resulting from baffle interaction which is unknown and constitutes the objective of this study. Dynamic similarity is attained by adopting the Froude number,  $F_r$ , which governs the behaviour of gravity-driven flows in open channels. The  $F_r$  number is the ratio of inertial forces to the gravitational forces and is given as follows:

$$F_r = \frac{v}{\sqrt{gh}} \quad (1)$$

where  $v$  = frontal velocity (m/s),  $g$  = gravitational acceleration ( $\text{m/s}^2$ ), and  $h$  = debris flow depth (m).

Debris flow can be characterised with approaching  $F_r$  which ranges from 0 to 4.5 (Arrattano et al. 1997, Hubl et al. 2009) based on field observations. An  $F_r \approx 3$  is adopted for characterising the approaching flow in this study. This corresponds to debris flow event with an approaching velocity of about 10 m/s and flow depth of about 1 m. Details of the scaling process and control test are discussed by Ng et al. (2012).

## 2.2 Flume model

Further to flume experimental studies of debris flow mechanisms (Law et al. 2008, Zhou et al. 2009) at the Hong Kong University of Science and Technology (HKUST), a new five metre long rectangular flume (see Figure 2) with a channel base width of 0.2 m and height of side walls of 0.5 m was developed for this study. Based on calibration exercises, an inclination angle of  $26^\circ$  is used (Ng et al. 2012) to match an  $F_r \approx 3$ . Instrumentation and lighting are mounted on the external frame surrounding the flume. Debris material is contained in a storage container located at the most upstream end of the flume. The storage container has a maximum storage volume of  $0.08 \text{ m}^3$  and is equipped with a spring-loaded door secured by a magnetic lock. At the most downstream end of the flume is a deposition container for collecting debris materials.

## 2.3 Instrumentation

Ten photoconductive sensors are installed throughout the base of the flume at intervals of 0.5 m. When debris passes over the sensor, a signal is sent to the data logger at that particular instant. With the known spacing and difference in time at which signals are received between two sensors, the average debris frontal velocity can be deduced along the entire transportation zone. The uncertainty of photoconductive sensors is estimated to be  $\pm 0.05 \text{ m/s}$ .

Laser sensors are mounted over the top of the channel to capture centreline flow depths at specific locations along the flume. Furthermore, high speed cameras are installed above and at the side of the flume to capture the flow dynamics during interaction with the array of baffles. The full resolution capacity of the cameras is  $1024 \times 1024$  pixels and with a potential frequency of 759 frames per second.

## 3 TEST PROGRAMME

A series of four flume experiments are presented in this paper. The details of experiments are given in Table 1. The four experiments consist of one control experiment without baffles in the channel to serve as reference and the three baffle configurations which vary in number of staggered rows (one to three rows). All experiments have been repeated to ensure repeatability. For simplicity, a single baffle height of 0.75 times the approach debris flow depth ( $h = 80 \text{ mm}$ ) is adopted for all configurations. Details on the approach debris flow depth are discussed by Ng et al. (2012). The degree of transverse

blockage is selected as 30% in this study. The degree of transverse blockage is defined as the sum of obstruction in the transverse direction divided by the width of the flume channel. According to Ikeya and Uehara (1980) and Watanabe et al. (1980), slit dams function primarily to retain flow material through the mechanism of arching, while baffles primarily impeded the flow mobility. Slit dams entail an equivalent degree of transverse blockage of greater than 40%, therefore the degree of transverse blockage selected in this study (i.e. 30%) is appropriate for modelling debris flow baffles.

Figure 2. Flume model setup

Table 1. Test programme

Test ID	Baffle height (h)	Transverse blockage (%)	Number of rows
H0 R1	0	0	0
H075 R1	0.75h	30	1
H075 R2	0.75h	30	2
H075 R3	0.75h	30	3

$h$ : approach flow depth (80 mm)

The arrangement of full and half sized baffles used to create a staggered formation as shown in Fig. 3. The dimensions of full baffles are  $20 \text{ mm} \times 20 \text{ mm} \times 60 \text{ mm}$ , and the dimensions of half baffles are  $20 \text{ mm} \times 10 \text{ mm} \times 60 \text{ mm}$ . The spacing between successive rows is selected to be 50 mm or 0.25 times the width of the flume channel. This spacing is selected based on recommendations by Hakonardottir et al. (2001) that baffles should be placed as close together as possible to promote the deflection and interception of discharge from the slits of the previous row.

## 4 EXPERIMENTAL RESULTS

### 5.1 Flow dynamics

As a flow front impacts an array of baffles, streams of debris material discharge through the slits and part of debris also runs up along the upstream vertical face of the baffles simultaneously. The debris run up eventually exceeds the baffle height and some materials become airborne. Synchronously, material is deposited upstream of the baffles. The upstream flow eventually rides over the deposited material and cascades over the array of baffles. There are essentially two components of downstream discharge, namely discharge through and overtop of the baffles, both of which combine and propagate downslope after the landing of overflow trajectory.

Figure 3. Baffle arrangement and dimensions (all dimensions in mm)

### 5.2 Frontal velocity

The measured debris frontal velocity profiles of different tests are compared and shown in Fig. 4. The measured debris frontal velocity is plotted against normalised distance travelled along the transportation zone ( $N_d$ ), which is the ratio of distance travelled by the debris front along the 5 meter flume. The debris flow direction is from left to right on x-axis and the location of the baffles along the transportation zone is shown as a vertical dashed line.

The frontal debris velocity profile of the control test (H0\_R0) is shown as a reference for comparison purposes. The debris frontal velocity of the control test rapidly increases upon release from the storage container. At  $N_d = 0.2$ , a steady debris flow profile develops, beyond  $N_d = 0.6$ , the debris frontal velocity begins to decrease. A similar debris velocity profile is observed in the experiment of one-row baffle test (H075\_R1). However, for the two-row and three-row baffle tests, a prominent debris velocity reduction at the immediate downstream of the baffle groups was observed. The velocity profile rapidly decreases to less than 2 m/s after which it gradually increases beyond  $N_d = 0.3$ .

Results show that one row of baffles (H075\_R1) exhibits negligible reduction in frontal debris velocity and the propagation of the front is similar to unobstructed flow (H0\_R0). Obvious reduction in debris frontal velocity is observed in the test with two rows of baffles (H075\_R2) at the location immediately downstream of the baffle group. This may be attributed to the second row of staggered baffles intercepting the discharge from the slits of the first row which dissipates energy by disrupting streamlines of the flow (USFHA 2006). The provision of an additional row of baffles (i.e. the third row; test H075\_R3 refers) exhibits a frontal debris velocity reduction of 47% at  $N_d = 0.3$  relative to the control experiment, whereas two rows of baffles (H075\_R2) only exhibits 30% reduction of frontal debris velocity relative to the control experiment at  $N_d = 0.3$ . Moreover, the higher frontal velocity reduction may be attributed to an additional third row of baffles which intercepts discharge from the second row and disrupts streamlines. Beyond  $N_d = 0.4$ , two rows (H075\_R2) and three rows (H075\_R3) baffle groups exhibit a similar gradual increase in frontal debris velocities. An increase in frontal debris velocities may be attributed to subsequent excessive overflow of material due to the use of shorter baffles (0.75 times the approach flow depth) in this study. Overflow of debris in test H075\_R1 is captured from high speed imagery at the side of the flume model and is shown in Fig. 5. Overflow does not experience impedance and launches downstream (Barbolini et al. 2009) to increase the momentum and thus the frontal velocity of the flow. Overflow is hazardous particularly in situations where its trajectory is not easily predicted. Johannesson (2001) surveyed a torrent which had been deflected by a dam at Flateyri in north-western Iceland and observed that the deflected stream came to rest 100 m further downslope than the un-deflected part. The mechanism of overflow appears to be significant and results from this study require further interpretation.

Figure 4. Comparison of measured frontal velocity

Figure 5. Observed overflow dynamics (test H075\_R1)

### 5.3 Preliminary Particle Image Velocimetry (PIV) analysis

A preliminary Particle Image Velocimetry (PIV) analysis has been carried out to investigate the flow dynamics and quantify the flow velocity by interpreting the results of the flume test using the Particle Image Velocimetry package (geoPIV) developed by White et al (2003). This package is developed based on close-range photogrammetry techniques capable of tracing movements of soil grains captured in high-resolution images. It produces displacement and velocity vectors of the soil grains.

Typical flume test results for three rows of baffles produced by geoPIV are presented in Figure 6. It shows the flow dynamics of the debris upon hitting the baffles. Details of debris run-up against baffles, deposition behind baffles and filling up of the baffle zone and the subsequent overflowing from the crest of baffles were captured. In general, the preliminary results of the calculated velocity vectors by PIV method are consistent with the measured debris frontal velocity by the instrumented photo-sensors. Further PIV analysis will be carried out in the next stage of interpretation of the experimental study.

Figure 6. Preliminary results using PIV method

## 5 CONCLUSIONS

A series of systematic flume experiments modelling debris-baffle interaction has been conducted. The influence of increasing the row number on frontal debris velocity is presented and some preliminary conclusions are drawn as follows:

1. One row of baffles exhibits negligible reduction of frontal debris velocity compared to unobstructed channelised flow.
2. Two and three rows of baffles result in reduction of frontal debris velocities immediately at the downstream from the array of baffles. Increasing the number of staggered rows of baffles disrupts streamlines and intercepts discharge from slits of the previous row of baffles which dissipates energy and reduces the frontal debris velocity.
3. Overflow resulting from the use of baffles may result in subsequent increase in frontal velocity downstream and warrants further studies.

# GPS instrumentation and remote sensing study of slow moving landslides in the eastern San Francisco Bay hills, California, USA

Instrumentation GPS et télédétection de glissements de terrains lents dans les collines est de la Baie de San Francisco, Californie, USA

Cohen-Waeber J., Sitar N.  
*University of California Berkeley, Civil and Environmental Engineering*

Bürgmann R.  
*University of California Berkeley, Earth and Planetary Science*

**ABSTRACT:** Active slow moving landslides in the East Bay Hills, San Francisco, California, have been the object of many investigations over recent decades, though their mechanisms are still poorly understood. Contemporary geodetic technologies, such as continuous Global Positioning Systems (GPS) and Interferometric Synthetic Aperture Radar (InSAR), allow for remote detection and characterization of ground surface displacements with sub-centimeter precision and accuracy. This project combines GPS and InSAR time series analyses for the characterization of spatial and temporal landslide deformation as a result of static and dynamic forces. Several independent InSAR time series analyses show accelerated landslide surface deformation as an effect of precipitation, though not in relation to recent seismic activity. Additionally, recent advances in InSAR analysis methods allow the observation of intra-slide deformation patterns. Since the implementation of a comprehensive continuous GPS network in January 2012, landslide related surface displacements have also been recorded in response to precipitation. Both InSAR and GPS studies not only confirm strong correlation and sensitivity to periods of precipitation but downslope sliding velocities of around 30 mm/year as well.

**RÉSUMÉ :** Bien que leurs mécanismes soient encore mal compris, des glissements de terrains lents dans les collines Est de la baie de San Francisco, Californie, font depuis plusieurs décennies l'objet de nombreuses recherches. Les technologies géodésiques d'aujourd'hui comme le GPS continu et l'InSAR, permettent la télédétection et la caractérisation de déplacements de la surface terrestre avec précision et exactitude millimétrique. Ce projet a donc pour but de caractériser les déformations spatio-temporelles de la surface terrestre, liés aux glissements de terrains sous effets statiques et dynamiques, par l'application de ces outils géodésiques. Plusieurs analyses indépendantes de séries chronologiques InSAR montrent une accélération superficielle de ces glissements sous l'effet de précipitation mais pas sous l'effet d'activité sismique. D'avantage, de récents progrès des méthodes analytiques d'InSAR permettent l'étude des modes de déformation intra-glissements. La mise en place d'un réseau GPS en Janvier 2012, montre aussi une accélération des glissements sous l'effet de précipitation. Ces deux méthodes confirment non seulement une sensibilité aux périodes de précipitation, mais aussi une vitesse approximative de 30 mm/an.

**KEYWORDS:** Landslides, creep, GPS, InSAR.

## 1 INTRODUCTION

Recent advances in geodetic technologies allow for remote data collection and the analysis of spatial and temporal ground surface deformation at a scale that was previously not possible. Technologies such as continuous GPS and Interferometric Synthetic Aperture Radar (InSAR) are capable of measuring active surface displacement with as much as sub-centimeter precision and accuracy. This clearly lends itself to the characterization of active slow moving landslides. Furthermore, the urgency for improved efficiency of primary geologic and geotechnical site investigations stresses that these methods be incorporated in the current state of practice.

Active landsliding across the Lawrence Berkeley National Laboratory (LBNL) site and the East Bay Hills, California, has been the object of many investigations over recent decades. Though studies suggest a trend in landslide mobility is associated with regional climate and active tectonic conditions in addition to the local geologic setting, the mechanisms of these currently slow moving slides are still poorly understood. Thus, the objective of this study is to characterize slope deformation as a result of static and dynamic forces by a careful observational program using the most current geodetic technologies. The intent is to help develop a method for the remote determination and evaluation of landslide hazards and their eventual risk assessment.

This monitoring program includes the instrumentation of individual landslides with a comprehensive network of permanent, continuously streaming GPS stations, and regional

monitoring of slope surface deformation by InSAR time series analysis. To date, historical InSAR and recent GPS observations confirm similar downslope sliding velocities as an effect of precipitation, though not in relation to seismic activity. A closer review of InSAR time series also reveals a pattern of intra-slide surface deformation and important insight on internal slide mechanisms. This is a presentation of preliminary GPS findings and an observation of InSAR time series analyses.

## 2 GEOLOGIC SETTING

The study area for this project is located along the western flank of the Berkeley Hills, east of the San Francisco Bay, California. The local geology is the product of an approximately 360 million year old accretionary process during which the North American Plate margin transitioned from subduction of the Farallon Plate to a transform boundary against the Pacific Plate. Hence, several orogenies and accreted terranes are responsible for a wide variety of metamorphic, volcanic and sedimentary formations in this relatively small area known as the California Coast Range geomorphic province, characterized by a northwest trending and low lying mountain range.

As part of the California Coast Range geomorphic province, the Berkeley Hills are an uplifted block of Jurassic to Tertiary sedimentary, volcanic and metamorphic rocks bound by the Hayward and Calaveras faults and folded in a northwest trending synclinal form during regional transpression related to the active plate margin 1-2 million years ago. Now largely

overlain by Quaternary colluvial and alluvial deposits, this highly fractured, intensely weathered, moderately soft rock is prone to landsliding.

In addition to the geologic setting, studies suggest that Berkeley Hills landslide mobility is driven by precipitation and regional active tectonic conditions (Alan Kropp and Associates 2002, Hilley et al. 2004, Quigley et al. 2010). Local orographic precipitation forms a wet microclimate and the close proximity to active fault traces within the San Andreas Fault zone brings strong seismicity. Today, several hundred landslide-related geologic and geotechnical investigation reports are available for LBNL and the Berkeley Hills alone, and form a solid background to this project.

### 3 METHODOLOGY

Two state of the art geodetic sensing technologies form the primary modes of data acquisition in this project: high rate, continuously streaming, GPS and InSAR. While these methods have individually been shown capable of measuring active ground surface displacement at scales that were previously not possible; the appropriate characterization of landslide related slope movement benefits from the application of both.

Where continuous GPS provides three dimensional ground surface displacement measurements with millimeter scale accuracy and precision at full temporal resolution, the spatial distribution of measurement points is sparse. On the other hand, InSAR time series analysis produces improved spatial averages at decameter resolution with sub-centimeter precision, and the inclusion of datasets spanning several decades of observations. These methods are complimentary using deformation detected across a GPS network to calibrate that measured using InSAR.

The objective is thus to accurately measure landslide slope deformation over time. Combining these methods allows for spatial and temporal analysis of ground surface displacements due to landsliding in relation to local precipitation and ground shaking events. By incorporating these surface observations with previous investigations and monitoring, the landslide mechanisms can then be modeled.

#### 3.1 GPS Data Acquisition

The first phase of this project has been to establish a network of continuously streaming GPS stations to track landslide related ground surface displacement over time. This involves the instrumentation of individual landslides with autonomous, continuously streaming GPS stations, as well as several permanent reference stations. Each landslide station has been specifically designed for permanent, stand-alone installation and built to capture landslide displacement at depth. Anchored on a deep seated reinforced concrete foundation to limit the effects of surficial disturbance, the stations are solar powered and equipped with a wireless antenna for remote access. Reference station locations are chosen on the basis of proximity to the "mobile" devices and being seated on immobile ground.

Since January 2012, 5 such "mobile" stations have been successfully installed at LBNL and one at the University of California Blake Garden on the Blakemont Landslide. One reference station has been established at the Lawrence Hall of Science above LBNL. Average daily solutions are being obtained for each station based on a 1Hz data set, and a 25Hz buffer is held for displacement-time histories in the case of seismic activity. Three additional sites are in the process of being developed.

#### 3.2 InSAR Time Series

InSAR time series are a record of change in radar signal return phase over time, reflecting the change in distance between the ground surface and a satellite based radar platform (or range-

change). The strength of the return signal for each radar pulse is dependent of the physical properties of the target (or scatterer). Where distinct structures will return a persistent strong signal, less prominent surfaces will return lower intensity distributed signals and noise. Among others, two types of InSAR time series analyses are thus known as Permanent or Distributed Scatterer methods (respectively).

With the concurrent development of the GPS network, analysis of InSAR time series has also begun, though is not presented here in detail. Rather, a brief review of prior results is described with observations based on TerraSAR-X satellite data processed with the Tele-Rilevamento Europa (TRE) SqueeSAR™ algorithm (Ferretti et al. 2011, Giannico et al. 2011).

### 4 PRIOR GEODETIC RESULTS

The use of InSAR time series analysis has been shown to successfully track landslide related ground surface displacement in the Berkeley Hills area using data sets from different satellites over several time periods between 1992 and 2011 (Hilley et al. 2004, Quigley et al. 2010, Giannico et al. 2011). In each case, analysis of Permanent and/or Distributed Scatterers over the period of interest clearly exhibit accelerated rates of displacement related to periods of high precipitation. Though no such relationship could be established with local seismicity, it is considered to be likely that large earthquakes can accelerate landslide motion. Furthermore, one attempt at the use of Continuous GPS to track landslide motion was also of no avail (Quigley et al. 2010).

#### 4.1 1992-2007 Time Series of ERS and RADARSAT

In the InSAR time series analysis of Permanent Scatterers performed by Hilley et al. (2004), known landslides across the Berkeley Hills were successfully detected and tracked from 1992 to 2001 using ERS-1 and ERS-2 data acquisitions. Over this period, these data indicate landslide related surface displacement rates varied between 5 to 7 mm/year range-change in the radar line of sight direction. Based on local average slope inclinations, this implies equivalent downslope velocities of 27 to 38 mm/year and has been verified in the field by subsurface inclinometer displacement measurements of approximately 33 mm/year (Allan Kropp and Associates 2002). Hilley et al. (2004) also observed that periods of landslide acceleration were closely related to seasonal precipitation, though non-linear in that precipitation related displacement did not occur immediately, with lag times of up to 3 months, and did not predictably increase with larger events. Additionally, Hilley et al. (2004) suggest the potential for seismic related landslide displacement given a  $M_w \approx 3.9$  Hayward fault event on December 4, 1998. Though the temporal resolution of the time series could not directly document seismically triggered deformation, unexpectedly high InSAR displacement measurements were observed relative to the amount of precipitation during the same period.

Similarly, Quigley et al. (2010) examine seasonal precipitation-related displacement, supplementing the same ERS data set with RADARSAT-1 acquisitions from 2001 to 2006. Landslide displacement was shown not only to be of same magnitude, but clearly seasonal and sensitive to variations in rainfall patterns. Detrended and stacked (by month) observations plotted against average monthly precipitation exhibited a clear 1 to 3 month displacement response lag time and a positive correlation to the intensity of precipitation.

#### 4.2 2007-2009 Continuous GPS Tracking.

Quigley et al. (2010) used Continuous GPS at one known active landslide location to track surficial displacements between 2007 and 2009. Though InSAR time series (Hilley et

al. 2004) and local inclinometer data (Quigley et al. 2010) clearly illustrated slide activity in the years before the station's installation, the GPS monitoring did not. This was likely due to a particularly dry period and the station was disassembled before an adequate data set could be collected to observe long term landslide behaviors.

## 5 RECENT INSAR TIME SERIES OBSERVATIONS

While the Permanent Scatterer InSAR method uses stable coherent targets as shown in the examples above, it is also limited by their presence. To increase the number of observed scatterers and improve time series resolution, the new proprietary algorithm (SqueeSAR™) developed by TRE (Ferreti et al. 2011), utilizes both the Permanent and Distributed Scatterer methods. Thus, a third InSAR time series analysis was performed over the Berkeley Hills by Giannico et al. (2011) applying the SqueeSAR™ method to TerraSAR-X data acquisitions from 2009-2011.

As observed in the 1992-2007 InSAR time series analyses (Hilley et al. 2004, Quigley et al. 2010), landslide related displacements were clearly identifiable with velocities averaging between 6 and 8 mm/year range-change and with periods of precipitation-related acceleration. Figures 1 and 2 show the location and average displacement time histories for different areas (top, middle and bottom) within the Blakemont Landslide (respectively), plotted against cumulative precipitation over the period of observation.

Located at the northern-most end of the study area, field investigations have described the Blakemont Landslide as an approximately 915-m-long, 215-m-wide translational soil and rock landslide with nested rotational failures, and an active sliding depth of 8 to 20 m (Alan Kropp and Associates 2002). While the entire slide appears to be moving coherently downslope (increasing range-change displacement from the descending orbit acquisition), clear accelerations occur in early 2010 and early 2011, some 3 months after the onset of each wet season. Furthermore, the landslide exhibits a positive correlation between displacement and intensity of precipitation with smooth variations during a more gradual 2009-2010 wet season, in comparison to abrupt accelerations during a higher intensity 2010-2011 season.

An important advantage of the higher spatial resolution afforded by the TRE SqueeSAR™ method is a better understanding of landslide mechanisms as expressed at the ground surface. A closer look at the downslope displacements of different areas within the Blakemont Landslide (Figure 2) reveals that it is in fact not moving as one coherent mass, rather with what physicists would call an "accordion effect". Differencing the average downslope displacements of each of the highlighted areas from top to bottom of the landslide, a pattern of apparent landslide shortening (positive) and extension (negative) becomes evident (Figure 3). Here the largest differential displacement variations are observed between the top and bottom areas of the landslide. During wet seasons, the difference in displacement between top and bottom of the landslide increases as the lower portions of the slide accelerate earlier than the upper portions. The same can be said for the opposite case during dry periods, when the difference in displacement between the top and bottom of the landslide decreases as the lower portions of the landslide slow and the upper portions catch up. Naturally, as this currently short dataset is augmented, it is the authors' hope to observe similar trends over longer time periods.

## 6 PRELIMINARY GPS RESULTS

Daily solutions from the first 6 continuously streaming GPS stations have been recorded since their installation in January 2012. Highlighted here are stations "LRA 1-3" located on the same landslide in Chicken Canyon at LBNL, as depicted in the 1935 air photo (Figure 4). While historical ground surface displacement related to this landslide has yet to be characterized and quantified, extensive field investigations have described it

as an approximately 230-m-long, 75-m-wide and 24-m-deep translational soil and rock landslide with nested rotational failures (Alan Kropp and Associates 2009).

Already, a clear signal at each of these 3 stations is apparent, showing down-slope displacements of up to 3 cm which occurred directly related to local precipitation. As an example, Figure 5 illustrates the time history of daily solutions for station LRA 2 from January through October 2012, plotted against cumulative rainfall. To remove tectonic related displacements and measure actual displacement of the station, daily solutions for the station's North and East baselines are taken with respect to a fixed station (P224) several kilometers to the South. As such, LRA-2 clearly exhibits long term down-slope displacement to the southwest, accelerating during large rainfall events. Also indicated in Figure 5 is the time of the March 5, 2012  $M_w = 4.0$  Hayward fault earthquake with epicenter in El Cerrito, CA, approximately 10 km north of the site. While no clear seismically driven permanent slope displacements can be discerned, this may be due to the "dry" state of the landslide as well as the event's size and distance.

Figure 4. 1935 Oblique view of LBNL landslide with current GPS station locations.

Figure 5. GPS position time series of station LRA 2 with respect to reference station P224. North (circles) and east (triangles) components of relative displacement with respect to reference site P224 are show together with cumulative precipitation (solid line) and time of  $M_w = 4$  earthquake (dashed line).

## 7 CONCLUSION

A review of three independent InSAR time series analyses of the Berkeley Hills, from separate satellite acquisitions and over different time intervals from 1992-2011 shows remarkable consistency. In each case, similar mean landslide velocities were estimated, and precipitation dependent displacement behavior was observed. Though we were not able to document any motions induced by recent moderate earthquakes in the region, improved spatial resolution has allowed us to draw preliminary conclusions on the mechanics of displacement within one landslide. Further insight is expected as the quality of analysis improves and larger datasets are acquired.

After a mild wet season, the GPS instrumentation of several landslides in the Berkeley Hills, has recorded well-defined precipitation triggered slope movement. In contrast, the occurrence of a nearby  $M_w = 4$  earthquake did not appear to have produced a measurable effect. Overall, the system has already demonstrated its capability to record landslide motions that otherwise would not have been observed with such level of detail and it continues to function and collect new data.

While both methods of observation presented here have not yet been directly compared, they do exhibit similar trends. In both cases, records of landslide related surface displacement have comparable down-slope velocities, increased with periods of precipitation and varied with its intensity. Observations over longer periods will provide important insight on the triggering mechanisms and internal landslide behavior we have described.

**ABSTRACT:** A large number of Brazilians live in conditions that involve elevated risk for landslides. Both technical and social problems are involved. This study presents results of a research project involving technical support for the Municipal administration of the City of Camaragibe - PE. An important landslide occurred in an occupied area after a period of intense rainfall, causing considerable losses for the local population. Three years later, another period of intense rainfall exacerbated the problem, causing cracks to develop in the walls and foundations of many houses, and broadening the area initially affected. An important program involving investigation that included field and laboratory activities, instrumentation, and stability and flow analysis was carried out. The results produced were considered to be very satisfactory, and they were able to point out the main causal factors, along with the mechanisms involving the landslide, which could then be better understood, and thoroughly studied. Afterwards, a proposal for stabilization for the entire area was elaborated, aiming to significantly reduce the risk levels by means of superficial and sub-superficial drainage, geometric modifications, placement of structures for stabilization of the land, and other activities.

**RÉSUMÉ :** Un grand nombre de brésiliens vivent dans des zones à risque d'un point de vue des glissements de terrain. Cela engendre des problèmes aussi bien techniques que sociétaux. Les travaux présentés dans cet article découlent d'un projet de recherche financé par l'administration municipale de la ville de Camaragibe – PE. Suite à un épisode pluvieux très important, un glissement de terrain s'est produit et a causé des dégâts considérables pour la population locale. Trois années plus tard, un nouvel épisode pluvieux a aggravé la situation et de nombreux ouvrages furent endommagés (murs de soutènement, fondations de maisons, ...). Un programme d'investigation important fût alors mis en place : instrumentation sur site, analyses de stabilité et d'écoulement. On présente dans cet article une synthèse des résultats obtenus ainsi que les mécanismes aux origines des instabilités. Pour finir, une solution de stabilisation du site est proposée, avec pour but de réduire significativement le niveau de risque (drainage, modification géométrique de la pente et mise en œuvre d'ouvrages de stabilisation).

**KEYWORDS:** geotechnical characterization, slope stability, stabilization process.

## 1 INTRODUCTION

This paper presents study results from a research project, including details involving technical support supplied to the Municipal administration of the City of Camaragibe – PE, Brazil. The area investigated is located in the Township of Camaragibe, belonging to the western portion of the Recife Metropolitan Region. The landslide that occurred was classified as a multiple rotational landslide, characterized by the appearance of various steps along its slope. Geological characteristics of the area studied define an unsaturated granite residual soil that is partially covered by the Barreiras Formation. The residual soil of granite is found throughout the entire city. In some places, the granite rock mass is exposed.

In the Recife Metropolitan Region, it is common to find crystalline based rocks (Granite-Gneissic complex) covered by granite residual soils that originate from a crystalline structure; and by sediments from the Barreiras Formation. The crystalline base is formed by ancient intrusive rocks (1.5 to 21 billion years) belonging to the Pernambuco – Alagoas Massif. It presents at least four phases of deformation, the latter of which, associated to the faults deformed, resulted in the formation of the “Pernambuco Lineamento”.

The results presented here refer to a synthesis of the program of geotechnical characterization (field and laboratory testing, along with instrumentation), flow and stability analysis, and proposals for stabilization of the area in an attempt to significantly reduce the level of risk. This study aims to give

continuity to a research project by the GEGEP – DEC / UFPE, with support from the CNPq/FACEPE, designed to comprehend and elaborate mechanisms involving instability of slopes, and providing manners in which stabilization can be achieved.

## 2 GEOTECHNICAL CHARACTERIZATION

In the studies, an extensive effort involving *in situ* and laboratory investigation was carried out. For basic geotechnical characterization, laboratory analysis consisted of physical, chemical, and mineralogical characterization tests, strength tests (including direct shear tests, and direct shear tests utilizing controlled suction), and oedometer tests.

The *in situ* investigation carried out in the area was performed by using topographic profiles of the region, cross sections, geological engineering mapping, subsurface exploration (soil / rock mass – SPT / RQD measurements), soil moisture content profiles, sampling of soils (Block and Denison), and field permeability tests (Guelf). Field instrumentation utilized piezometer, water table level, inclinometer, and rainfall measurement equipment. More information can be found in Silva (2007) and Silva *et al.* (2009).

### 2.1 Field Investigation Results

For the subsurface exploration, twelve boreholes were utilized in the area investigated. Ten were carried out in soil (SPT), and

two more in soil and rocky mass (SPT / Core boring–RQD). All boreholes the SPT was measured for each 0.5 m, in general with a depth of 10 to 15 m, but some went down to 20 m (SM-01, SM-02 and SP-02). Geological characteristics were identified together with soil / material descriptions.

In general, for all borehole tests performed, the SPT values ranged from 2 to 17 down to a depth of 7 m from the level of the natural ground surface, within the limits of the two geological formations. From this point on, the SPT values increase markedly, up to an order of 30, until becoming impenetrable to the SPT borehole. In the vertical profile, soil types vary from clayey sand, to sandy clay, silty sand, and sandy silt, with the layers varying in thickness, and showing the presence of increased amounts of sandy materials. The greatest alterations in SPT values were found very close to the Barreiras Formation contact with the granite residual soil. An exception involved the SP-02 borehole, found to be basically granite residual soil (Figure 1). Due to high sand content, the Barreiras Formation in the area is identified as an alluvial plain facie. Based on technical interpretation, the failure surface was shown to be near to the geological formation contact point, later confirmed by instrumentation (inclinometer results).

The presence of granite residual soil from the ground level in the SP-02 region demonstrated a profound influence on the landslide process, as evidenced later on in the study.

Soil profile cross-sections were detailed from the subsurface exploration, along with results from geological engineering mapping. Typical soil profile information is shown in Figure 1.

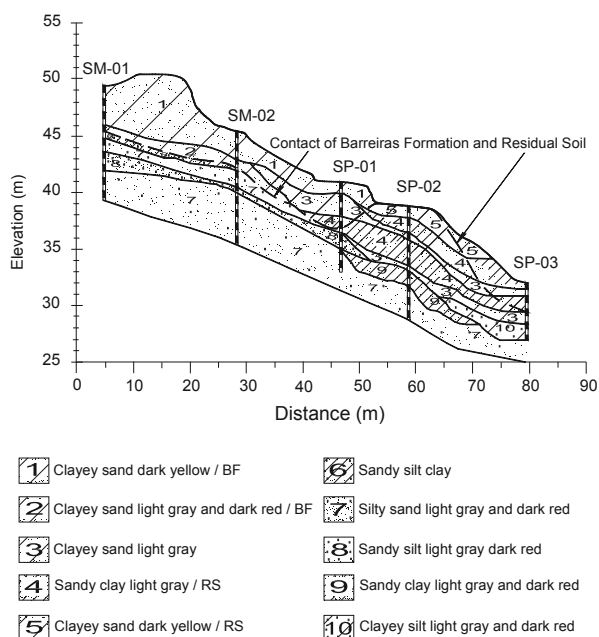

Figure 1. Typical Soil profile-cross section – post failure.

The climate in the area is classified by Koppen, as ‘As’, described as humid tropical, with rainy periods during the autumn – winter seasons, and a dry period during the summer.

Rainfall precipitation in the Camaragibe township region was measured by instruments installed in two places, initially in a location within the city (during 2000 to 2004), and then later via instrumentation installed in the landslide area (2004 to 2006).

The rainy season is concentrated in the months from March to August, with the precipitation approximating average monthly maximum levels ranging from 150 mm to 600 mm. From January to March the average maximum monthly precipitation is around 150 mm, with April, May, July and August showing 250 mm. The month of June presented

precipitation above 500 mm, being considered the critical period for landslides. During the period from September to December, precipitation levels were lower, averaging around 50 mm. The period from September to February normally presents less precipitation; however, in some years (examples being 2000, 2002, 2004 and 2010) significant rainfall occurs in the months of January and February. During 2000, the annual rainfall level was above the general average, with increased precipitation during most of the calendar months. This occurrence coincided with the first appearance of signals of a non-stabilization condition in the area. Landslides occurred in June of 2002, after a period of intense rainfall.

Hydraulic conductivity of the soils was determined through field testing using a Guelph permeameter, an in-hole constant head permeameter employing the Mariotte Principle. It delivers essentially a “point” measurement. The tests were made along of the slide, close for the SPT boreholes, and was performed for each 0.5 m to a depth of 2.5 m. In the Barreiras Formation soils, permeability results varied from 2 to 6 x 10<sup>-6</sup> m/s, with higher values from the materials containing a higher percentage of sand. In the SP-02 region (Figure 1), granite residual soils are present in the surface levels, presenting permeability results in the order of 2 x 10<sup>-7</sup> m/s, and demonstrating values 10 times lower than the corresponding Barreiras Formation. This difference influenced flow conditions in the slide area.

The field instrumentation program in the landslide area was based on 25 Casagrande type piezometers (with 18 Casagrande piezometers having the ability to register maximum levels during a rainy period), 6 water level instruments, 5 vertical inclinometers, and 1 rainfall registration instrument.

In general the period of highest elevation of the piezometric level coincides with the period of high rainfall, in the months from March to August (with water managing to emerge from the surface level of the ground near borehole SP-01). Starting during the month of September, piezometric levels show a reduction, tending to remain constant until March, coinciding with the dry season. Similar behavior can be observed regarding the water levels encountered. Even in periods of low rainfall intensity, piezometric levels are observed to be quite high, demonstrating hydraulic influence on slope stability.

Results obtained in the vertical inclinometer analysis relating to borehole SP-02 showed maximum horizontal displacement of 130 mm as a block mass. It should be noted that horizontal displacements measured refer to the stage of reactivation, featuring movements along the existing failure surface, given that instrumentation was implemented in November 2004, after the occurrence of the failure. The influence rainwater had in the acceleration of horizontal movements was clear in observations regarding the slope studied. It appears that during a period of reduced rainfall (November 2004 to March 2005) the displacements observed were virtually nil, without significance.

Results of the vertical readings from inclinometers confirmed the information obtained from the SPTs boreholes, showing that the failure surface seems to be very close to the contact between the Barreiras Formation, and the granite residual soils, measured to be located at a depth just over 7 m from the surface of the ground, the exception being the region around SP-02, where only residual soils are found.

## 2.2 Laboratory Investigation Results

The mature residual granite soil studied presents a fine texture, with a liquid limit of 54%, plasticity limit of 32% (PI=22%), grain size distribution of 39% clay, 26% silt, 23% fine sand, and 12% a mixture of medium and thick sand. The soil is classified as CL in the Unified Classification System.

Grain-size distribution test without the use of deflocculates was also performed. Grain size distribution was designated as

5% clay; 33% silt; 50% fine sand, and 12% medium and thick sand; showing a strong reduction in the portions of clay, and increases in the fine sand portions. Results indicate that the particles of clay in this soil are aggregated in their natural state.

The soil-water characteristic curve obtained through the paper filter method, Haines funnel and Richard's chamber, is presented in Figure 2. The format of the curve displays a saddle aspect, allowing it to be divided into three distinct stretches. The curves indicate an initial air entry suction of 1 kPa, where desaturation begins. After that, a region approximating horizontal is observed, where suction varies from 20 to 200 kPa. In the last stretch, a second air entry value is depicted, where the water content starts to diminish with the increase in suction due to the removal of water from the soil micro pores (see more information in Silva and Coutinho, 2009).

Figure 2. Soil-water characteristic curve from mature residual soil from Camaragibe-PE - Silva and Coutinho (2009)

The shear strength was determined using conventional and controlled suction direct shear tests. The equipment used consisted of a conventional press, adapted for use with a cell that allowed the imposition and control of suction through the principle of translation of axes.

The suction is imposed on the soil by the difference between air pressure supplied by hydrogen applied through an air valve, and the water column maintained in the reservoir fixed on top of the press. The tension is applied through a system of hanging weights, identical to the conventional direct shear tests. The air pressure was applied only under the weight of a charge transference plate, and it was maintained during 10 days. The horizontal force was determined through a load ring. The suctions employed were 25, 100, 300 and 500 kPa. After this period (of suction equilibrium), specific normal stress values were applied, accompanying the deformations up to stabilization. The normal stresses adopted were 50, 100, 150 and 200 kPa, and they were maintained for a minimum of 24 hours. Square samples were used that measured 50 mm or 100 mm the side, and 22 mm or 44 mm in height.

The shear strength envelopes in the plain ( $\sigma_v$ ,  $\tau$ ) for the suction values of 25, 100, 300 and 500 kPa are represented in Figure 3. Envelopes considering suction of 0 kPa, obtained through conventional direct shear tests in the submerged condition, are also presented in this figure. It can be observed that the friction angle, in general, is close to 31°. The results indicate that the envelopes are near to linear in the stress range.

( $U_a - U_w$ )= 0kPa	$c = 9,7\text{kPa}$	$\phi = 26,3^\circ$	$R^2 = 0,996$
( $U_a - U_w$ )= 0kPa	$c = 0,0\text{kPa}$	$\phi = 31,0^\circ$	estimated
( $U_a - U_w$ )= 25kPa	$c = 15,4\text{kPa}$	$\phi = 31,6^\circ$	$R^2 = 0,999$
( $U_a - U_w$ )= 100kPa	$c = 36,5\text{kPa}$	$\phi = 31,3^\circ$	$R^2 = 0,991$
( $U_a - U_w$ )= 300kPa	$c = 58,7\text{kPa}$	$\phi = 31,5^\circ$	$R^2 = 0,987$
( $U_a - U_w$ )= 500kPa	$c = 74,7\text{kPa}$	$\phi = 34,4^\circ$	$R^2 = 0,956$

Figure 3. Shear strength envelopes for different values of suction - mature residual soil from Camaragibe.

### 3 STABILITY ANALYSIS

Through the field investigation, together with flow and stability studies (failure and post failure conditions), a clear perception and understanding of the landslide mechanism was made possible. In this paper, only results corresponding to the failure state are presented. The slope stability evaluation was performed using Spencer method with consideration given to the original topography for the main cross section, as a two-dimensional saturated stability analysis, and considering the "actual" failure surface, along with the pore pressure distribution obtained from the flow analysis, and the geotechnical parameters obtained from laboratory testing (conventional direct shear tests in the submerged condition). Due to the intense rainfall during the failure period, the water level was considered at the surface position from the results produced through instrumentation and field observation, with the materials being in a saturated condition (Silva et al. 2009).

Flow analysis was performed for the failure condition, considering all the information from the studies, including the geotechnical profile, the geotechnical parameters of hydraulic conductivity for the materials composing the Barreiras Formation and residual soils, along with the rainfall and water level conditions. A summary of pore pressure distribution results is shown in Figure 4. Higher positive pore pressure values in the SP-01 and SP-02 regions were obtained showing ascends flow. These results are due to the variability of the soil profile and differences among the hydraulic conductivity values occurring for the materials. This condition is in conformity with water flow observed in this area during the period of intense rainfall.

With the flow analysis results that were provided, stability evaluation for global failure was initially performed (one-step failure) for the complete slope cross-section. The safety factor result was 1.278, showed not to be a condition for failure. Stability analysis was then performed considering the possibility of two-step failure, taking into account the concentrated high pore pressure values around the SP-01 region.

Figure 4. Flow Analysis – Pore Pressure Distribution.

The first landslide occurred between the positions SM 02 and SP-01. For this case, the safety factor value was 1.002, for practical purposes, considered to be a condition of failure, and initiating the landslide mechanism in the area (Figure 5).

Figure 5. Back-analysis of the first slope failure – from SM-01 to SP01

The mass that moved in this area (from the first failure) caused a surcharge estimated at 30KN/m between positions SP-01 and SP-02, which associated with pore pressure conditions, provoked the second step of the landslide. With this understanding, stability analysis was performed (back-analysis) using geotechnical information from the field and laboratory investigations. Figure 6 presents the minimum safety factor value obtained (1.047), confirming the displacements, and the failure mechanism considered to be the cause of the landslide that occurred in the area.

Figure 6. Back-analysis of the second slope failure – SP-01 to SP-03

After three years, another intense rainfall period amplified the problem, with cracks forming in many other houses, and extending the area initially showing damage. See the right side of the two upper-center squares of Figure 7.

#### 4 MITIGATION AND REHABILITATION MEASURES

The mitigation and rehabilitation measures consisted of reducing damage and losses through control of the processes, and protection of the exposed elements in order to reduce their vulnerability. During the investigation and studies, it became possible to understand the processes involved, and to identify the causal factors and triggering mechanisms in the area. The general plan was to propose a risk management program that included both structural and non-structural mitigating actions, considering the social conditions of the area (Coutinho, 2011).

The stabilization measures proposed for all damaged areas (initial and extended areas) included: surface and subsurface drainage (sub-horizontal drains), surface protection, placement of access stairs with surface drainage, modification of slope shape, installation of retaining walls, definition of areas where occupation was to be prohibited, definition of houses to be relocated, dissemination of information to the public, and raising overall awareness of the conditions, along with community consciousness. Figure 7 shows some of the mitigation and control measures proposed.

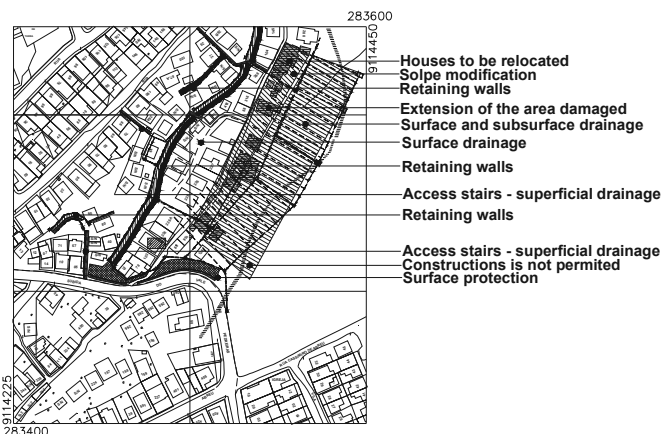

Figure 7. Measures Proposed for Mitigation and Control

#### 5 CONCLUSION

The geotechnical characterization, along with flow and stability analyses / back-analysis results, were considered to be very satisfactory, and in accordance with the literature, permitting that the principal causal factors, and the mechanisms of the landslide could be comprehended and studied. It was understood that due to the heavy rainfall, the water level became elevated, saturating the soil, and producing a concentrated flow. The strength parameters used in the analysis were derived from direct shear laboratory tests in the corresponding condition. Considering all of the information available, mitigation and rehabilitation measures were then proposed, generating a risk management program that included structural and non-structural stabilization actions, considering the social conditions of the area.

#### 6 ACKNOWLEDGEMENTS

The authors are grateful to the CNPq, FACEPE, and Camaragibe City Administration for research support, and all members of the GEGEP/UFPE who participated in the projects.

**ABSTRACT:** Progressive failure of slopes can trigger large scale landslides. The presence of sensitive clay layers is one of the main reasons for progressive failure of a slope. The whole soil mass involved in a potential landslide might be of sensitive clay, while in some cases there exist only thin layers of sensitive clay interbedded with relatively strong soils. The movement of a slope might be initiated due to the presence of a weak soil layer, where the shear stress is increased or soil strength is reduced by various triggering factors. Once the failure/movement is initiated in a small zone, the imbalanced force is transferred to the surrounding soil in which slip surface might propagate in the form of a shear band through the sensitive clay layer even though the sensitive clay layer is relatively thin. The propagation of shear band in sensitive clay is also associated with post-peak strain softening behaviour of soil. In this study, upward progressive failure due to river bank erosion has been modelled using nonlinear post-peak strain softening behaviour. It is shown that the pattern of propagation of shear band varies with soil type and slope geometry.

**RÉSUMÉ :** La rupture progressive de pentes peut déclencher des glissements de terrain de grande envergure. La présence de couches d'argile sensible est l'une des principales raisons de la rupture progressive d'une pente. La masse de sol impliquée dans un glissement de terrain potentiel pourrait être totalement constituée d'argile sensible, alors que dans certains cas, il existe seulement des couches minces d'argile sensible intercalées entre des sols relativement résistants. Le mouvement d'une pente peut être initié en raison de la présence d'une couche de sol peu résistant, dans laquelle le taux de cisaillement augmente ou sa résistance diminue en raison de divers facteurs de déclenchement. Lorsque la rupture / le mouvement sont initiés dans une petite zone, le déséquilibre de force se développe vers le sol environnant, dans lequel la surface de glissement peut se propager sous forme d'une bande de cisaillement à travers la couche d'argile sensible, même si la couche d'argile sensible est relativement mince. La propagation des bandes de cisaillement dans l'argile sensible est également associée au ramollissement post-pic du comportement du sol. Dans cette étude, la rupture progressive amont due à l'érosion des berges a été modélisée par le ramollissement non-linéaire post-pic du comportement. Il est montré que le faciès de propagation des bandes de cisaillement varie en fonction du type de sol et de la géométrie de la pente.

**KEYWORDS:** Sensitive clay, progressive failure, spread, shear band propagation, strain softening.

### 1. INTRODUCTION

Large landslides in soft sensitive clays are common in Eastern Canada and Scandinavia. Most of the onshore slides which occurred in soft sensitive clay have been reported as progressive in nature (Bernander 2000, Locat et al. 2008, Quinn 2009, Locat et al. 2011). The presence of strain-softening clay layers is one of the main reasons for progressive failure of a slope. These slides could be in the form of multiple retrogressive, translational progressive or spreads (Tavenas 1984, Karlsrud et al. 1984). Failure might be initiated in a fully stable and/or marginally stable slope depending on the nature of triggering factors. Failure could propagate either in upward or downward direction and the movement of the slope might be initiated due to the presence of a weak soil layer, where the shear stress is increased or soil strength is reduced by various triggering factors. Large landslides in sensitive clays classified as spread (Cruden and Varnes 1996) might be triggered by erosion near the toe of the river bank slope (Quinn et al. 2007, Locat et al. 2008). Numerous spread failures such as Sköttorp landslide in Sweden (Odenstad 1951) and the landslides occurred in Quebec including 1989 Saint-Liguori landslide (Grondin and Demers 1996), Saint-Ambroise-de-Kildare landslide (Carson 1979), Saint-Barnabé-Nord slide (Locat et al. 2008) have been reported to be triggered by erosion at the toe of the slope (Bernander 2000, Locat et al. 2008, Quinn et al. 2007, Locat et al. 2011), although it is very difficult to identify the true disturbing agents which caused these spread failures.

Progressive failure might occur in drained as well as undrained conditions. Bjerrum (1967) explained upward

progressive failure initiation in an intact slope containing overconsolidated plastic clays and clay shales and considered the failure as drained. Sensitive clays from Eastern Canada and Scandinavia show strain softening behavior under undrained loading which has been considered as one of the main reasons for developing progressive failure (Bernander 2000, Locat et al. 2008, Quinn 2009, Locat et al. 2011). Hence undrained condition is considered in this study for analyzing spread failure.

During Ormen Lange field development, numerical simulations have been carried out by Norwegian Geotechnical Institute (NGI) using PLAXIS software to analyze the potential of retrogressive sliding due to strain softening effect in mild clay slopes (NGI 2001). Anderson and Jostad (2007) conducted numerical analyses of progressive failure of slope by modeling the shear band as an interface element using the NGI finite element (FE) code BIFURC. Quinn (2009) also demonstrates the use of linear elastic fracture mechanics concept in progressive failure of slopes.

This paper describes a numerical technique which can be used to analyze the spread or upward progressive failure of a slope typically occurs in river banks due to toe erosion.

### 2. PROBLEM DEFINITION

The geometry of the slope modeled in this study is shown in Fig. 1. The river bank has a slope of 30° to the horizontal. A thick crust of overconsolidated clay near the face of the slope and below the ground surface is assumed. For simplicity the

groundwater table is assumed at the crest of the slope and the river is full. A block of soil near the toe of the slope shown by the hatched zone is removed, which could be caused by erosion or by excavation in the field. This block will be referred as “excavated/eroded soil block.” It is also assumed that the erosion or excavation is occurred relatively fast such that the deformation/failure of remaining soil is in undrained condition.

Three cases are simulated in this study. In Case-I, the ground surface is horizontal and there is a 15 m thick layer of sensitive clay below the 5 m crust. The Case-II is same as Case-I but the ground surface is inclined upward at 4°. Sometimes in the field there may not be a thick sensitive clay layer. To investigate the effect of thickness of the sensitive clay layer, in Case-III only 1.0 m thick sensitive clay layer parallel to the horizontal ground surface from the toe of the slope is assumed. The soil above this layer has the same geotechnical properties of the crust used in Cases I & II. In all three cases, the base layer below the toe of the slope is very stiff and therefore the failure is occurred in the soil above the base layer. The length of the soil domain in the present FE model is 500 m and therefore no significant effects on the results are expected from the right boundary.

Figure 1. Geometry of the slope used in numerical analysis

### 3. FINITE ELEMENT MODELING

#### 3.1 Numerical technique

ABAQUS 6.10 EF-1 is used in this study. The progressive slope failure is fundamentally a large deformation problem as very large plastic shear strain is developed in a thin layer of soil through which the failure of the slope is occurred. Conventional finite element techniques developed in Lagrangian framework cannot model such large strain problems because significant mesh distortion occurs. In order to overcome these issues, Coupled Eulerian-Lagrangian (CEL) technique currently available in ABAQUS FE software is used. The finite element model consists of three parts: (i) soil, (ii) excavated/eroded soil block, and (iii) void space to accommodate displaced soil mass. The soil is modeled as Eulerian material using EC3D8R elements, which are 8-noded linear brick, multi-material, reduced integration with hourglass control elements. In ABAQUS CEL, the Eulerian material (soil) can flow through the fixed mesh. Therefore, there is no numerical issue of mesh distortion or mesh tangling even at large strain in the zone around the failure plane.

The excavated/eroded soil block is modeled in Lagrangian framework as a rigid body, which makes the model computationally efficient. A void space is created above the model shown in Fig. 1 using the “volume fraction” tool. Soil and void spaces are created in Eulerian domain using Eulerian Volume Fraction (EVF). For void space EVF is zero (i.e. no soil). On the other hand, EVF is unity in clay layers shown in Fig. 1, which means these elements are filled with Eulerian material (soil).

Zero velocity boundary conditions are applied at all faces of the Eulerian domain (Fig.1) to make sure that Eulerian materials are within the domain and cannot move outside. That means, the bottom of the model shown in Fig. 1 is restrained from any movement, while all the vertical faces are restrained from any lateral movement. No boundary condition is applied at the soil-

void interface (efgh in Fig. 1) so that the soil can move into the void space when displaced.

Only a three-dimensional model can be generated in ABAQUS CEL. In the present study the model is only one element thick, which represents the plane strain condition.

The numerical analysis consists of two steps of loading. In the first step geostatic load is applied to bring the soil in in-situ condition. Note that under geostatic step the slope is stable with some shear stress especially near the river bank. In the second step, the rigid block of excavated/eroded soil is moved horizontally 2 m to the left using displacement boundary condition.

#### 3.2 Soil parameters

Table 1 shows the geotechnical parameters used in this study. The crust has an average undrained shear strength of 60 kPa, and a modulus of elasticity of 10 MPa (=167s<sub>u</sub>). The soil in the base layer is assumed to be very strong and s<sub>u</sub>=250 kPa and E<sub>u</sub>=100 MPa is used.

Table 1. Parameters for finite element modelling.

Crust	
Undrained modulus of elasticity, E <sub>u</sub> (kPa)	10,000
Undrained shear strength, s <sub>u</sub> (kPa)	60
Submerged unit weight of soil, γ <sub>2</sub> (kN/m <sup>3</sup> )	9.0
Poisson's ratio, ν <sub>u</sub>	0.495
Sensitive clay	
Undrained modulus of elasticity, E <sub>u</sub> (kPa)	7,500
Poisson's ratio, ν <sub>u</sub>	0.495
Peak undrained shear strength, s <sub>up</sub> (kPa)	50
Residual undrained shear strength, s <sub>ur</sub> (kPa)	10
Submerged unit weight of soil, γ <sub>2</sub> (kN/m <sup>3</sup> )	8.0
Plastic shear strain for 95% degradation of soil strength, γ <sup>p</sup> <sub>95</sub> (%)	33

Proper modeling of stress-strain behavior of sensitive clay layer is the key component of progressive failure analyses in sensitive clays. When sensitive clay is subjected to undrained loading it shows post-peak softening behavior. Various authors (e.g. Tavenas et al. 1983, Quinn 2009) showed that the post-peak softening behavior is related to post-peak displacement or plastic shear strain. The following exponential relationship of shear strength degradation as a function of plastic shear strain is used in the present study.

$$s_u = [1 + (S_t - 1) \exp(-3\delta/\delta_{95})] s_{ur} \quad (1)$$

where s<sub>u</sub> is the strain-softened undrained shear strength at δ; S<sub>t</sub> is sensitivity of the soil;  $^{TM} = ^{TM}_{total} - ^{TM}_p$  where  $^{TM}_p$  is the displacement required to attain the peak undrained shear strength (s<sub>up</sub>); and δ<sub>95</sub> is the value of δ at which the undrained shear strength of the soil is reduced by 95% of (s<sub>up</sub>-s<sub>ur</sub>). Equation 1 is a modified form of strength degradation equation proposed by Einav and Randolph (2005) and was used by the authors (Dey et al. 2012) to model submarine landslides. If the thickness of shear band (t) is known, the corresponding plastic shear strain (γ<sup>p</sup>) can be calculated as, γ<sup>p</sup>=δ/t assuming simple shear condition. Therefore, Eq.1 in terms of γ<sup>p</sup> can be written as

$$s_u = [1 + (S_t - 1) \exp(-3\gamma^p/\gamma^p_{95})] s_{ur} \quad (2)$$

where γ<sup>p</sup><sub>95</sub> is the value of γ<sup>p</sup> at 95% strength reduction (i.e. γ<sup>p</sup><sub>95</sub>=δ<sub>95</sub>/t). Note that, it is very difficult to determine the thickness of the shear band in the field. Similar to some previous studies (e.g. Quinn 2009) t=0.375 m is used which is same as the mesh height used in the present FE analysis. In ABAQUS the degradation of shear strength of sensitive clay is varied as a function of plastic strain. The parameters used to

model the sensitive clay using Eq. 2 are also shown in Table 1. These parameters are estimated based on the laboratory tests conducted on sensitive clays (e.g. Tavenas et al., 1983) and the interpretation of test data and constitutive model development by other researchers (e.g. Bernander 2000, Leroueil 2001, Locat et al. 2008, Quinn 2009, Locat et al. 2011).

#### 4. FINITE ELEMENT RESULTS

##### 4.1 Propagation of shear band

Figure 2 shows the variation of equivalent plastic shear strain for three cases. In Cases-I & II the shear band initially propagates horizontally and then curved upward resulting in global failure. The failed soil mass follows the excavated/eroded soil block. Figures 2(a) & 2(b) show the equivalent plastic shear strain when the plastic shear strain in the entire failure plane is greater than  $\gamma_{95}^p$ . Global failure does not occur in Case-III (Fig. 2c). There is an approximately 1.4 m gap between the vertical face of the block and soil mass at the right. The shear band propagates horizontally and finally ended at certain length. Figure 2(c) also shows the plastic shear strain when the shear band propagation is ended. Whether the shear

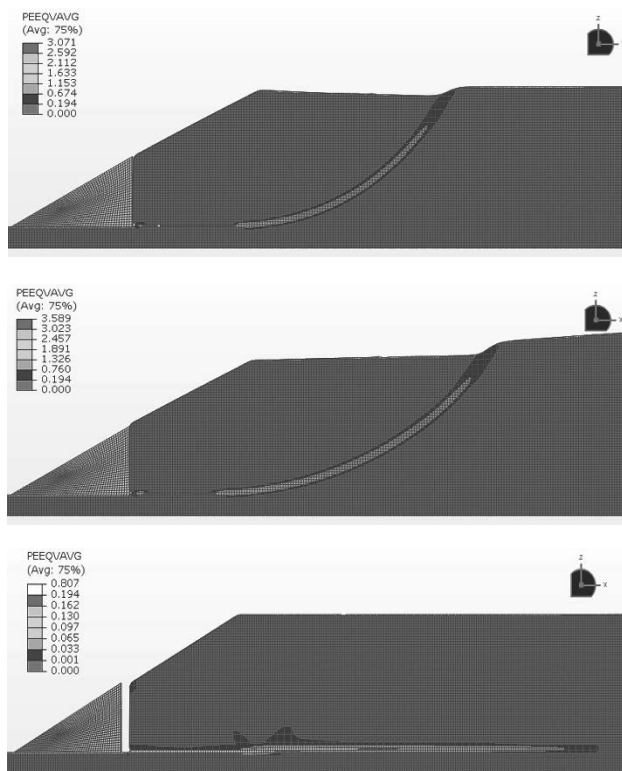

Figure 2. Developed equivalent plastic strain in the softening layer in case I, II and III respectively

band will propagate upward and cause the global failure or not, depends on the shear strength of the upper soil layer and mobilized shear strength along the shear band. For the soil properties and geometry used in the present study the failure pattern is almost same for Cases-I and II. However, the released energy from the excavated/eroded soil block is not sufficient to move the shear band upward in Case-III to cause the failure of the slope.

The equivalent plastic shear strain, denoted by the symbol PEEQVAVG in Fig. 2, is related to  $\gamma^p$  as  $PEEQVAVG = \gamma^p / \epsilon_{95}^p$ . According to Eq. (2), when  $\gamma^p \epsilon_{95}^p (=33\%)$ , that means  $PEEQVAVG=0.194$ , the undrained shear strength is less than

12 kPa ( $=50 \cdot 0.95(50-10)$ ). Figure 2(c) shows that the equivalent plastic shear strain greater than 0.194 is developed in the shear band only near the vertical face of excavated/eroded block in Case-III. However, the equivalent plastic shear strain greater than 0.194 is developed in the entire length of the failure plane in Case-I & Case-II. Therefore, the failure of the slope is occurred in both cases at residual shear strength on the failure plane as large strain is developed.

##### 4.2 Shear stress and mobilized shear strength

The Case-III is considered for further examination of the development of shear stress and mobilized shear strength along the potential failure plane. Figure 3 shows the variation of shear stress along the failure plane with movement of excavated/eroded block. Shear stress for four displacements (115 mm, 245 mm, 380 mm and 500 mm) are shown. In order to explain the process, consider the shear stress on the potential failure plane for the block displacement of 115 mm. The maximum shear stress (50 kPa) is developed at 12.5 m from the vertical face of the cut. The shear stress between 0 to 12.5 m is less than 50 kPa (i.e.  $s_{up}$ ) and greater than 10 kPa (i.e.  $s_{ur}$ ). That means, 0-12.5 m of the shear band represents the post-peak softening zone where the reduction of shear strength is occurred because of plastic strain as Eq. 2, and the mobilized shear strength is in between the peak and residual shear strength of the soil. In the right side of the peak (i.e. distance greater than 12.5 m) the shear stress is again reduced with distance. For this displacement of the block (115 mm), the shear stress in the

Figure 3. Shear stress along the potential failure plane

potential failure plane at a distance greater than 12.5 m is not increased to the peak, and therefore it represents the pre-peak behavior. At a very large distance, the shear stress is reduced to zero in Case-III as the ground surface is horizontal. The pattern of shear stress development for any other displacement of the block is similar as shown in Fig. 3. The location of the peak shear stress shifts to the right with increase in block displacement; that means a greater length of the potential failure plane is in post-peak stress-strain condition. For example, for 500 mm block movement the peak is occurred at 45.5 m and therefore 0-45.5 m is in post-peak condition with approximately 30 m in residual shear strength level. This process will be continued until the shear band propagation is ended for stable slopes as in Case-III. However, if the failure is occurred, as in Case-I and II, the large plastic shear strain will reduce the shear

strength of soil in the entire failure plane to the residual shear strength and global failure will occur.

Figure 4 shows the variation of shear stress at 4 different locations A, B, C and D (Fig. 1) which are located from the vertical face of the excavated/eroded block at horizontal distance of 3 m, 12.5 m, 25 m and 35 m, respectively. Consider the soil element B at 12.5 m distance. The shear stress in this element is increasing with movement of the excavated/eroded soil block. When the block is displaced by an amount of 115 mm, the shear stress in this element is reached to the peak shear strength of the soil (50 kPa). However, at this displacement of the block, the element A is almost at the residual shear strength. On the other hand, the elements C and D are still in the pre-peak state. That means the shear stress is gradually transferred to the soil elements in the right with displacement of the excavated/eroded soil block. For the soil element under the slope of the river bank there is an initial shear stress. With movement of the block the shear stress is increased from that initial value. However, the initial shear stress is less in the elements far from the river bank. Similar variation in shear stress and mobilized shear strength are obtained for Case-I and II.

Figure 4. Variation of shear stress at four different locations from the cut

## 5. CONCLUSION

This paper presents a new numerical approach to model the initiation and propagation of shear band in upward progressive failure as encountered near the river banks. Toe erosion is considered as the triggering factor. Coupled Eulerian-Lagrangian (CEL) approach currently available in ABAQUS FE software is used for numerical analysis. Nonlinear strain softening behavior of sensitive clay is incorporated in this large deformation finite element analysis. Three cases are analyzed in this study. In Cases I and II global failure is occurred. However, in Case-III, although global failure is not occurred, the shear band propagation reduced the shear strength in the potential failure plane significantly over a large distance and the slope might be marginally stable for further loading.

# Quantitative vulnerability estimation for individual landslides

## Estimation quantitative de la vulnérabilité aux glissements de terrain

Du J., Yin K.

China University of Geosciences (Wuhan), China

Nadim F., Lacasse S.

International Centre for Geohazards / Norwegian Geotechnical Institute (NGI), Norway

**ABSTRACT:** Vulnerability has not been systematically considered for landslides until recently, but is a fundamental component in the evaluation of risk. Vulnerability depends on the landslide intensity, the characteristics of the elements at risk, and the impact of landslide. A quantitative model is proposed to estimate the vulnerability of the exposed structures and individuals. The model accounts for landslide intensity, different classes of vulnerable elements and the impact of both slow and rapid moving slides.

**RÉSUMÉ :** La vulnérabilité est un facteur important du risque associé aux glissements et n'a pas été considérée jusqu'à tout récemment. Elle dépend de l'intensité et de l'impact du glissement et des propriétés des éléments exposés. L'article propose un modèle calculant la vulnérabilité de structures et d'individus. Ses paramètres caractérisent l'intensité du glissement, tiennent compte de différentes classes de vulnérabilité et distinguent l'impact de glissements évoluant lentement et rapidement.

**KEYWORDS:** Landslide, Quantitative vulnerability evaluation, Intensity, Susceptibility

## 1 INTRODUCTION

The ISSMGE glossary of risk assessment terms defines vulnerability as the degree of loss to an element within the area affected by the landslide hazard. It is expressed on a scale of 0 (no loss) to 1 (total loss). In contrast to flooding and earthquakes, it is not straightforward to define or assess, the vulnerability to landslides, due to the complexity and range of the landslide process (Leroi 1996). However vulnerability can influence the losses to a greater degree than the hazard (Einstein 1988; Alexander 2004). Despite this, it is an economic and political necessity to quantify vulnerability (Varnes 1984; Alexander 1984).

Two different perspectives exist for the vulnerability estimation: that based on the natural sciences and that based on the social sciences (Crozier 2004). Most often, the assessments of landslide risk are based on the natural science approaches. Some apply damage matrices (Leone 1996) based on qualitative (Cardinali 2002) and quantitative approaches (Fell, 1994). Conceptual frameworks for quantitative vulnerability estimation have been presented (Düzgün and Lacasse 2005, Uzielli *et al* 2008).

## 2 PROPOSED MODEL

Following Uzielli *et al* (2008) and Li (2010), the proposed model defines vulnerability as a function of landslide intensity and susceptibility of element at risk. The parameters are established on the basis of the landslide impact mechanism and categories of vulnerable elements. The proposed vulnerability model is defined by Eq. 1 and represented graphically in Fig. 1:

$$\begin{aligned} \text{For } I \leq 1-S & \quad V = \frac{1}{2}[I/(1-S)]^2 \\ \text{For } I > 1-S & \quad V = 1 - \frac{1}{2}[(1-I)/S]^2 \end{aligned} \quad (1)$$

$V \in [0, 1]$  is the vulnerability of elements exposed to the threat. For structures, 1 means that the structure is completely destroyed, while values less than one represent the degree of damage and 0 describing no damage. For individuals, 1 means loss of life, while a value  $< 1$  is the probability of loss of life.  $I \in [0, 1]$  is the intensity of landslide. An intensity of 1 means that the landslide has the potential of destroying all elements in its path.

Fig. 1 Vulnerability ( $V$ ) from susceptibility ( $S$ ) and landslide intensity ( $I$ ).

$S \in [0, 1]$  is the element susceptibility:  $S=0$  means that the vulnerable element has high inherent resistance under impact. The terms  $V$ ,  $I$  and  $S$  are non-dimensional and the values of 1 and 0 indicate the highest and lowest boundaries for the three parameters. To account for the landslide impact in the vulnerability estimation, two stages of deformation are considered: 1) a slow deformation stage and 2) the failure (rapid movement) stage.

## 3 LANDSLIDE INTENSITY

The definition of vulnerability requires information on landslide intensity (Guzzetti *et al* 1996), which should include information on the landslide severity degree and spatial dimensions.

### 3.1 Slow deformation stage

Under slow deformation, cracks and tilting may occur in structures located on the landslide, due to displacement and velocity of the ground surface and foundation substrata. The intensity parameters include landslide velocity and local deformation,

which describe the severity degree, and landslide depth, which reflects the spatial dimensions. The model is defined as:

$$I_{def} = 1 - (1 - I_{d-def})(1 - I_{d-vel})(1 - I_{d-dep}) \quad (2)$$

where  $I_{d-def}$ ,  $I_{d-vel}$  and  $I_{d-dep}$  are the parameters for deformation, velocity and landslide depth at the location of the structure. The deformations include settlement, horizontal movement and inclination (Bell 1978; Peng 1992; Zheng 2007). A basic relationship (Eq. 3) seems to provide a good approximation:

$$W_s = aW_g + bW_s \quad (3)$$

where  $W_s$  and  $W_g$  are the deformations of structure and ground,  $a$  is the slope and  $b$  is the intercept. Table 1 gives the range of  $a$  and  $b$  vs movement and structure types (Peng 1992; Zheng 2007). The deformation intensity depends on the ratio of deformation to allowable threshold value as shown in Table 2.

Table 1.  $a$  and  $b$  as function of ground deformation and structure type

Structure	Brick masonry, concrete structures		Reinforced (RC) concrete structures	
	$a$	$b$	$a$	$b$
Settlement (mm)	0.87-0.99	0.50-1.27	0.96-1.03	1.19-3.57
Tension (mm/m)	0.74-0.89	—	0.68-0.71	—
Compression (mm/m)	0.28-0.32	—	0.24-0.27	—
Inclination (mm/m)	0.99-1.06	0.80-0.90	0.69-0.97	0.03-0.2

Table 2. Proposed value of intensity parameters for deformation

Ratio of deformation to allowable threshold	$I_{d-def}$
<0.2	0.1
0.2-0.4	0.2
0.4-0.6	0.4
0.6-0.8	0.6
0.8-1.0	0.8
1.0-1.2	0.9
≥1.2	1.0

According to the landslide movement scale and response of structures (Cruden and Varnes 1996), the intensity of the landslide velocity can be obtained by the model described in Eq. 4 (Li 2010).  $V$  is the velocity of landslide (mm/s).

$$\begin{aligned} \text{For } v \leq 5 \times 10^{-7} & \quad I_{d-vel} = 0 \\ \text{For } 5 \times 10^{-7} < v \leq 5 \times 10^{-1} & \quad I_{d-vel} = 1/36[\log_{10} v + 6.30]^2 \\ \text{For } v \geq 5 \times 10^{-1} & \quad I_{d-vel} = 1 \end{aligned} \quad (4)$$

For structures on a moving landslide, the degree of damage depends mainly on the relative depth of the structure foundation to the sliding surface. Ragozin (2000) quantified the vulnerability of structures as a function of the foundation depth  $h$  (m) depending on the depth of predicted landslide  $d$  (m). The model described by Eq. 5 is proposed used.

$$\begin{aligned} \text{For } d/h < 0.8 & \quad I_{d-dep} = (1.25 \cdot d/h)^{1/3} \\ \text{For } 0.8 < d/h \leq 1.2 & \quad I_{d-dep} = 1 \\ \text{For } d/h > 1.2 & \quad I_{d-dep} = 1.44 \cdot (d/h)^{-2} \end{aligned} \quad (5)$$

### 3.2 Failure stage

#### 3.2.1 Landslide intensity for structures

The structures located within the release zone of a rapidly moving landslide are completely destroyed and have a vulnerability of 1.0. For the structures within the run-out distance, the impact mechanisms can be divided into two main categories: burial and impact pressure. For structures, the intensity of the landslide is defined as a function of its depth and impact pressure, where  $I_{pre}$  and  $I_{f-dep}$  are impact pressure and landslide depth parameters:

$$I_{fai-s} = 1 - (1 - I_{pre})(1 - I_{f-dep}) \quad (6)$$

#### (1) Impact pressure

After the landslide fails, the horizontal impact pressure is the main cause of damage to structures (Glade 2004; Ulusay 2007). Petrazzuoli (2004) analyzed the collapse limit load of regular and irregular RC structures to horizontal pressure with the strong beams and weak columns structural models. The proposed vulnerability model uses the average value of each typology to estimate the horizontal pressure limit  $P$  vs the number of

stories  $n$ , in which the values of coefficient  $\alpha$  and  $\beta$  for each structure type are listed in Table 3.

$$P = \alpha n(n) + \beta \quad (7)$$

Table 3. Coefficients  $\alpha$  and  $\beta$  in Eq. 7 for different structure types.

Structure	Strongly aseismic	Weakly aseismic	Strongly non-aseismic	Weakly non-aseismic
Regular structure				
A	-4.384	-2.717	-2.157	-1.276
B	19.125	13.164	10.568	7.693
Irregular structure				
A	-3.779	-2.467	-1.821	-1.343
B	14.553	10.288	8.068	6.066

The ratio of landslide impact pressure on the building to horizontal pressure limit is defined as the intensity parameter  $I_{pre}$  (Table 4). The horizontal pressure limit of RC frame can be obtained according to Eq. 7, while the limit pressure of terracotta panels in Table 5 can be used for masonry structure.

Table 4. Proposed values of impact pressure intensity parameter.

Landslide impact pressure/Structure horizontal pressure limit	$I_{pre}$
<0.1	0.05
0.1-0.2	0.20
0.2-0.4	0.40
0.4-0.7	0.70
0.7-1.0	0.90
≥1.0	1.00

Table 5. Estimated resistances of buildings and elements (Spence 2004)

Building elements	Failure pressure(kPa)
Terracotta tile infill panel with openings	7.6-8.9
Terracotta tile infill panel without openings	5.5
Tuff infill panel (length 4 m, thickness 40 cm)	6.8-9
Tuff infill panel (length 4 m, thickness 60 cm)	10-13
Weak non-aseismic RC buildings (1 to 3 storeys)	4.5-8
Strong non-aseismic RC buildings (4 to 7 storeys)	5-9
Weak aseismic RC buildings (multi-storeys)	5-10
Strong aseismic RC buildings (multi-storeys)	6-14

#### (2) Landslide depth

As inferred from the structural damage, the intensity parameter for landslide depth should be defined as the ratio of landslide depth to height of structure. When landslide depth is equal to or greater than the structure, the structure loses completely lose its functionality. The proposed values of  $I_{f-dep}$  are found in Table 6.

Table 6. Proposed values of landslide depth intensity parameter

Ratio of landslide depth to height of structure	$I_{f-dep}$
<0.2	0.10
0.2-0.4	0.30
0.4-0.6	0.50
0.6-0.8	0.70
0.8-1.0	0.90
≥1.0	1.00

Depending on location, the persons within the affected area can be divided into two categories: indoors and outdoors. Landslide velocity, depth and width become the intensity parameters:

$$I_{fai-p} = 1 - (1 - I_{f-vel})(1 - I'_{f-dep})(1 - I_{wid}) \quad (8)$$

where  $I_{f-vel}$ ,  $I'_{f-dep}$  and  $I_{wid}$  are the parameters of landslide velocity, depth and width, respectively. A moving slide depth greater than knee-height makes it difficult to escape. Using 1.6 m and 0.482 (Swami 2006) as average height and leg ratio, a threshold value of 0.8m for critical landslide depth is obtained. The values of  $I'_{f-dep}$  in Table 7 are proposed:

For landslide width, five degrees are identified to allow for change in landslide activity conditions (Table 8). The landslide velocity scale defined by Eq. 9 is identical to that proposed by Li (2010). The value  $v$  is the velocity of the landslide (mm/s).

$$\begin{aligned} \text{For } v \leq 5 \times 10^{-1} & \quad I_{d-vel} = 0 \\ \text{For } 5 \times 10^{-1} < v \leq 5 \times 10^3 & \quad I_{d-vel} = 1/16[\log_{10} v + 0.3]^2 \\ \text{For } v \geq 5 \times 10^3 & \quad I_{d-vel} = 1 \end{aligned} \quad (9)$$

Table 7. Proposed values of landslide depth intensity parameter

Landslide depth (m)	$I'_{f-dep}$
<0.1	0.10
0.1-0.3	0.30
0.3-0.6	0.70
0.6-0.8	0.90
≥0.8	1.00

Table 8. Proposed values of landslide width intensity parameter

Landslide width (m)	$I_{wid}$
< 50	0.10
50-200	0.30
200-400	0.50
400-700	0.80
≥ 700	1.00

## 4 SUSCEPTIBILITY

### 4.1 Susceptibility of structures

The capacity of a structure to withstand the landslide hazard depends on the morphological characteristics and utilization conditions (Amatruda 2004; Coburn 2002). Four parameters were considered, including structure type  $s_{str}$ , maintenance state  $s_{mai}$ , ratio of service years to design service life  $s_{ser}$  and the difference in the directionality of landslide movement and the principal longitudinal direction of the structure  $s_{dir}$ , with the model given in Eq. 10. Together, these parameters describe the susceptibility of the structures to be damaged by a landslide (Table 9 for  $s_{str}$ , Table 10 for  $s_{mai}$ , Table 11 for  $s_{ser}$ , Table 12 for  $s_{dir}$ ).

$$S_s = 1 - (1 - s_{str})(1 - s_{mai})(1 - s_{ser})(1 - s_{dir}) \quad (10)$$

Table 9 Structure susceptibility parameter (Heinimann 1999)

Structural typology	Resistance	$S_{str}$
Lightest, simple structures	Very high	1.00
Light structures	High	0.90
Rock masonry and concrete	Medium	0.70
Brick masonry, concrete structures	Low	0.50
Reinforced concrete structures	Very low	0.30
Reinforced structures	Extremely low	0.10

Table 10 Proposed values of maintenance state susceptibility parameter

State of maintenance	$S_{mai}$
Extremely good	0.00
Good	0.05
Slight deformation	0.25
Medium deformation	0.50
Serious deformation	0.75
Extremely Serious deformation	1.00

The damage would be most serious when the angle between the two directions is 0° and be lightest when the angle gets close to 45° (Table 12).

Table 11 Proposed values of service year susceptibility parameter

Ratio of service year to design service life	$S_{ser}$
≤ 0.1	0.05
0.1 - 0.4	0.10

Table 14. Proposed values of “generic” early warning system susceptibility parameter

Completeness level	$S_{war}$	Description of risk reduction or risk avoidance measure
None	1.0	Investigate the geological background and deformation of the landslide, without any monitoring measures.
Simple	0.6-1.0	Simple manual monitoring measurements with low precision and measurements at long interval (one month), e.g. manual measurement of extension velocity of crack and subsidence velocity of head of landslide.
Moderate	0.2-0.6	Accurate monitoring equipment with moderate precision, long interval readings (one month) and low distribution density of monitoring points; monitoring involves only geological parameters; investigation of population exposed to landslide risk; simple emergency plan includes warning transmission and evacuation paths.
Comprehensive	0.0-0.2	Accurate monitoring equipment with high precision and close interval readings (one day/one week); density of monitoring points high enough to sense deformation of entire landslide; monitoring involves geophysical, atmospheric, hydrodynamic and soil quantities; decision procedures in place based on experience with time prediction, triggering threshold and evacuation successes/failures with landslide; overview of population and public facilities exposed; overall emergency plan includes warning transmission, evacuation paths, logistics, medical assistance and so on.

0.4 - 0.6	0.30
0.6 - 0.8	0.50
0.8 - 1.0	0.70
1.0 - 1.2	0.80
> 1.2	1.00

Table 12. Values of directionality difference susceptibility parameter.

Directionality of landslide movement (°)	$S_{dir}$
0-5	1.0-0.6
5-15	0.6-0.4
15-30	0.4-0.2
30-45	0.2-0.0

### 4.2 Human susceptibility

The susceptibility of persons to be hurt or killed by the landslide depends strongly on the cognitive and reaction capacity upon the occurrence of a landslide and the protection measures at the site, e.g. escape routes or early warning system. The following model was proposed to describe the landslide susceptibility for persons:

$$S_p = 1 - (1 - s_{hel})(1 - s_{age})(1 - s_{war}) \quad (11)$$

where  $s_{hel}$ ,  $s_{age}$  and  $s_{war}$  are the susceptibility parameters, health condition, age and existence of a warning system, respectively.

A person's health condition, i.e. evacuation capacity, can be divided into three classes: 1) healthy, 2) weak physical condition, e.g. chronic disease slowing down movement, and 3) complete incapacitation with inability to evacuate. The susceptibility parameter values listed in Table 13 are proposed.

On the basis of fatality rate-age distribution data from earthquakes, Li (2010) proposed a quadratic polynomial function (Eq. 12) in terms of age  $a$ , which was adopted in this paper:

$$s_{age} = 0.95 - 0.00486 [\text{INT}(a/5) - 5]^2 \quad (12)$$

where INT() is the downward rounded integer function.

Table 13. Proposed values of health condition susceptibility parameter.

Health condition	$S_{hel}$
Healthy	0-0.1
Weak physical condition	0.1-0.8
Complete incapacitation	0.8-1.0

“Early warning” refers to all the measures that can be taken before the occurrence of a catastrophic event reducing the risk or contributing to avoid it (Table 14). Completeness level in the table refers to the efficiency of early warning or other mitigation measures in place to reduce or avoid risk.

## 5 VULNERABILITY OF PERSONS IN STRUCTURES

When a landslide occurs, the vulnerability of persons in the structures is directly correlated with the structure damage.

To estimate the casualty level in a building, one needs to assess the proportion of people trapped in the debris of a collapsed building and the casualty level for different degrees of damage.

When buildings collapse, not all the occupants are trapped inside. The number of people trapped in a collapsed building depends on the size and type of building, the collapse itself, the time of collapse and the escape options during and after the col-

lapse. Masonry and reinforced concrete, have different collapse mechanisms and rubble characteristics. The total collapse of masonry buildings provides smaller cavities than the collapse of frame structures. Li (2010) proposed an exponential description of the vulnerability of persons inside structures. Coburn (2002) estimated the average percentage of occupants trapped in a collapsed building to range between 30% and 70%, and estimated the injured proportion of occupants at collapse (Table 15).

The four levels of casualty, i.e. fatalities, seriously injured, moderately injured and lightly injured or uninjured, were denoted by vulnerability values of 1, 0.8, 0.5 and 0.2. The vulnerability of persons ( $V_p$ ) in different structures is listed in Table 16 ( $V_s = 1$  or collapse). Equation 13 quantifies the vulnerability of persons  $V_p$  (index  $\alpha$  for different structures is listed in Table 16).

$$V_p = 0.001 \exp(\alpha V_s) \quad (13)$$

Table 15. Casualty distribution, collapsed buildings (Coburn 2002)

Class	Fatalities	Seriously injured	Moderately injured	Lightly injured or uninjured
Masonry	17.5	10	17.5	55
RC frame	21	0.8	9.2	70
RC shear wall	10	0.7	9.3	80
Steel	16	0.6	9.4	75
Timber	0.6	0.2	10.2	89

Table 16. Vulnerability of persons and value of index  $\alpha$

Structure type	Masonry	RC frame	Steel	RC shear wall	Timber
$V_p$ (when $V_s = 1$ )	0.45	0.40	0.36	0.31	0.24
$\alpha$	6.1	6	5.9	5.75	5.5

## 6 CONCLUSIONS

A model for the quantitative estimate of landslide vulnerability is proposed with two parameters: landslide intensity and susceptibility of the elements at risk. A reliable estimate of landslide intensity should consider the relationship between landslide severity and spatial dimensions. For the slow-moving landslides, the quantitative relationships for three categories of ground deformation and structure response are considered in the assessment of the landslide intensity. Based on empirical data, a function describing the ratio of landslide depth to foundation depth can be used to estimate the effect of geometric intensity.

In the landslide failing stage, intensity models were established for stationary and non-stationary vulnerable elements. Impact pressure and landslide depth were included in the vulnerability assessment of structures. For persons in open space, the parameters include landslide velocity, depth and width.

Functions of horizontal limit pressure versus the number of storeys of different structures were proposed to quantify the landslide impact intensity parameter of the moving mass. For the human susceptibility, generic mitigation measures were proposed to include a component of risk prevention and emergency awareness. Further, collapse mechanisms and construction characteristics of different construction types, the vulnerability functions for persons in different structure categories were proposed.

The model has limitations and needs further research. Some of the subjective and empirical parameters in the model should be calibrated and gradually documented with the addition of objective data, experience, observations and expert judgment.

## 7 ACKNOWLEDGEMENTS

This research was funded by The National Natural Sciences Foundation of China (40872176). The work described was done while the first author was a guest researcher at the International Centre for Geohazards (ICG) at NGI. The first author thanks the China Scholarship Council, NGI and the Research Council of Norway for funding her stay at ICG/NGI. The authors thank also Prof. O. Hungr (University of British Columbia), who kindly provided a beta version of DAN3D to NGI, and Drs. J.M. Cepeda and D. Issler of NGI for their help and guidance.

# A site specific early warning system for rainfall induced landslides

Utilisation d'un site spécifique pour l'élaboration d'un système d'alerte rapide pour les instabilités de pente induites par les pluies.

**ABSTRACT:** An early warning system (EWS) to warn users of imminent landsliding caused by rainfall has been developed. The EWS is deterministic, based on a pre-determined failure mechanism present at a specific site. A prototype of the EWS was developed for a roadway embankment located in Silverdale, New Zealand. Prolonged rainfall caused a landslide at the site in 2008. Soil debris from this landslide event almost obstructed a major highway, which could have been potentially dangerous to motorists as well as causing major delays to the Auckland roading network. Volumetric water content sensors were installed at various depths and locations along the same cross section of the site. A 2D finite element model was used to replicate the response of the sensors to rainfall, using monitored rainfall events as an influx in the model. Next, a limit equilibrium analysis was used to obtain the factor of safety against slope failure for each time step in the finite element model. An artificial neural network was then trained to predict this factor of safety using the sensor readings as inputs. Thus, the factor of safety of the slope can be predicted in real time. This predicted factor of safety forms the basis of the EWS.

**RÉSUMÉ :** Un système d'alerte précoce (SAP) pour avertir les utilisateurs de glissements de terrain provoqués par des pluies imminentes a été développé. Le SAP est déterministe, basée sur les mécanismes de rupture pré-déterminés présents sur un site spécifique. Un prototype du SAP a été développé pour un remblai de la chaussée située à Silverdale en Nouvelle-Zélande. Des pluies prolongées ont causé un glissement de terrain sur le site en 2008. Les coulées de sol engendrées par ce glissement de terrain ont presque obstrué une route importante, ce qui aurait pu être potentiellement dangereux pour les automobilistes ainsi qu'être à l'origine de retards importants sur le réseau routiers d'Auckland. Des capteurs volumétriques de teneur en eau ont été installés à des profondeurs différentes et à des emplacements variés le long de la section transversale du site. Un modèle par éléments finis 2D a été utilisé pour reproduire la réponse des capteurs aux précipitations, en utilisant les données expérimentales de comme données d'entrée. Ensuite, une analyse d'équilibre limite a été utilisée pour obtenir le facteur de sécurité pour la stabilité de la pente pour chaque pas de temps. Un réseau neuronal artificiel a ensuite été formé pour prédire ce facteur de sécurité en utilisant les relevés du capteur comme modèle. Ainsi, le facteur de sécurité de la pente peut être prédite en temps réel. Ce facteur de sécurité prévu est à la base du SAP.

**KEYWORDS:** rainfall, landslide, artificial neural network, early warning system

## 1 INTRODUCTION

As a means to mitigate the risk of rainfall induced landslides which cause millions of dollars' worth of damage each year in New Zealand (NIWA & GNS Science, 2010), an early warning system (EWS) has been developed. A prototype of this EWS was installed at a site in Silverdale, Northland, New Zealand. Much of the damage which incurs from rainfall induced landslides occurs in this region of New Zealand (NIWA & GNS Science, 2009).

EWSs for rainfall induced landslides started as empirical relationships which related the number of landslides in a given region to the intensity and duration of rainfall events. Examples can be seen in Dhakal & Sidle (2004), Keefer et al (1987) and Caine (1980). As technologies have developed, focus on EWSs has become more site specific. Current EWSs rely on measuring parameters such as pore pressure and displacement at a given site. Such EWSs are based on issuing an alarm when a predetermined level of these parameters has been reached (Chae & Kim, 2012; Intrieri et al., 2012). The EWS developed in this research was required to return to the user a number related to the possibility of failure, and also a timeframe for failure to occur. To achieve this, volumetric water content (VWC) sensors were installed at a variety of depths at the toe, mid-point and top of the slope. A tipping bucket rain gauge was used to monitor the intensity and duration of rainfall events. The fluctuations in VWC recorded by the sensors were replicated in a finite

element model (FEM), using the recorded rainfall events as an influx into the slope. Next, a limit equilibrium analysis was used to determine the factor of safety (FOS) at each time step in the FEM. Thus, a database was created which contained values of the VWC as measured by the sensors at the site, and the corresponding FOS. This database was then used to train an artificial neural network (ANN). The ANN can thus predict the FOS of the slope in real time, using sensor readings as an input. The ANN can also predict the future FOS of the slope, using rainfall forecasts for the site as an input. The trend of the predicted FOS using the sensor data, and the future FOS obtained according to the rainfall forecast, form the basis of the EWS. Based on this information the user of the EWS can take the required action; in this case, lowering speed limits and putting detours in place.

### 1.1 Site and Soil Description

The site consists of a roadway embankment created from a cut operation during the construction of State Highway One, which runs parallel to the toe of the embankment. State Highway One is a major arterial which services Auckland city. The slope angle of the embankment is approximately 15°. A concrete dish drain is located on a bench at mid-height of the slope. The site is grassed, with some low height trees present. Debris from a landslide which occurred at the site in 2008 following prolonged rainfall almost crossed into the traffic lanes of State

Highway One, which could be potentially dangerous to motorists and cause significant disruption to the Auckland road network.

The soil at the site consists of weathered soil from the Northland Allochthon formation, which is renowned for its montmorillonite content (Power, 2005). This formation is susceptible to landsliding due to seasonal pore-pressure changes (Lentfer, 2007; O'Sullivan, 2009). The site consists of 3 strata; the underlying parent rock, a transition zone and a completely weathered residual soil. The transition zone consists of unweathered rock fragments in a silty clayey matrix. This transition zone has many slickensided shear surfaces present, and is thought to be one of the underlying factors that give rise to the susceptibility of the formation to landslides. The residual soil is a silty clay, susceptible to shrink swell movement. In general, sites in the Northland Allochthon have high ground water tables even in dry periods (O'Sullivan, 2009).

For a more detailed description of the site and soil properties, the reader is referred to Harris et al. (2012).

## 2 METHODOLOGY

A total of 13 VWC sensors were installed along the same cross section of the slope; at the toe, mid-height and crest. The sensors consisted of MP406s and ECH<sub>2</sub>O probes (ICT International Pty Ltd, 2012), which were installed at approximately 0.25m depth intervals. A tipping bucket rain-gauge was used to record rainfall events. Recordings were made via a data logger at an hourly interval.

*SEEP/W* (GEO-SLOPE International Ltd, 2009a) was used for the FEM. The hourly rainfall captured at the site was input as an influx into the slope. A general evaporation pattern was applied to the model as a negative influx between rainfall events. This generalised evaporation pattern was based on a trial and error method to get the best agreement between the FEM results and the field monitoring results. The level of evaporation applied following a rainfall event was determined by the cumulative rainfall amount of the event. This FEM was coupled with the limit equilibrium analysis (LEA) program *SLOPE/W* (GEO-SLOPE International Ltd, 2009b). Thus at each hourly time step in the FEM, the FOS was obtained.

The soil properties used in these models are given in Table 1. The soil water characteristic curve was described using the Van Genuchten (1980) method, the parameters of which were obtained using the pressure plate apparatus. The permeability was determined using the falling head method. A variety of triaxial tests, including constant shear drained tests, were used to determine the shear strength parameters. The shear strength values used for the top soil layer were reasonably high to force the slip surface obtained in the LEA to a reasonable depth.  $\phi^b$  represents the angle of shearing resistance due to matric suctions, as described by Fredlund et al. (1978)

Table 1. Soil parameters used in the models.

	Van Genuchten (1980) Parameter					Shear Strength		
	k	a	n	m	$\theta_r$	$\phi^a$	$\phi^b$	c
	m/hr $10^{-3}$	kPa <sup>-1</sup>			%	°	°	kPa
Top Soil	36	608	3.27	0.69	38.5	40	20	10
Residual Soil	0.36	608	3.27	0.69	38.5	36	20	0
Transition Zone	0.036	297	5.23	0.81	37.2	21	20	3
Underlying Rock	0.0036	29	5.23	0.81	37.2	35	20	5

The ANN was developed using the software *Matlab* (The MathWorks Inc, 2012). For more information regarding ANNs and their use in geotechnical engineering, the reader is referred to Khanlari et al. (2012). The ANN was trained to predict the LEA-obtained FOS using the sensor readings from the field monitoring as inputs. The ANN was developed as a closed-loop

recurrent dynamic network, where the FOS predicted by the ANN for the previous time-step was used as an input for the prediction of the FOS for the current time-step. The Levenberg-Marquardt method (Mathworks, 2010) was used to optimize the ANN, which had 10 hidden layers. The accuracy of the ANN improved when cumulative rainfall amounts were included as inputs into the ANN. Thus, cumulative rainfall amounts ranging from 2 to 200 hours were included as inputs into the ANN.

A second ANN was developed which predicts the LEA obtained FOS based solely on rainfall data. Thus the future FOS could be predicted at the site using rainfall forecasts obtained from the Meteorological Service of New Zealand (2012).

## 3 RESULTS

A reasonable agreement was obtained between the field measured and FEM obtained VWC. The permeability of the top soil layer had to be increased in the FEM in comparison to the underlying soil layers to obtain the required infiltration amount. Presumably this reflects the discontinuities such as surface cracks and vegetation of the soil. In some locations the agreement was very good, in others the agreement quite poor. The reason for this is thought to be due to natural variability within the soil, as described by Dai et al. (2002).

To confirm this modelling process, the rainfall record obtained from the Meteorological Service of New Zealand (2012) leading up to the 2008 landslide was input into the models. As a FOS of just above unity was obtained at approximately the same time as the landslide occurred, it is assumed that the models used in the development of this EWS were reasonably accurate.

Because few extreme rainfall events occurred during the field monitoring period, artificial rainfall events were input into the rainfall record. Such artificial rainfall events can be seen in the upper graph of Figure 1, at an elapsed time of 1500 hours and 2200 hours. The comparison between the FOS obtained from the LEA, that obtained from the ANN using sensor data, and that obtained from the ANN using just rainfall data is shown in the lower graph of Figure 1. As observed, at each significant rainfall event there is a large decrease in the FOS. This FOS recovers rapidly following the rainfall event.

The ANNs are reasonably accurate at predicting the LEA obtained FOS. The mean squared error of the ANN using sensor was 0.41. Using just rainfall data, the mean squared error increased to 1.16. The FOS predicted by the ANNs is susceptible to large fluctuations, particularly during times of evaporation. This is seen at elapsed times of approximately 1600 hours and 2600 hours. Because these fluctuations occur during times of evaporation, they are not critical to the accuracy of the EWS; however they do indicate that some discrepancies occur due to the generalised evaporation pattern which was used. If a deterministic approach was used to measure evaporation, such as that described by Penman (1948), it is thought that such discrepancies will be minimised. The improvement in accuracy from the ANN which uses just rainfall data as an input, compared to the ANN which uses sensor data also, indicates that the use of the sensors provides an indication as to the actual amount of rainfall infiltration in the slope.

To provide an example of the EWS in use, the data corresponding to the point shown in Figure 1 was input into the EWS. The resulting plot is shown in Figure 2. Elapsed time = 0 corresponds to the point in time when the data was obtained from the site. The upper graph in Figure 2 shows the rainfall record obtained from the site (from an elapsed time of -24 to an elapsed time of 0). The rainfall is constant as it is obtained during an artificial rainfall event, as shown in Figure 1 (a). The rainfall record in Figure 2 from an elapsed time of 0 to and elapsed time of 5 hours is that obtained from the forecast.

The solid line in the lower graph of Figure 2 is the ANN – predicted FOS of the last 24 hours, using the sensor data as inputs. The dotted line is the predicted FOS over the next 5

hours, using the rainfall forecast data as an input. Because the ANN using the sensor data is more accurate than that using just rainfall data, this predicted FOS using rainfall forecasts loses

accuracy over time. Thus, the predicted future FOS using rainfall forecast data is set to equal the FOS predicted using sensor data each time the sensor data is downloaded.

Figure 1. (A) Rainfall events input into the FEM and (B) corresponding FOS obtained from LEA, the ANN using field measured data, and the ANN using only rainfall events. The black line shows a FOS of unity (i.e. when failure will occur).

Figure 2. Example of the EWS in use. Elapsed time = 0 corresponds to the point in time at which the data was downloaded from the site (shown in Figure 1). The upper graph (A) shows the rainfall recorded at the site, and the forecasted rainfall at the site. The lower graph (B) shows the predicted FOS using the field data, and the predicted future FOS using the rainfall forecast. A FOS of unity is shown by a black line.

#### 4 APPLICATION OF THE EWS

The use of the EWS is summarised as follows. During a heavy rainfall event the field data is downloaded from the site in real time via the internet. This field data is then uploaded into the EWS. The FOS of the previous 24 hours, using the field data, is then obtained using the ANN. Based on the rate of change of this predicted FOS, the time until the FOS will reach a FOS of unity is returned to the user.

Next, the rainfall forecast for the next 5 hours for the site is obtained from the Meteorological Service of New Zealand (2012) via the internet. This forecast can be freely obtained by the public. This forecast is based on the Weather Research and Forecasting model, using data obtained from automatic weather stations, weather radar facilities, upper air sites and marine observation stations (Bridges, 2011). The predicted FOS over the next 5 hours is obtained using this rainfall forecast as an input into the ANN. The starting FOS for this predicted FOS is the last FOS obtained using the actual sensor data. Because of the difficulty in verifying forecasts at a local scale (Hodson, 2009), both the predicted FOS according to this forecast, and the rate of change of the FOS obtained from the field monitoring data, are used to estimate when failure may occur.

If failure is predicted to occur within five hours, then a stage one warning is issued. This involves warning motorists to lower speed limits around the landslide site. If failure is to occur within one hour, then a stage two warning is issued. This puts a detour in place, so motorists avoid the site altogether. Two warnings were used because the detour route adds approximately 25 minutes to the journey. Thus this detour route is put in place as late as possible to avoid frustration with the EWS due to false alarms. Warning motorists to lower speeds around the possible landslide site in advance is intended provide a balance between minimising the cost should the landslide occur, and avoiding frustration at the delay to motorists. During periods of heavy rainfall, the EWS should be updated on an hourly basis.

#### 5 CONCLUSIONS

A site specific EWS for rainfall induced landslides has been developed. The EWS is based on the ability to predict the current FOS of the site using ANNs, rainfall forecast data and real time field measurements. The EWS proves to be useful at predicting when failure might occur, and also returns to the user a parameter related to the possibility of failure (the current FOS).

A FEM was used to replicate the field response of the site to rainfall events. This FEM was coupled with a LEA to predict the FOS at each time-step. The results of this modelling process were reasonably accurate, considering discrepancies caused by natural variation within the soil and the generalised evaporation pattern which was applied within the model.

The ANN which uses field measured data could predict the LEA obtained FOS with good accuracy; a mean squared error of 0.41 was obtained. To predict the future FOS, an ANN using just rainfall forecast data was developed. This ANN was less accurate, with a mean squared error of 1.16 obtained.

It is envisioned that the methodology used to develop this EWS can be replicated at a variety of sites as a means of risk reduction for rainfall induced landslides.

#### 6 ACKNOWLEDGEMENTS

The Authors would like to thank the Auckland Motorways Alliance, Babbage Consultants, Beca Consultants and Hiway Geotechnical for their assistance throughout the project.

# Characteristics of Ground Motion on Colluviums Slope Induced by Heavy Rainfall

## Caractéristiques du déplacement du sol sur la pente de colluvions induit par la pluie violente

Jeng C.J., Sue D.Z.  
Huafan University, Taiwan

**ABSTRACT:** In this study, a slope covered with various depths of colluvium soil and set up with monitoring system has been studied. The results from hundreds of settlement and displacement observation marks were taken into account. It was found that the maximum settlement and displacement were concentrated around the buildings of Hui-tsui, Zhian and Wu-Ming, and coincided with rainfall records for the area. The direction and distribution of displacement and surface cracks supports previous findings of a sliding block. The slope stability analysis for this study was carried out with the STABL program. A drainage system with additional stability measures was proposed to prevent an unstable slope caused by the rising up of the ground water table during rainfall. Finally, a curve showing the relationship between rainfall and slope stability is established and presented.

**RÉSUMÉ :** Dans cette étude, une pente couverte de colluvions de différentes profondeurs et équipée d'un système de surveillance a été étudiée, ayant recours aux remarques tirées des observations sur les affaissements et les déplacements de la pente. Nous avons découvert que les plus grands affaissements et déplacements de pente, coïncidant avec les précipitations dans la région, avaient lieu autour des bâtiments Hui-tsui, Zhian et Wu-Ming. La direction et la répartition des déplacements de pente ont confirmés nos recherches précédentes sur un bloc coulissant. Cette recherche a été faite avec le programme STABL. Un système d'évacuation des eaux avec des mesures de stabilité a été proposé pour protéger une pente instable contre les eaux souterraines qui montaient lors des averses. À la fin de cette étude, une courbe a été présentée pour expliciter la relation entre les précipitations et la stabilité de pente.

**KEYWORDS:** colluviums slope, ground monitoring, settlement and displacement, slope stability analysis, threshold value of rainfall.

### 1 INTRODUCTION

Rainstorms frequently trigger colluvium landslides. For example, in November 1993, more than 800 landslides were triggered by rainstorms on Lantau Island, Hong Kong (Dai & Lee 2002). In Taiwan, colluvium slope disasters related to rainfall are very common (Jeng et al, 2007; Jeng and Lin, 2011; Pan et al, 2008). The threshold values of typhoon disasters were studied extensively by Wang and Yeh(2011) and Hu and Liao (2010). This paper focuses on the effects of heavy rainfall on the colluvium slopes in northeastern Taiwan. The results from 295 points of settlement and displacement monitoring marks and their significance to ground motion were evaluated. Finally, a threshold value curve for typhoon rainfall is proposed.

### 2 BASIC INFORMATION OF THE FIELD CASE

The field case discussed in this research is the campus of Huafan University in northeastern Taiwan. The University was constructed on the slope. For risk management and research on slope stability, a monitoring system was set up and data was collected for over ten years. The monitoring system includes the inclinometer, building tilt measurement, tiltmeters, crack gauges, water level observation wells, settlement and displacement monitoring marks, rebar strain gauges, concrete strain gauges and rain gauges. According to the records obtained from the rain gauges from 2003 to 2010, the average annual rainfall is about 4000mm, most of which is attributed to torrential rainfall concentrated in the period of typhoon season. The maximum monthly rainfall record is in October 2010 with 1208mm.

#### 2.1 Geological Condition

The base stratum of the site consists of the Miocene Mushan Formation. On the ground surface is 10 to 20 meters of

colluvium comprised of a bottom layer of sandstone (SS) and thin alternating layers of sandstone and shale (SS-SH). The attitude of the bedrock is strike in the east-west direction with the dip-anchor 10° to 20° toward south.

#### 2.2 Ground Motion Monitoring Results

##### 2.2.1 Settlement and Displacement Monitoring

Since 2001, hundreds of settlement and displacement monitoring marks were set up and recorded every six months. Some additional marks were gradually included over the years. Data was recorded until January 2011, and after ten years of monitoring, a total of 295 marks were collected. The accuracy of the investigation was controlled to within 1/5000 by the plane triangulation method with GPS (TRIMBLE 4800) for six fixed station points. Four traverse points were then laid within the survey area and double-checked for accuracy to be within 1/10000. The coordinates and elevation of each observation mark were then surveyed based on those traverse points. The displacement and settlement values were obtained by comparing the coordinates and elevation results of each survey to the initial results from the first survey. The data marks were then divided into two categories for buildings, and for roads and land.

##### 2.2.2 Settlement and Displacement Distribution

Figure 1 shows the results of the settlement distribution. The settlement marks around buildings are shown in solid triangle and the settlement marks for roads and other land are shown in solid circles, while the heaving points are shown in hollow circles. The values of settlement or heaving are discriminated into five levels from 5 to 25mm and are represented by different size circles. As indicated in Fig. 1, the maximum annual settlement is more than 20mm, distributed around the Hui-tsui building(B1), Chih-an building(B2) and Wu-Ming

building(B3). Although these values did not reach a dangerous level per the general management criteria, for some areas, the cumulated settlements reached over 10cm in the 10 years data. Moreover, when comparing the settlement distribution in Fig. 1 to the distribution of thickness of filled land, in the greater thickness of the filled land areas such as the Sport Ground(B4), the Basketball Court(B5) and Asoka Square(B6), the settlement is apparent. It is speculated that these higher settlement areas have something to do with the thicker fill. On the other hand, for the few heaving points like the upper slope of the Asoka Square, it is the result of the surface concrete pavement heaving caused by extrusion of the slope slide, not the ground surface condition.

Fig. 1 The settlement distribution diagram

Figure 2 shows the displacement tracks of each observation mark on the plan map. The scale of displacement has been enlarged to 200 times to highlight its tendency. It is shown in Fig. 2 that the main displacement direction is downward to the slope in the southwest or south direction. Meanwhile, the larger displacement is distributed, same as the aforementioned settlement distribution, around the areas of Hui-tsui building, Chih-an building and Wu-ming building. However, the upper slope of the Asoka Square shows movement in the upward direction to the slope. This also can be attributed to the aforementioned heaving phenomenon caused by extrusion of the slope slide, such that an overturning condition occurred in that area. The cracks created in the crown can also confirm this situation. Additionally, the direction of movement for the Sport court is different from the upper slope Dormitory building. That is because they are departing into different sliding blocks.

### 2.3 Correlation WITH rainfall

According to the results of the aforementioned settlement and displacement distribution, the most critical areas are concentrated in the Hui-tsui building, Chih-an building and Wu-ming building. As expected, the most significant contributing factor is rainfall. The correlation between settlement, displacement and, rainfall for the Hui-tsui building is discussed below.

The tendency of displacement with respect to time shown in Fig. 3 is generally similar to that of settlement vs. time shown in Fig. 4. Based on the increment tendency, both can be separated into four distinct time segments: (1) May 2001 to March 2002, (2) September 2004 to June 2006, (3) June 2007 to April 2009; (4) April 2010 to January 2011.

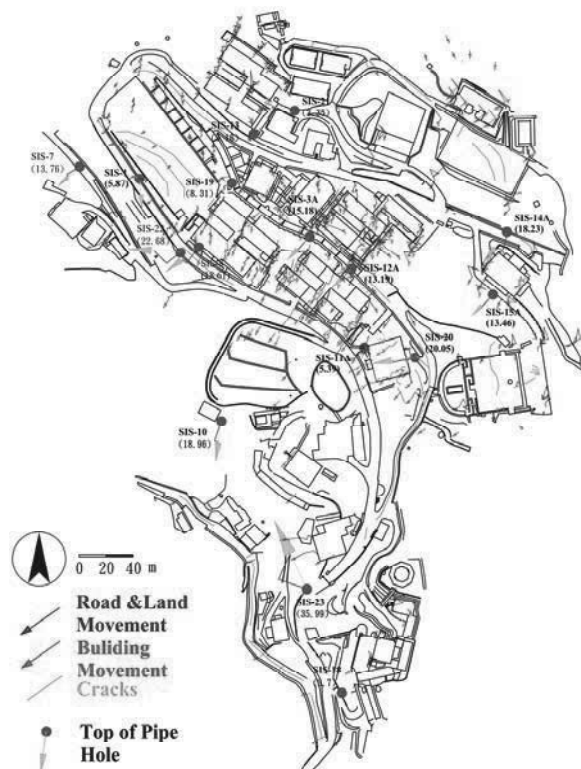

Fig. 2 displacement tracks and ground surface cracks distribution

When comparing the displacement and settlement time in Fig. 3 and Fig. 4 with the rainfall record, the displacement and settlement of the slope have a strong correlation with the rainfall record. In addition to the rainfall, another important influence factor to the displacement and settlement of the slope is the construction. For instance, within the third time segment, a new Library and Information Building were built with the excavation for the foundation at the toe of the slope. This may be the cause for the increased amount of displacement and settlement in the third time segment, despite the greater total accumulated rainfall in the second time segment (8973.5mm) versus the third (7241.5mm).

Aside from accumulated amounts, rainfall rate and duration also contribute to the threshold value that triggers displacement and settlement of the slope. Jeng and Sue (2008) illustrated that a rainfall threshold value of 800mm/month is able to trigger the displacement and settlement of the slope.

### 3 THE INCLINOMETER MONITORING

Many inclinometers have been installed starting the year 2000. Since then they have gradually settled in the test field, with some being damaged due to deformation. At present, 32 holes remain functional and are recording measurements. The results shows a sliding layer that deforms in depth from 14 to 15m. As seen from the core box the sliding occurs along the fracture layer.

### 4 COMPARISON THE RESULTS BETWEEN DISPLACEMENT MONITORING MARKS AND THE INCLINOMETER

The displacement monitoring marks are able to characterize the ground surface deformation and the inclinometer pipes can describe the ground deformation for the entire depth. To investigate the deformation of the slope, efforts were made by comparing the deformation of the top of the inclinometer pipes to the displacement monitoring marks. The comparison results shown in Fig. 2 indicated that the tendency of slope surface deformation obtained from both of these two data sets is

generally consistent. The primary slope deformation is toward the southwest and south direction, similar to the slope surface direction, which means the slope soil is generally moving downward along the slope.

Fig. 3 Relation curves of displacement and rainfall for Hui-tsu building

Fig. 4 Relation curves of settlement and rainfall for Hui-tsu building

5 SLOPE STABILITY ANALYSIS

After learning of the significant amount of slope deformation, there was concern for the integrity of the slope and any potentially hazardous contributing factors. To determine the slope stability, the limite equilibrium program - STABL was adopted and used for analysis. A simplified Bishop method with circular failure type was selected for the study. The input soil parameters were based on previous study (Jeng, 2003; Jeng and Li, 2009 ), as shown in Table 1. Areas with similar ground water variation and rainfall conditions were compared, and the crack distribution on the slope were used to assess potential failure areas.

Table 1 soils and rocks parameters

soils and rocks type	Cohesion (kPa)	Friction angle (°)	Unit weight (kN/m <sup>3</sup> )
Colluviums	18.45	29.92	19.31
sandstone and shale alternation	41.52	32.24	25.52
Sandstone	41.85	34.60	23.86

Figure 5 shows the slope stability analysis results for normal conditions. The safety factor is 2.17, which higher than the suggested value 1.5, remains within a stable state. However for rainfall conditions, when the ground water rises 3m, the safety factor decreases to 0.86. An unstable condition can then happen. Thus, it is concluded that the slope stability is significantly influenced by the rise in ground water during rainfall events.

Fig. 5 Slope stability for normal condition (FS=2.17)

6 SLIDING BLOCKS DETERMINATION FROM SETTLEMENT AND DISPLACEMENT RESULTS

According to the inclinometer monitoring results provided by Jeng and Hsieh (2010), there are six sliding blocks within the slope. In that study, the sliding rate, depth and area of each block were presented. In addition to that information, this study evaluates the result of ground surface movement, including displacement direction and settlement, trend of ground water flow, and the distribution of ground surface cracks. A comprehensive evaluation was made to exam the previous sliding blocks study results. Fig.6 shows the finding which supports the presence of two sliding blocks. Among them, block No. A-1 is located in the area around Wu-Ming building, Asoca Square and the Chea-chau building; block No. A-2 is located in the area around Sport ground where there is 20m of fill. These two sliding blocks coincide with blocks R1 and L1 of the previous study (Jeng and Hsieh, 2010). Both blocks show movement in the shallow layer and are located in the active sliding areas. Numerous cracks can be found along the ground surface in these areas.

7 STABILIZE MEASURES AND THRESHOLD VALUE OF RAINFALL

According to aforementioned stability analysis results, it was learned that the rise of ground water in rainstorm conditions significantly impacts slope stability. Consequently, slope stability will be improved with the addition of drainage and drawdown systems and retaining structures. With budget and effectiveness in mind, the first step should focus on the area around the Wu-Ming building where the ground water and geological condition is least favorable. A detailed description of improvement steps includes :

1. Improvement of the ground surface drainage system for water runoff.
2. Installation of six catchpits with the horizontal drainage pipes, shown in Fig.7, to draw down the ground water level.
3. Filling of ground surface cracks to prevent seepage of water runoff into cracks.
4. Construction of bore piles and tiebacks with ground anchors behind the Wu-Ming building to strengthen the retaining structure for the toe of the slope.

Finally, for the safety management of the slope, threshold curves were established to illustrate the relationship between rainfall intensity and accumulation, and the observed slope deformation (Fig. 8). Looking ahead, these curves can be used for predicting slope stability before typhoons as it often brings significant amount of rainfall. The information correlating rainfall and slope stability improves slope management and risk assessment. To minimize the sloop disaster from occurring, the proposed approaches are believed to be beneficial to the community.

Fig. 7 Plan for catchpits location

## 8 CONCLUSIONS AND DISCUSSION

This paper discusses the displacement and settlement of the slope, evaluates the sliding block theory, and analyzes slope stability. After summarizing the results, stabilization measures

Fig. 8 Threshold value curves correlate with displacement

and rainfall threshold values were established. Based on the results, the following conclusions can be made:

1. The areas with the most significant settlement and displacement are located around the buildings of Hui-t sui, Zhian and Wu-Ming Building. Due to lack of slope stability, surface cracks appeared and several sliding surfaces have been observed.
2. The deformation of the top of the inclinometer pipes is consistent with the displacement monitoring marks. Findings indicate the primary slope deformation to be toward the southwest and south direction. In addition, rainfall was found to be the most significant factor for slope deformation and slope stability.
3. The results of the slope stability analysis show that an increase in ground water level is the most critical factor for slope stability.
4. The distribution of potential sliding blocks was examined by using slope displacement and settlement data, and the location of surface cracks. The sliding direction is strongly correlated to the direction of ground water flow. Depth or thickness of fill also contributes to slope sliding.
5. Several stabilization measures including catchpits with horizontal drainage pipes, bore piles and tieback ground anchors, and threshold value of rainfall are recommended to improve the slope stability. It was believed that the information presented is very important for slope disaster prevention.

# Stability and movements of open-pit lignite mines in Northern Greece

## Stabilité et mouvements de terrain dans les mines de lignite à ciel ouvert en Grèce du Nord

Kavvadas M.

National Technical University of Athens, Greece

Agıoutantis Z.

Technical University of Crete, Greece

P. Schilizzi P.

Public Power Cooperation, Greece

General Consulting Ltd "ISTRIA", Greece

**ABSTRACT:** This paper presents a case of a lignite mine in Northern Greece with excavated slopes exceeding 100-120m in depth in which substantial movement is occurring, with an average rate 10-20mm/day. The Mavropigi mine is very important for the power supply of Greece and uninterrupted operation is often critical, meaning that excavation is taking place on moving soil masses. The stability of the moving southeast slope is investigated and the information developed from an extensive monitoring campaign, with survey prisms, inclinometers and piezometers is presented. The use of the investigation data to evaluate the type of movement, the geometry of sliding surface and the effectiveness of remediation measures are analyzed in detail. The procedure of assessing the stability and safe slope operation during production, even with high rates of movement and the effect of precipitation are presented. It is shown that there are situations that mine slopes can move several meters laterally and still be operational without catastrophic failures.

**RÉSUMÉ :** On présente dans cet article une étude des mouvements de terrain dans une mine de lignite du nord de la Grèce. Dans cette mine à ciel ouvert de 100 à 120 m de profondeur, des glissements de pente (lents) sont observés : 10-20 mm/jour. L'exploitation de cette mine (Mavropigi) de lignite, primordiale pour la production d'énergie en Grèce, s'effectue sans interruption dans des pentes en mouvement permanent. Les problèmes de stabilité de la pente sud-est de la mine sont étudiés et les mesures effectués in situ à l'aide de différents appareillages (mesures topographiques, inclinomètres et piézomètres) sont présentés. L'analyse de l'ensemble des mesures est effectuée afin de caractériser le type de mouvement de terrain et la géométrie de la surface de glissement. Par ailleurs, l'efficacité des mesures adoptées pour stabiliser les pentes est analysée via les mesures effectuées sur le site. Une procédure permettant d'évaluer le risque de perte de stabilité pendant les phases d'exploitation (intensive) en tenant compte des effets défavorables des précipitations est proposée. On met ainsi en évidence des cas pour lesquels les pentes peuvent se déplacer latéralement de plusieurs mètres sans pour autant engendrer des ruptures majeures.

**KEYWORDS:** Slope movement, Coal open pit, Slope monitoring, Slope stability, Landslide.

## 1 INTRODUCTION

The Public Power Cooperation (PPC) operates a number of large open pit lignite mines in Northern Greece (Amyntaio-Ptolemais Basin). The Mavropigi mine has been mined since 2003 and at present the excavated slopes have reached depths exceeding 100-120m. Since 2011, the southeast slopes have shown persistent large horizontal movements at an average rate of 10-20mm/day, at times reaching more than 40-50mm/day affected by increased precipitation. The moving mass was estimated around 6Mm<sup>3</sup>. This paper presents a case of significant movements that occurred at the southeast slope (Fig. 1), and details the monitoring, evaluation and mitigation measures taken to safeguard mining operations which had to be uninterrupted for production management purposes.

Figure 1. Southeast slopes of Mavropigi lignite mine.

## 2 GEOLOGICAL AND GEOTECHNICAL CONDITIONS

The Mavropigi mine is in the sedimentary fill of the Ptolemais basin which includes terrestrial and lacustrine deposits of Miocene up to Pleistocene age, with abundant lignite horizons (Diamantopoulos, 2006). Near horizontal intercalations of Marls, Lignites, Stiff Clays and Sands are the predominant materials; from a geotechnical point of view they can be described as "Hard Soils – Soft Rocks". The main intercalations are Marl and Lignite. The Marl material is mostly classified as Elastic SILT or Organic SILT (MH-OH) per USCS (ASTM D2487). Locally in the Marl – Lignite intercalations, thin (few centimeters thick) beds of High Plasticity CLAY (CH) are found. These almost horizontal thin beds have very low residual shear strength and often act as slip surfaces. The mechanical properties of the different materials encountered in the area of Mavropigi are presented in Table 1. These parameters are assessed from triaxial, direct shear and ring shear tests performed on selected core samples and are used for the slope stability calculations of the Mine.

Table 1. Range of Geotechnical Properties of Mavropigi Mine Materials.

Parameters / Materials	Marl	Lignite	Clay (CH)
Unit weight $\gamma$ (kN/m <sup>3</sup> )	16-18	11-13	16-18
Effective Cohesion $c'$ (kPa)	50-150	150-200	5-50
Effective friction $\phi'$ (deg)	28-35	34-36	26-30
Residual Friction $\phi_r'$ (deg)	-	-	5-10

### 3 MONITORING OF SLOPE MOVEMENTS

At the end of 2010, tension cracks were observed at the crest of the Southeast mine slopes and visually observed horizontal transverse movements at the toe under prisms 5A3 and 6A4. Although this is usual in large and deep open pit mines, nevertheless, 20 prism monitoring stations, two inclinometers (KL-10, 11) and two piezometers (PM-10, 11) were installed on the slopes. The locations of the instruments are shown in Figure 2 together with the limits of the moving mass.

Prism measurement records were made available between January 2012 and up to the writing of this paper (Sept. 2012).

Figure 2. Monitoring equipment and trends on Southeast slopes

Initially the measurements were executed with a lower accuracy total station and only the “sloping distance” between the prism and the measurement base was evaluated. Due to the complexity and criticality of the situation, a new robotic total station of high accuracy (0.5cc) replaced the old one. With the new total station the movement vectors could easily be measured and evaluated. The use of the robotic total station eliminated the surveyor operation error and the high accuracy significantly reduced the horizontal and vertical angular measurement error.

Due to the high rate of movement, few measurements were taken from the inclinometers before they were sheared off. From inclinometer KL-10, six measurements were obtained in a period of one month which recorded a total displacement 100mm at 27m depth from ground surface. Inclinometer KL-11 recorded only three measurements in a period of 11 days, with maximum displacement 150mm at 9m depth. The two piezometers could only be measured twice due to operational reasons and recorded water table elevation at 18.4m in PM-10 and 9.9m in PM-11. A precise water table could not be estimated based on the piezometer measurements because of the number of measurements and since the faces of the slopes were found dry. Piezometric conditions and water pressures are very difficult to model with a high degree of accuracy in mines (Sullivan, 2007) mainly due to the presence of multiple perched aquifers. Figure 3 shows a geological cross section with the monitoring equipment and the failure surface location (white line). Dark zones indicate the lignite beds.

Figure 3. A-A' cross section with monitoring locations

### 4 EVALUATION OF SLOPE MOVEMENTS

The operation of Mavropigi mine is very important for the power supply of Greece and uninterrupted operation is often critical. Mining operations may take place even in moving slopes, as long as safety of personnel and equipment is satisfied. Zavodni (2000) states that “*mining operations can proceed safely with minimum interruption if failure mechanisms are understood and slopes are properly monitored*” even in moving slopes. The way to assess if a “moving slope” can be mined safely is to determine if the slope movement is regressive or progressive. A regressive movement is cyclic decelerated while a progressive movement exhibits overall acceleration without appreciable deceleration intervals (Zavodni, 2000). In regressive movements, mining operation can continue after incorporating a monitoring system. If monitoring data indicate a progressive type of movement the operations are in danger of imminent collapse. The question posed to the Geotechnical Engineer is to determine the type of movement that characterizes each particular slope. The failure mechanism needs to be understood and a sufficient quantity of qualitative measurements is required. In the literature, most case studies are analyzed after an incident and with adequate monitoring data and the type of movement is identified (Ryan & Call 1992). At the Mavropigi mine, decisions had to be made based on the day to day data becoming available without a priori having a large amount of data that could be used to determine the type of movement.

Initially, based on the geological model of the area, the visual observations of the cracks in the crest and the translational surface located by the inclinometers, a limit equilibrium model was analyzed to evaluate if the movement was possible and to back calculate the material properties of the shear surface. Based on back analysis (Figure 4) it was found that a sliding surface was possible with residual friction angle of  $\phi_r=7^\circ$  for the near horizontal surface and  $\phi^*=24^\circ$  for the back scarp. These values were considered to be the lower bounds since no water pressures were introduced and were in good agreement with the laboratory ones provided in Table 1 for the area.

Figure 4. Back analysis of the sliding surface

From the geological model, the inclinometer readings and the back analysis it was found that the movement is taking place in a failure shear zone (thin high plasticity clay interlayer) with an inclination of about 4-5°. Based on this information an initial estimate was made that the movement could be of the regressive type based on the recommendations by (Zavodni and Broadbent, 1980), by which movements are deemed regressive when taking place on a surface with a lower angle in relation to the slope face inclination and the shear resistance (friction angle) of the material. Initial remediation measures consisting of excavating part of the top two benches were analyzed with the same data. Analysis showed that the FS became 1.06 which was considered

positive for reducing the rate of movement. The slope stability analysis was considered only indicative due to the complex nature of the sliding mass (fig 2) and greater emphasis was placed on slope monitoring.

The data were further analyzed to verify the regressive type of movement and to identify a possible onset of a progressive type of movement, leading to failure. One method to evaluate monitoring data is the inverse velocity measurement versus time. Based on this method, as described by (Rose and Hungr, 2007), when the inverse velocity of slope movement is plotted against time, failure is imminent as the trend line approaches zero values (velocity increases asymptotically). In Figure 5 the inverse velocity versus time is presented for prism 2A4.

Figure 5. Inverse velocity versus time for prism 2A4

Figure 5 suggests that if this method is to be followed, at numerous times the mine slopes could be at imminent collapse. This is evaluated based on the extrapolation to zero of the regression lines for different time intervals (straight lines). For example the first imminent collapse could have been evaluated to have occurred on 01/03/12, which did not happen.

Figure 6. Velocity versus time for prisms of bench 2

Figure 7. Precipitation versus time from two stations

Subsequently regression analysis presented times that failure could take place. This graph presents a situation where the

method could not work properly without evaluating other critical factors such as precipitation or excavation unloading.

Figure 6 presents velocity versus time for all prisms of bench 2 while figure 7 shows the daily and cumulative precipitation for two weather stations. The mine is located in between these stations with a distance of about 7km. No precipitation data at the mine were available.

From the evaluation of figures 6 and 7, a strong correlation between the precipitation and the increase of velocity is observed. Further observation of figure 6 provides information of a stick – slip mechanism and a regressive type of movement in which the velocity does not increase or decrease at a constant rate but undergoes abrupt changes. During and after heavy precipitation the water filled tension cracks provide an increasing driving force. As displacement continues, the width of the cracks increase and the water level drops with a dissipation of water pressure. This is a repetitive situation which modifies the velocity of the sliding mass. Beginning of February 2012 limited (day shift) remedial excavation was executed on bench 1 and above to reduce the weight of the sliding mass. Such excavation increased after March 2012 being conducted on 24hour shifts. As a result movement velocities were reduced after that date.

In retrospect the movement was of the regression type (or behaved in this respect due to the excavation at the top of the slope) as can be seen from the displacement measurements at bench 4 presented in Figure 8. In this graph the displacement at the bench is plotted versus time for four different prisms in different locations transversally placed on the slope (Figure 2).

Figure 8. Cumulative displacement of prisms on bench 4

When the cumulative displacement becomes convex, movement acceleration is evident and a progressive type of movement can be inferred. When the cumulative displacement becomes concave then deceleration takes place. As can be seen from Figure 8 displacements “cyclically” change from convex to concave and back to convex meaning that this is of a mixed condition where the regressive type of movement prevails. Although the cumulative displacement of this slope for a period of 7 months is over 3m, the slope is still in a regressive type of movement and therefore mine operations continue.

## 5 GEOMETRICAL MOVEMENT INFORMATION

The dense grid of monitoring prisms together with the high accuracy of the robotic total station produced additional invaluable data for the moving mass. As can be seen from Figure 2 the vectors of motion are presented with arrows. The continuous arrows present monitoring information until the writing of this paper. The dashed arrows present monitoring data that were discontinued for operational reasons at different times. As can be seen from the arrows and the displacements at bench 4 (figure 8) the slope moves more to the east than to the west while both translation and rotation occurs at the same time. The reason for this complex movement can be explained taking

into account the sloping surface geometry and the kinematic conditions of the adjacent southwest slopes.

The southwest slopes can be considered in a regressive moving condition as well. The movement there occurs at a very deep seated slip surface which is, partly formed on the schist bedrock probably on top of an old "inactive" fault and partly on the Neogene formation. The movement of that deeper slide may be generating lateral forces that are applied on the moving mass at the southeast mine slopes.

The complex movement of the southeast slope is also affected by the inclination of the sliding surface where the southeast slopes are moving on. As was shown previously in section A-A', the shear surface was found to have an unfavorable inclination of about 4-5°. This unfavorable situation is not continuous transversely across the slope. This can be safely stipulated after careful evaluation of the vertical – horizontal displacement of different prisms in the same bench (figure 9). In this plot the abrupt change of measurements is due to maintenance of the prisms.

Figure 9. Vertical versus horizontal displacement

As can be seen from figure 9 and especially after about 1500mm of horizontal displacement, when no abrupt changes are recorded, the prisms at the east (4A1, 4A2) produce a downward movement with an angle of about 4-5°. The 4A2 prism which is located at cross section A-A' produces the same shear surface inclination as determined by the inclinometers. Further to the west the sliding surface becomes horizontal or even with slight favorable inclination. This sliding surface geometry is responsible for the increased movement to the east and the rotation of the moving mass.

This detailed evaluation of the moving mass could not be possible without the dense grid of measuring points and the high accuracy of the robotic total station. It is evident that with accurate monitoring data shear surface inclinations can be evaluated from surface measurements.

## 6 CONCLUSIONS

A case study of high horizontal movements recorded on operational surface mine slopes has been presented. The slopes have been moving with an average velocity of about 10-20mm/day and until today they have moved more than 3m.

The sliding mechanism was investigated and, based on back-analysis, it was determined that the southeast slopes of the mine are moving on top of a near horizontal shear surface with a residual friction angle of about 7°. As no water pore pressure was used in the analysis, this value is considered a lower bound, and coincides with values determined through lab experiments for similar material in the mine area. The slope stability analysis is considered only indicative due to the complex geometry of the moving mass. It is not possible to exactly model this mass with plain strain limit equilibrium methods.

Great emphasis was given in the monitoring program in which twenty prisms, two inclinometers and two piezometers were used. The surface monitoring of the prisms was greatly

enhanced when a high accuracy robotic total station was used. With the high accuracy of the robotic total station, movement vectors could easily and accurately be measured.

The measurements presented a complex type of movement of the slopes which most of the time was of the regressive type. The slope movement has been found to be greatly affected by the periodic precipitation and the infilling of the tension cracks.

Based on the regressive type of movement, the mining operation could continue and at the same time remedial measures taken with excavation of the top benches for unloading. This remediation decreased but did not stop slope movements. Although the slopes have moved more than 3m horizontally, they are still in operation without significant problems. Movements were found to be very sensitive to external conditions such as precipitation.

The increased accuracy of the prism measurements allowed the identification of the sliding surface inclination along the mine slopes. It was found that the sliding surface changed inclination transversely.

High mine slopes can be in operation even if they produce high rates of movement, as long as the sliding mechanism type is identified and continuously monitored. Remedial measures can be incorporated in the mine plan in order to reduce movements.
