**ABSTRACT:** As part of the European project SafeLand, a compendium of structural and non-structural mitigation measures for different landslide types in Europe was prepared, and the measures were assembled into a web-based "toolbox". The purpose of web-based toolbox is to assist decision-making and to guide the user in the choice of the most appropriate mitigation measures. The paper presents an overview of the toolbox features, mitigation measures considered and an example of the report for one application of the toolbox.

**RÉSUMÉ :** Parti intégrante du projet européen « SafeLand », un recueil des mesures d'atténuation structurelles et non structurelles pour les différents types de glissements de terrain en Europe a été établi. Les mesures d'atténuation ont été assemblées dans une "boîte à outils" utilisable via internet. Le but de la boîte à outils est d'aider la prise de décision et de guider l'utilisateur dans le choix des mesures de diminution des risques les plus appropriées. Le document présente un aperçu des fonctionnalités de la boîte à outils, des mesures de diminution des risques envisagées et un exemple de rapport pour une utilisation spécifique de la boîte à outils.

**KEYWORDS:** Landslide, Quantitative vulnerability evaluation, Intensity, Susceptibility

## 1 INTRODUCTION

As part of the research done in the European project SafeLand "Living with landslide risk in Europe: assessment, effects of global change, and risk management strategies", a compendium of structural and non-structural mitigation measures for different landslide types in Europe was prepared, and the measures were assembled into a web-based "toolbox". Emphasis was placed on providing a rational and flexible framework applicable to existing and future mitigation measures.

The purpose of web-based toolbox is to assist decision-making and to guide the user in the choice of the most appropriate mitigation measures.

The mitigation measures were classified into three categories, describing whether the mitigation measures addressed the landslide hazard, the vulnerability or the elements at risk themselves. The measures considered include structural measures reducing hazard and non-structural mitigation measures, reducing either the hazard, the vulnerability or the exposure of the elements at risk. The structural measures include surface protection and control of surface erosion; measures modifying the slope geometry and/or mass distribution; measures modifying surface water regime - surface drainage; measures modifying ground-water regime - deep drainage; measured modifying the mechanical characteristics of unstable mass; transfer of loads to more competent strata; retaining structures (to modify slope geometry and/or to transfer stress to competent layer); deviating the path of landslide debris; dissipating the energy of debris flows; and arresting and containing landslide debris or rock fall.

The non-structural mitigation measures, reducing either the hazard or the consequences: early warning systems; restricting or discouraging construction activities; increasing resistance or coping capacity of elements at risk; relocation of elements at risk; sharing of risk through insurance. The measures are described in the toolbox with fact sheets providing a brief description, guidance on design, schematic details, practical examples and references for each mitigation measure. Each of the measures was given a score on its ability and applicability for differ-

ent types of landslides and boundary conditions, and a decision support matrix was established.

The web-based toolbox organizes the information in the compendium and provides an algorithm to rank the measures on the basis of the decision support matrix, and on the basis of the risk level estimated at the site. The toolbox includes a description of the case under study and offers a simplified option for estimating the hazard and risk levels of the slide at hand. The user selects the mitigation measures to be included in the assessment. The toolbox then ranks, with built-in assessment factors and weights and/or with user-defined ranking values and criteria, the mitigation measures included in the analysis. The toolbox includes data management, e.g. saving data half-way in an analysis, returning to an earlier case, looking up prepared examples or looking up information on mitigation measures. The toolbox also generates a report and has user-forum and help features.

The paper presents an overview of the toolbox features, mitigation measures considered and an example of the report for one application of the toolbox. The reports in the reference list can be found on the SafeLand project website, [www.safeland-fp7.eu](http://www.safeland-fp7.eu). Much more details and the descriptions of each mitigation measure along with references for each can be found in the reports in the list of reference.

## 2 TOOLBOX FEATURES

The toolbox is organized to guide the user in ranking different mitigation measures and to assist in the decision-making about the most appropriate mitigation measures to select for a site. The toolbox suggests the ranking of mitigation measures for a given landslide situation. The toolbox offers an extensive menu of different mitigation measures, and the user selects those that he wishes to consider in the study at hand.

The toolbox documents "do's and don'ts" and "how to". It estimates relative costs, benefits, hazards, effectiveness and vulnerability of each measure to mitigate hazard and/or risk.

The toolbox offers a simplified option for estimating the hazard and risk levels of the slide at hand. The user selects the mitigation measures to be included in the assessment. The toolbox then ranks, with built-in assessment factors and weights and/or with user-defined ranking values and criteria, the mitigation measures included in the analysis.

The web-based toolbox does data management, generates a report and provides help to the user, as well as a user forum. The web-based toolbox has the following features:

- Algorithm to describe a case study, estimate the expected hazard and risk level and to rank, on an engineering judgment basis, the mitigation measures included in an analysis.
- Data management (e.g. save data half-way in analysis, return to an earlier case, look up prepared examples or look up in database for information on mitigation measures).
- Report generation function.
- User forum.
- Help function.
- User management, with password-protected user login.

The toolbox will probably always be in evolution, even after the SafeLand project is completed, as it has "dynamic" technical contents that need to be updated as experience grows and new information becomes available. At all times, the user has access to the toolbox with options to Create a new case, Open a saves case, View a case study, Save a current case, Save as, Delete a current case, and Print.

Several modern technologies were implemented in developing the toolbox. One of them includes desktop toolbar that can automatically be enabled, disabled or hovered to improve user-interface. These toolbar icons of 64 x 64 pixels were designed using graphic software.

### 3 DECISIONS IN TOOLBOX

#### 3.1 Risk classes and need for mitigation

The risk classes used in the toolbox are shown in Figure 1. Depending on a combination of levels of consequence and hazard selected by the user, three risk classes can be assigned by the toolbox: Low, Medium and High. In this simplified model, "High risk" represents an unacceptable risk that requires new site investigations, stability calculations and mitigation measures, "Medium risk" is a risk level that requires considering doing new site investigations and analyses. For "Low risk" situation, further risk reducing measures are not necessary.

Consequence Hazard	Low	Medium	High
High	Medium Risk	High Risk	High Risk
Medium	Low Risk	Medium Risk	High Risk
Low	Low Risk	Low Risk	Medium Risk

Figure 1. Risk classes in Toolbox of Mitigation measures.

#### 3.2 Ranking of measures

The selection of the most appropriate mitigation measures to be adopted in specific situations take into account the following:

(1) the factors that affect the hazard, in terms of the type, rate, depth and the probability of occurrence of the movement or landslide, such as, for example:

- the physical characteristics of the geo-system, including the stratigraphy and the mechanical characteristics of the materials, the hydrological (surface water) and the hydro-geological (groundwater) regime;
- the morphology of the area;
- the actual or potential causative processes affecting the geo-system, which can determine the occurrence of movement or landslides;

(2) the factors that affect the nature and the quantification of risk for a given hazard, such as the presence and vulnerability of elements at risk, both in the potentially unstable area and in the run-out area; and (3) the factors that affect the feasibility of specific mitigation measures, such as, for example:

- the phase and rate of movement at the time of implementation;
- the morphology of the area, accessibility and safety of workers and the public;
- environmental constraints, e.g. archeological, historical and visual values;
- pre-existing structures and infrastructure that may be affected directly or indirectly;
- capital and operating cost, including maintenance.

The user selects in the toolbox the mitigation measures to be considered. To rank the selected mitigation measures, a simple additive algorithm with weighted scoring factors for both default criteria and user-defined criteria in the toolbox was developed. The ranking ( $R_i$ ) is therefore done on the basis of the summation of weighted ( $w_i$ ) contributing factors ( $F_i$ ) for each evaluation criterion:

$$R_i = \sum w_i \cdot F_i \quad (1)$$

Where  $i$  are the mitigation measures selected by the user for analysis, from 1 to  $n$ ;  $w$  is the weighting factor proposed by the toolbox; the default value for all  $w_i$  at start is 1.0 and can be changed by the user; and  $F$  is the scoring factor proposed by the toolbox and which can be changed by the user

Values for  $F$  and  $w$  are proposed by the toolbox, based on a decision support matrix. The user can change the values of  $F$  and  $w$  according to his/her experience and/or engineering judgment. The user can also add additional factors  $F_i$  that will then be automatically included in the analysis.

The scoring factors ( $F_i$ ) for each mitigation measure offered as default in the toolbox are for the user to consider, adopt or modify during his/her assessment of the problem at hand. The scoring for all ranking parameters is on a scale of 1 to 10, where 1 describes the least favourable attribute (worst, lowest, poorest, most expensive), and 10 the most favourable attribute (best, highest, strongest, least expensive or not expensive). The scoring of 0 is used when the mitigation measure is inapplicable or inappropriate.

The weighting factor ( $w_i$ ) reflecting the relative importance of criteria or corresponding scoring factors is in the range of 0 (least) to 1 (most). The default value is set to zero, and the toolbox assigns a values of unity (1) as a function of the input provided by the user in the following technological criteria categories: type of movement, type of sliding material, depth of movement, rate of movement, groundwater, and surface water.

#### 3.3 Priority setting

At the end of the ranking process, the toolbox lists the ranking of the selected mitigation measures in the order of most appropriate to least appropriate measures. The calculated value for  $R_i$

is also given as well as which factor(s)  $F_i$  has the most significance on the result. The user can compare the ranking order and can go back to the previous steps and change the weighting and scoring factors, especially those with high effect on the ranking  $R_i$ , if necessary.

#### 4 CLASSIFICATION OF MITIGATION MEASURES

The Safeland partner Studio Geotechnico Italiano S.r.l. (SGI) prepared a "Compendium of tested and innovative structural, non-structural and risk-transfer mitigation measures for different landslide types" (SafeLand 1). This review was used as a basis for the selection and evaluation of the different mitigation measures included in the toolbox for landslide hazard and risk mitigation measures.

The classification of the mitigation measures was done in terms of the components of a risk assessment (hazard, vulnerability and elements at risk). Table 1 presents this classification. The classification system addresses three components of risk: hazard, vulnerability and elements at risk, where risk R can be expressed as:

$$R = H \cdot C = H \cdot V \cdot E$$

where H is the hazard or the probability of occurrence of an adverse event (landslide); C is the consequence(s); V is the vulnerability or the degree of loss of an element at risk for a given hazard; and E are the elements at risk.

To reduce (or mitigate) the risk, one can reduce the hazard or reduce the consequences (reduce the vulnerability or reduce the exposure of the elements at risk).

Table 2. Classification of mitigation measures (structural measures on top, non-structural measures on bottom)

Class	Component of risk addressed	Brief description	Notes and other terms used
Stabilization	Hazard (H)	Eng'g works to reduce the landslide probability of occurrence	Preventive, remedial, hard, soft, active stabilization.
Control	Vulnerability (V) (consequence)	Eng'g works to protect, reinforce, isolate the elements at risk from the landslide area	Preventive, hard, soft, passive stabilization.
Avoidance	Elements (E) (consequence)	Temporary or permanent reduction of exposure w/ warning systems, evacuation/-relocation, sheltering, land-use planning.	Reduction of the exposure of the elements at risk. Monitoring, early warning systems and civil protection procedures, often temporary, selective avoidance measures.
Tolerance	Elements (E) (consequence)	Awareness, acceptance and/or sharing of risk	Indirect reduction of the exposure of the elements at risk.

Within the general domain of the structural mitigation measures classified above as "stabilization", i.e. reduction of hazard, it is possible to consider a further subdivision in relation to the triggering factors and mechanisms that each measure addresses.

#### 5 MITIGATION MEASURES CONSIDERED

The toolbox includes near 70 structural mitigation measures and six non-structural mitigation measures. The structural measures are divided into ten categories and belong to the class of measures either reducing hazard or reducing consequences. The structural mitigation measures included are:

- A Structural measures reducing hazard
  - 1 Surface protection and control of surface erosion
    - 1.1 Hydro-seeding, turfing and trees/bushes
    - 1.2 Fascines/brush
    - 1.3 Geosynthetics
    - 1.4 Substitution - drainage blanket
    - 1.5 Beach replenishment, rip rap
    - 1.6 Dentition
  - 2 Modifying the slope geometry and/or mass distribution
    - 2.1 Removal of (actual or potentially) unstable soil/rock mass
    - 2.2 Removal of loose or potentially unstable blocks/boulders
    - 2.3 Removal of material from driving area
    - 2.4 Substitution in driving area with lightweight fill
    - 2.5 Addition of material to the area maintaining stability
  - 3 Modifying surface water regime - surface drainage
    - 3.1 Surface drainage works (ditches, channels, pipe works)
    - 3.2 Local re-grading to facilitate run-off
    - 3.3 Sealing tension cracks
    - 3.4 Impermeabilization (geo-membranes, impervious facing)
    - 3.5 Vegetation - hydrological effect
    - 3.6 Hydraulic control works (channel lining and check dams)
    - 3.7 Diversion channels
  - 4 Modifying groundwater regime - deep drainage
    - 4.1 Shallow trenches filled with free-draining material
    - 4.2 Deep trenches filled with free-draining material
    - 4.3 Sub-horizontal drains (conventional drilling)
    - 4.4 Sub-horizontal drains (directional drilling)
    - 4.5 Wells
      - 4.5.1 Small and medium dia. vertical wells (<800 mm)
        - 4.5.1.1 Relief of artesian pressure
        - 4.5.1.2 Under-drainage of perched aquifer
        - 4.5.1.3 Pumps
        - 4.5.1.4 Siphons
      - 4.5.2 Medium diameter vertical wells (1200-1500 mm)
      - 4.5.3 Large diameter vertical wells (>2000 mm)
      - 4.5.4 Caissons (>5-6 m) with gravity drainage
  - 4.6 Drainage tunnels, adits, galleries, with secondary drains
- 5 Modifying mechanical characteristics of unstable mass
  - 5.1 Vegetation - mechanical effects
  - 5.2 Substitution
  - 5.3 Compaction from surface
  - 5.4 Deep compaction (e.g. vibro-compaction)
  - 5.5 Mechanical deep mixing with lime and/or cement
  - 5.6 Low pressure grouting with chemical binder
  - 5.7 Jet grouting
  - 5.8 Modification of ground water chemistry
- 6 Transfer of loads to more competent strata
  - 6.1 Counterfort drains (trench drains)
  - 6.2 Piles
  - 6.3 Barrettes (diaphragm walls)
  - 6.4 Caissons - mechanical effects
  - 6.5 Soil nailing
  - 6.6 Dowels and harnessing
  - 6.7 Rock bolting
  - 6.8 Strand anchors
- 7 Retaining structures (to modify slope geometry and/or to transfer stress to competent layer)
  - 7.1 Reinforced soil structure
  - 7.2 Gabion walls
  - 7.3 Crib walls
  - 7.4 Dry stack masonry walls
  - 7.5 Mass concrete or masonry walls
  - 7.6 Reinforced concrete stem walls
- B Structural measures reducing consequences
  - 8 Deviating the path of landslide debris
    - 8.1 Deflection structure
    - 8.2 Debris flow/rockfall shed
  - 9 Dissipating the energy of debris flows
    - 9.1 Drop structure
    - 9.2 Debris-restraining structure
    - 9.3 Debris flow impediments

10 Arresting and containing landslide debris or rockfall

- 10.1 Debris-resisting barrier
- 10.2 Rock fall barrier
- 10.3 Rock fall net
- 10.4 Debris retention basin

The following non-structural mitigation measures, reducing either the hazard or the consequences (or vulnerability and exposure of elements at risk) or in some cases both hazard and consequence, are included in the toolbox:

- a Early warning systems
- b Restricting construction activities
- c Discouraging construction activities
- d Increasing resistance/coping capacity of elements at risk
- e Relocation of elements at risk
- f Sharing of risk through insurance

6 RANKING CRITERIA

Six criteria categories were implemented to rank the appropriateness of each mitigation measure: type of movement, type of sliding material, depth of movement, rate of movement, groundwater, and surface water. Table 3 lists the criteria used in the toolbox.

Table 3. Ranking criteria used for each mitigation measure

Ranking criterion	Descriptor
Type of movement	Falls Topples Slides Spreads Flows
Material type	Earth Debris Rock
Depth of movement	Superficial (< 0.5 m) Shallow (0.5 to 3 m) Medium (3 to 8 m) Deep (8 to 15 m) Very deep (> 15 m)
Rate of movement	Moderate to fast Slow Very slow Extremely slow
Groundwater	Artesian High Low Absent
Surface water	Rain Snowmelt Localized Stream Torrent River
Maturity of technology	
Reliability of performance	
Reliability in terms of uncertainty in design	
Reliability in terms of uncertainty in implementation	
Safety during construction	
Service life required (durability)	
Aesthetics	
Typical cost	

7 EXAMPLE RESULT

Table 4 presents a typical result of the ranking algorithm for a potential instability in a soft clay slope.

Table 4. Typical report from toolbox.

Rank	Category	Measure	Score	Most significant parameters *
1	Surface protection	Vegetated cover	66	Material/debris Type of movement/-flow
2	Surface protection	Surface drainage	65	Depth of movement Surface water/-stream
3	Surface protection	Infilling of cracks	62	Surface water/stream Rate of movement/-slow
4	Reducing consequence	Early warning system	36	Depth of movement/-superficial Material/rock

\* With respect to measure appropriateness

8 SUMMARY

The paper provides only a glimpse in the toolbox. One has to use it to actually see how it functions. The toolbox will be available at the Safeland web site in 2013.

The purpose of web-based toolbox is to assist decision-making and to guide the user in the choice of the most appropriate mitigation measures. The mitigation measures are classified into three categories, describing whether the mitigation measures addressed the landslide hazard, the vulnerability or the elements at risk themselves. The measures are described in the toolbox with fact sheets providing a brief description, guidance on design, schematic details, practical examples and references for each mitigation measure. Each of the measures was given a score on its ability and applicability for different types of landslides and boundary conditions, and a decision support matrix was established.

The web-based toolbox organizes the and provides an algorithm to rank the measures on the basis of a decision support matrix, and on the basis of the risk level estimated at the site.

# A Numerical Study of Granular Surge Flow through a Row of Baffles

## Une étude numérique des écoulements granulaires à travers une rangée de chicanes

Law R.P.H., Lam A.Y.T., Choi K.Y.

*Geotechnical Engineering Office, Civil Engineering and Development Department, The Government of the Hong Kong Special Administrative Region, Hong Kong, China*

**ABSTRACT:** A numerical study that utilizes three-dimensional discrete element method was undertaken to investigate the impact process and the dynamic interaction between granular surge flow and baffles. In the numerical analyses, the granular flow medium and the baffles were modelled as frictional spherical discrete elements and rigid square objects respectively. The location, velocity and forces acting on the individual discrete elements during the impact and interaction process were captured and recorded in the analyses. A detailed assessment of the numerical output data indicates that a single row of baffles is effective in reducing the kinetic energy and discharge of the granular surge flow.

**RÉSUMÉ :** Une étude numérique utilisant une approche par éléments discrets en 3D a été mise en oeuvre pour étudier le processus d'impact et l'interaction dynamique entre un écoulement granulaire et des chicanes. Dans cette étude, le milieu granulaire a été modélisé par des objets sphériques et les chicanes par les objets carrés. Les grains comme les chicanes sont considérées comme parfaitement rigides. L'emplacement, la vitesse et les forces agissant sur les éléments discrets au cours du processus d'impact et l'interaction ont été ainsi calculés. Une évaluation détaillée des données de sortie indique qu'une seule rangée de chicanes est efficace pour la réduction de l'énergie cinétique et l'évacuation de l'écoulement granulaire.

**KEYWORDS:** baffles, granular flow, discrete element method, energy dissipation, impact pulse, discharge.

## 1 INTRODUCTION

Granular surge flows such as debris flows and snow avalanches are dangerous natural hazards. Baffles have been employed to dissipate the kinetic energy of such flows and reduce the entrainment of channel bed deposits. Rows of baffles could be constructed across the flow path in order to reduce the flow velocity, the entrainment potential and dynamic impact force on downstream structures. Baffles constructed across the debris flow path are potentially more advantageous than the conventional rigid debris-resisting barriers because baffles are generally easier to construct without the need for extensive site formation works. However, the dynamic interaction of granular surge flow with baffles is still an emerging area of research to both the academics and the practitioners.

Discrete element method was introduced in geomechanics by Cundall and Strack in 1979 and was later adopted as a research tool by other researchers (e.g. Muir et al., 2008; Sibille et al., 2008; Thompson et al., 2009). The discrete element method is an appropriate and useful tool for modelling debris flow and snow avalanche because of the granular flow nature (Zwinger 2000; Nicot 2004; Hutter et al., 2005; Pudasaini & Hutter 2007) of these phenomena. In a previous study by Law 2008, a series of flume model tests and three dimensional discrete element analyses were conducted to investigate the impact behaviour of granular surge flow on a rigid barrier. The study has been extended to investigate granular surge flow through a row of baffles. This paper focuses on the numerical study of the impact process and the dynamic interaction between baffles and granular surge flow using the discrete element method.

## 2 NUMERICAL STUDY

### 2.1 Introduction

The granular medium was modelled as incompressible frictional discrete elements and the planar rigid surfaces were used to model the baffles and the ground surface. In the analyses, the location and velocity of the individual discrete elements together with the forces acting on each element were captured and recorded in order to study the impact process and the dynamic interaction between baffles and granular surge flow. The displacement of individual discrete elements is independent of one another, and they only interacted when coming into contact with each other or with the baffles and other rigid boundaries. The motion of each discrete element was calculated on the basis of the forces acting on it by the Newton's laws of motion. The displacements and rotations of the discrete elements were computed in the numerical analyses.

### 2.2 Numerical model setup and test procedure

Figure 1 shows the geometry of the flow path and the baffles. The granular medium comprises a total of 30,000 spherical discrete elements and all the discrete elements have a uniform diameter of 0.05m. The material density of each discrete element is 2,650 kg/m<sup>3</sup>. The discrete elements were not intended to simulate motion of individual particles in the granular medium. Instead, the macroscopic behaviour of the granular medium was represented by the contact behaviour between the discrete elements. Planar rigid surfaces were used to model the baffles and the ground surface.

Figure 1. Numerical model setup

The length and width of the computation domain were 15m and 1.2m respectively. The slope gradient was chosen to be 35°. The plan area and the height of the individual baffle were 0.2m x 0.2m and 1m respectively. The baffle was located in the middle of the flow path. The periodic boundary condition (PBC) was applied along the y-direction (Figure 1) of the computation domain. With the PBC, discrete elements leaving one side of the computation domain in the y-axis will emerge on the opposite side with the same dynamic properties, such as velocity, force, etc. This boundary condition helps to reduce the computation time since the impact of granular flow medium on an array of baffles could be simulated using a single baffle and a reduced number of discrete elements (i.e. only the dark particles shown in Figure 1 need to be modelled). With reference to Chen 2009, a baffle spacing of 1m and the ratio of baffle spacing to element diameter of 20 were adopted in the analysis to prevent clogging of the discrete elements between the baffles.

Each numerical analysis is divided into two stages, namely the initial stage and the impact stage. At the initial stage, the granular medium comprising an assembly of discrete elements with random packing was placed on a rigid surface inclined at 35° as shown in Figure 1. The individual discrete elements stabilized itself under the action a body force, which was equivalent to gravity and acting perpendicularly downwards at the ground surface. The body force acting on the individual discrete elements was rotated to the vertical direction in the next stage to enable the granular medium to flow downslope under the action of gravity and impact the baffles. The initial thickness of the granular medium was uniform and chosen to be 0.5m before impacting on the baffles. At the impact stage, the granular medium was given an initial velocity of 8 m/s. The corresponding Froude number of the initial flow condition is close to 4 which fall within the range of Froude number of debris flow events reported by Hubl et al 2009.

### 2.3 Contact law applied in numerical model

The local rheology of the flow material was simulated by applying the contact law in the numerical model. The linear Hookean stiffness model was adopted for the discrete elements and the rigid planar surfaces in the numerical analyses. According to Crosta et al. 2001, the contact stiffness of the discrete element has negligible influence on the computed mobility of granular material. Given that the chosen stiffness value have only minimal influence on the computed result, the discrete element and wall stiffness used were both chosen to be 1x10<sup>8</sup> (N/m) such that the elements almost behave like a rigid body.

The relative translational and rotational motions between the discrete elements are mainly resisted by contact friction. The macroscopic friction angle of dry sand was measured to be 35° (Teufelsbauer et al. 2011, Chiou 2005, Pudasaini et al 2005 and 2007, Pudasaini and Hutter 2007). Based on field and laboratory tests conducted by Chau et al. 2002, Azzoni and Freitas 1995 and Robotham et al. 1995, the coefficient of restitution was chosen to be 0.5.

According to Calvetti and Nova 2004, the macroscopic friction angle of the granular medium is typically much less than 30° irrespective of the value of the contact friction angle adopted on spherical discrete elements without rolling resistance. Calvetti et al 2003 and Tamagnini et al 2005 emphasized the need to inhibit particle rotations and calibrate the particle contact friction angle based on the desired value of the macroscopic friction angle of the granular medium.

In the numerical analyses, a rolling resistance term was added in the calculation of rolling motion of discrete elements. The rolling resistance was calculated using a directional constant torque model elaborated by Ai et al 2011. The model applies a constant torque on a particle to represent the rolling friction. The direction of the torque was always against the relative rotation between the two contact entities. The torque between two in-contact spheres *i* and *j* can be expressed as:

$$M_{rel} = -(\omega_{rel} / |\omega_{rel}|) \mu_r R_i F_n \quad (1)$$

$$\omega_{rel} = \omega_i - \omega_j \quad (2)$$

where  $\omega_i$  = the angular velocities of sphere *i*;  
 $\omega_{rel}$  = the relative angular velocity between two elements;  
 $\mu_r$  = the rolling friction coefficient;  
 $F_n$  = the normal contact force; and  
 $R_r$  = the radius of the discrete element

Figure 2. The effects of the rolling friction coefficient on the time history of the computed kinetic energy

A calibration exercise was carried out to identify the appropriate rolling friction coefficient for the numerical study. Figure 2 shows the numerical setup for the calibration work. The simulation box boundary was periodic in nature in order to allow the granular material to transport on the incline indefinitely. The granular material was given an initial velocity of 8m/s. By adopting a macroscopic friction angle of 35° (i.e. same as the channel inclination), a coefficient of restitution of 0.5 and trying different rolling friction coefficients (i.e.  $\mu_r = 0.2, 0.4, 0.6, 0.7, 0.8$  and 1) in the calibration exercise, the granular flow would eventually reach a steady kinetic energy.

Figure 2 shows the time history of the kinetic energy ( $k_e$ ) of all discrete elements relative to the computed  $k_e$  at time zero ( $k_{e0}$ ). The  $k_e$  is the sum of kinetic energy of all discrete elements. Based on the results of the calibration exercise, the granular flow could attain a steady velocity when the rolling friction coefficient reached a value of 0.7, which was chosen to be the appropriate rolling friction coefficient for the numerical study. The input parameters adopted is summarized in Table 1.

Table 1. Parameters adopted in the numerical study

Parameter	Magnitude
Slope angle	35°
Baffle dimension	0.2m x 0.2m x 1m
Particle diameter	0.05m
Density of each particle	2650kg/m <sup>3</sup>
Particle and wall stiffness	1x10 <sup>8</sup> (unit)
Contact friction angle	35°
Coefficient of restitution	0.5
Rolling friction coefficient	0.7
Approaching velocity	8m/s

### 3 COMPUTED RESULTS

#### 3.1 Flow Profile

Figure 3 shows the plan and side view of a number of snapshots recorded in the numerical analyses. The time difference between each snapshot is 0.012 second. The darker the particle colour, the lower was its velocity. A velocity reduction of the discrete elements immediately behind the baffles was observed on plane and Section A-A as shown in Figure 3.

In Figure 3a, at time = 0s, the particles at the front of the flow were just in contact with the baffle. In Figure 3b, at time = 0.012s, the dark region signified the slowing down of the discrete elements behind the baffle after impacting it. The boundary of the dark region where the momentum of the discrete elements was reduced by the baffle is marked by a white dashed line.

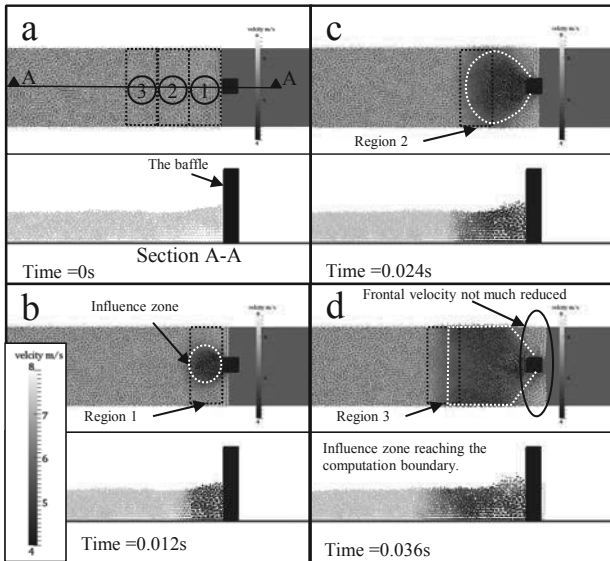

Figure 3. The snapshots showing the change of particle velocity during impact. The time difference between each snapshot is 0.012 second.

In Figure 3c, at time = 0.024s, the size of the dark region increased in size, and the dark region reached the computation boundary in Figure 3d. This indicates that the reduction of the momentum of the discrete elements behind each baffle was no longer localized, but a continuous zone of momentum reduction behind the row of the baffles. The presence of such a momentum reduction zone suggests that most discrete elements passing through the baffles will be decelerated by the flow resistance provided by the baffles. The only exception was the frontal discrete elements located between the baffles. As highlighted in Figure 3d, the velocity of the frontal discrete elements between the baffles was not reduced by the baffles. It is noted from the side view snapshots that the flow depth behind the baffle increases at the time of frontal impact. The

deceleration of the discrete elements was observed to be uniform over the flow depth.

In order to capture and record the dynamic behaviour of the discrete elements behind the baffles, three measurement regions (i.e. region 1, 2 and 3) as shown in Figure 3a were established. Each measurement region was 0.4m in length in the longitudinal direction. The unbalanced force, kinetic energy and discharge rate of the discrete elements within the measurement regions in the first 0.14 seconds of the impact process were recorded and presented as follows.

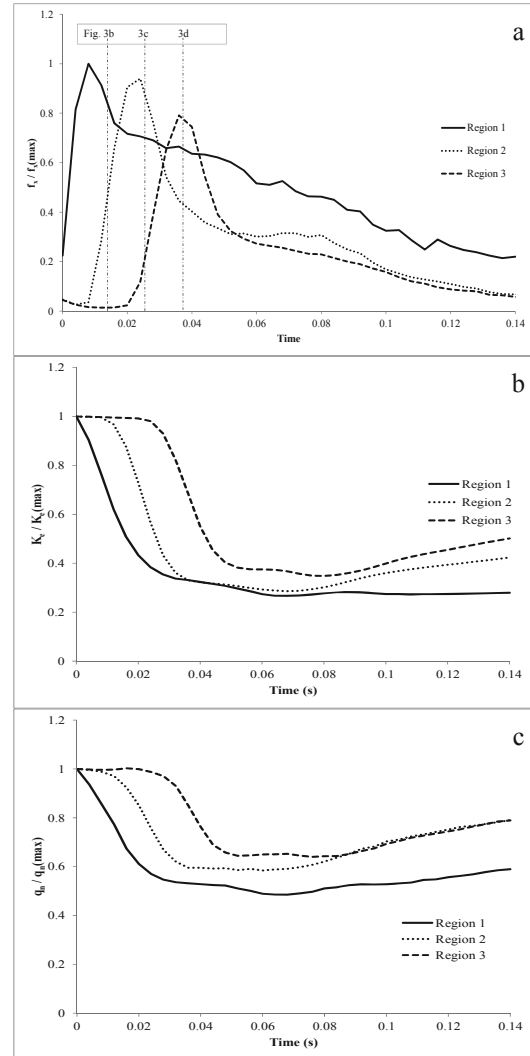

Figure 4. The computed  $f_x$ ,  $k_e$  and  $q_m$  of discrete elements located in region 1, 2 and 3 (please refer to Figure 3a for the location of the regions).

#### 3.2 Unbalanced force on discrete element close to the baffle

The unbalanced force ( $f_x$ ) is the sum of the unbalanced force of all discrete elements in the flow direction. When the granular flow approaches the baffles, a change in the normalized unbalanced force ( $f_x / f_{x(max)}$ ) with time is an indication of the internal stress experienced by the discrete elements due to the dynamic impact on the baffles. Figure 4a shows the relationship of ( $f_x / f_{x(max)}$ ) with time in region 1, 2 and 3. The built up and decline of  $f_x$  were recorded in the three measurement regions 1, 2 and 3 and presented in Figure 4a.

From Figure 4a, the duration of the peak  $f_x$  acting on the baffle was less than 0.01s, and the sequential peak  $f_x$  observed in all the three measurement regions had indicated the propagation of impact pulses in the opposite direction of the flow during frontal impact of granular flow on the baffles. By comparing Figure 3 and Figure 4a, it is observed that the

discrete elements located close to the edge of the dark region had the peak  $f_x$ . The impact pulse is therefore correlated to the propagation of the dark region where the discrete elements reduced their momentum notably. As the  $f_x$  decreased steadily with time after impact, the post-peak  $f_x$  was found to be less than 30% of the peak  $f_x$  after about 0.14s. This finding suggests the highly transient nature of the impact.

### 3.3 Energy dissipation and discharge

Figure 4b shows the relationship of the normalized kinetic energy ( $k_e/k_{e(max)}$ ) of the discrete elements with time in region 1, 2 and 3. The solid line, dotted line and dashed line represent the computed  $k_e/k_{e(max)}$  in region 1, 2 and 3 respectively. The  $k_e$  is the sum of the kinetic energy of all the discrete elements in a region. From Figure 4a and Figure 4b, it can be observed that  $k_e$  decreased much more rapidly with time than  $f_x$ . In region 1,  $k_e$  reduced to 30% of the peak  $k_e$  after less than 0.02s while  $f_x$  requires about 0.14s to reduce to 30% of its peak  $f_x$ . The magnitude of  $k_e$  rose gently following the rapid reduction.

Figure 4c shows the mean discharge rate ( $q_n$ ) of the discrete elements relative to the maximum computed  $q_n$  ( $q_{n(max)}$ ) in region 1, 2 and 3. Similar to the trend of  $k_e$ , the normalized discharge rate reduced with time. The reduction of the discharge rate was less rapid in comparison with the reduction of  $k_e$  shown in Figure 4b. A rising trend of  $q_n$  is observed following the reduction. It is interesting to note that both the  $k_e$  and  $q_n$  rose following the sharp reduction of their values. It is inferred that the deceleration effect caused by the baffles are more significant during the first impact (i.e. time before 0.04 second for regions 1 to 3) at which the impact pulse propagated along these regions. The trend of kinetic energy of these regions beyond 0.14 second is likely to be affected by the presence of various deposition mechanisms, such as runup, reflected wave, jet and hydraulic jump, etc (Armanini and Scotton 1993; Armanini 1997; Sun and Law 2012). Further research will be carried out to study the influence of these mechanisms on the computed kinetic energy and discharge. Based on the above observations of the first impact process, the baffles reduced the kinetic energy and the discharge of the discrete elements behind them effectively.

## 4 CONCLUSIONS

In this study, the three-dimensional discrete element method was used to analyse a granular surge flow through a row of baffles. The analysis focused on the short moment at which the first impact of the discrete elements on the baffles took place. The propagation of impact pulses in the upstream direction was observed at the moment of impact. The magnitude of the impact pulse decreased with the distance upstream from a row of baffles. The deceleration of the discrete elements was uniform over the flow depth at the moment of impact. More than half of the kinetic energy of the discrete element right behind the row of baffles was dissipated in less than 0.02s. The kinetic energy of the granular medium behind the row of baffles decreases more rapidly with time than the unbalanced force. Based on the findings of the analysis, a single row of baffles is effective in reducing the kinetic energy and discharge of the granular surge flow at the moment of impact.

# Full-Scale Field Monitoring of a Rainfall-Induced Sliding Slope in Hainan, China

## Étude en vraie grandeur d'un talus glissant soumis à des précipitations à Hainan en Chine

**ABSTRACT:** This paper investigates the mechanism of rainfall-induced sliding slope through a study based on a full-scale field monitoring conducted in a sliding slope in Shimei Bay, Wanning City, Hainan, China, where some premium hotels and residential buildings are being built along a natural hillside slope. Due to the heavy rainfall in October, 2011, it was found that the hillside slope was sliding during the heavy rainfall. A number of instruments, including soil moisture probes, tensiometers, open standpipes and piezometers, inclinometers, and a rain gauge were installed in the slope. Field monitoring of the sliding slope was conducted during one dry and one wet seasons before the stabilization of the sliding slope. The paper mainly introduced the instrumentation system of field monitoring of the sliding slope. It also introduced the preliminary analysis of the variations of rainfall intensity, soil moisture content, matric suction, ground water level, slope deformation during the dry season of 2011 and the wet season of 2012 before the stabilization of the sliding slope.

**RÉSUMÉ :** Cet article étudie le rôle des précipitations sur une pente glissante via une étude basée sur un suivi sur le terrain à grande échelle, menée dans une pente glissante dans Shimei Bay, ville de Wanning, Hainan, en Chine, où certains hôtels de luxe et des bâtiments résidentiels sont en cours de construction, le long d'une la pente naturelle. En raison des fortes pluies en Octobre 2011, il a été constaté que la pente (colline) glissait pendant les fortes pluies. Un certain nombre d'instruments, y compris les sondes d'humidité, tensiomètres, bornes-fontaines, des piézomètres ouverts, inclinomètres, et une jauge de pluie ont été installés dans la pente. Le contrôle du glissement a été effectué pendant une saison sèche et une saison humide, avant la stabilisation de la pente. Cet article présente le système d'instrumentation mise en place sur le site. On présente également dans cet article l'analyse préliminaire sur des variations de l'intensité des précipitations, l'humidité du sol, succion matricielle, le niveau de la nappe phréatique et la déformation de la pente pendant la saison sèche de 2011 et la saison des pluies de 2012, avant la mise en place des renforcements du site.

**KEYWORDS:** field-monitoring ; sliding slope ; rainfall-induced ; strumentation.

## 1 INTRODUCTION

Rainfall-induced landslides are common in the tropical areas in China, especially in Southern China. Each year hundreds of landslides, occur during the rainy season. Many of these landslides have caused heavy damage and numerous fatalities. The majority of these landslides are associated with heavy rainfall. Hence, rainfall-induced slope failure becomes one of the most common types of landslides in Hong Kong (Lumb, 1962a, 1962b, 1975; Brand, et al. 1984; Au, 1998; Franks, 1999, Dai, et al. 1999, 2001; Li, et al. 2002, 2003, 2005a, 2005b, 2006).

Due to the new policy that China aims to build the southern island of Hainan into a top international tourism destination by 2020, the Hainan local government promises to boost development not only by expanding oil and gas exploration, offering more duty free services, developing logistics, reducing pollution, but also by improving transportation networks and infrastructure. Thus, more premium hotels, resorts, family-run hotels and residential buildings are being built along the east coast of the island.

In area of our study site, a lot of landslides were reported. A total of 4 landslides were recognized within the site. Site investigation was also carried out, which found that there was even a big landslide with a scar volume of 500000 m<sup>3</sup> just one kilometer away from the site. There was even a heavy debris flow, which almost damaged the newly built east fast train for Haikou to Sanya, which is just 5 kilometers away. As little research work was carried out in Hainan for the landslides, there

are even few documents for the landslides, only occasionally in the local newspapers.

In order to investigate the mechanism of rainfall-induced slope failure, a study is being carried out based on a full-scale field monitoring conducted in a sliding slope in Shimei Bay, Wanning City, Hainan, China, where some premium hotels and residential buildings are being built along a natural hillside slope.

Due to the heavy rainfall in October, 2011, it was found that the hillside slope was sliding during the heavy rainfall. The sliding slope was a gentle hillside, which was cut to accommodate a temporary road construction, and consisted mainly of residual soil, CDG and HDG. To characterize the soil properties of the sliding slope, a detailed site investigation was carried out prior to the instrumentation.

A number of instruments, including soil moisture probes, tensiometers, open standpipes and piezometers, inclinometers, and a rain gauge were installed in the slope. Site investigation included borehole drilling, soil sampling, field and laboratory tests was carried out. Field monitoring of the sliding slope was conducted during one dry and one wet seasons before the stabilization of the sliding slope. The pre-stabilized slope was monitored during the dry season of 2011 and the wet season of 2012. The stabilization of the sliding slope started before the end of the wet season in 2012.

Anti-sliding piles plus pre-stressed anchors were designed to stabilize the sliding slope. Other instruments including load cells and strain gauges were suggested to be installed in the

anchors and piles during the stabilization of the sliding slope. It was suggested that the post-stabilized slope should also be monitored for another dry season of 2012 and another wet season of 2013.

The paper mainly introduced the instrumentation system of fielding monitoring of the sliding slope. It also introduced the preliminary analysis of the variations of rainfall intensity, soil moisture content, matric suction, ground water level, slope deformation during the dry season of 2011 and the wet season of 2012 before the stabilization of the sliding slope.

## 2 SITE CONDITIONS

The site is a natural hillside terrain covered by a lot of vegetation. The section was originally a gentle slope and then it was cut to accommodate the footpath for the main road. Ground investigation work was carried out during instrument installation. The site ground as revealed by the ground investigation is mainly residual soil, completely decomposed granite (CDG) and highly decomposed granite (HDG), which are underlain by moderately decomposed granite (MDG) and slightly decomposed granite (SDG).

Laboratory tests were carried out on the soil samples obtained at the sliding slope during the site investigation. The soil, as revealed by site investigation, is completely decomposed medium-grained granite and can be classified as a very weak to weak, light brown to brown, silty/clayey sand. The laboratory program to characterize the soil properties included: (1) Bulk density, (2) Dry density, (3) Specific gravity, (4) Atterberg limits and (5) Particle size distribution.

Part of the laboratory tests results are summarized in Table 1.

Table 1. Soil properties for the sliding slope.

Bulk density (Mg/m <sup>3</sup> )	1.76~1.93
Dry density (Mg/m <sup>3</sup> )	1.44~1.54
Specific gravity	2.627~2.655
Void ratio	0.7314~0.8443
Porosity	0.42~0.46
Liquid limit (%)	31.5~44.3
Plasticity index (%)	12~23

## 3 INSTRUMENTATION SYSTEM

The instruments included soil moisture probes to measure volumetric water content, tensiometers to measure matric suction (negative pore water pressure), open standpipes and piezometers to measure ground water level and positive pore water pressure, inclinometers to measure the lateral ground movements, and a rain gauge to measure rainfall intensity.

The philosophy for instrumentation design was as follows: The moisture probes and tensiometers were installed in the shallow depth to monitor volumetric water content and matric suction in the unsaturated zone of the soil. The open standpipes and piezometers were installed in both the shallow depth and greater depth to monitor both perched and deep ground water or positive pore pressure in the saturated zone of the soil. The inclinometers were installed in the soil to monitor horizontal deformation of the sliding slope. The rain gauge was installed to monitor the specific rainfall intensity of the monitored sliding slope. Figure 1 shows instrumentation layout plan.

A total of six moisture probes were used to measure volumetric water contents inside different parts of the sliding slope (Figure 1). Three moisture probes were installed in borehole M1 (M1-1 (1m), M1-2 (2m) and M1-3 (3m)) at depths

of 1 m, 2 m and 3 m, respectively, at the toe of the slope. The other three moisture probes were installed in boreholes M3 (M3-1 (1m), M3-2 (2m) and M3-3 (3m)) at depths of 1 m, 2 m and 3 m, respectively, near the crest of the slope. A total of six tensiometers were used to measure matric suction at different locations of the sliding slope (Figure 1). Three of them were installed in boreholes T1 (T1-1 (1m), T1-2 (2m) and T1-3 (3m)) at depths of 1 m, 2 m, 3 m and 4 m, respectively at the toe of the sliding slope. The other three were installed in boreholes T3 (T3-1 (1m), T3-2 (2m) and T3-3 (3m)) at depths of 1 m, 2 m, 3 m and 4 m, respectively, near the crest of the sliding slope. A total of three open standpipes were used to measure ground water levels at different locations of the sliding slope (Figure 1). A total of three vibrating wire piezometers (P1, P2 and P3) were used to measure positive pore water pressures at different locations of the sliding slope (Figure 1). A total of three inclinometer tubes (IN1, IN2 and IN3) were used to measure the lateral ground movements at different locations of the sliding slope (Figure 1). One 0.5 mm “tipping bucket” rain gauge with internal logger was used to monitor the rainfall intensity of the monitored slope site automatically (Figure 1).

Ground water levels in the open standpipes were monitored manually with the help of a dipmeter. An automatic data acquisition system was set up for the sliding slope to monitor moisture content, matric suction, positive pore water pressure and horizontal deformation continuously. The automatic data acquisition system consists of sensors, cables, data loggers and power supplies. An instrumentation hut was constructed at the top of the sliding slope to house the data loggers and power supplies. The data loggers were configured to collect data at 15/30-min intervals and the data were transmitted to both the office in the site and the office in Shenzhen instantly via wireless data transition system.

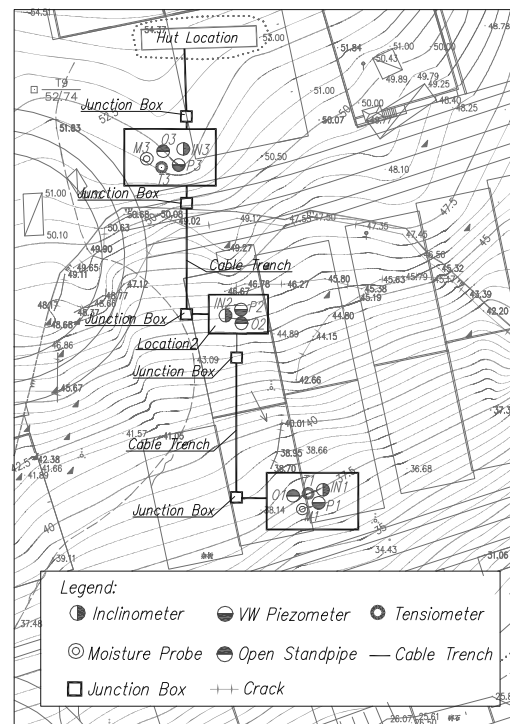

Figure 1. Boreholes and instrumentation layout plan.

#### 4 PRELIMINARY MONITORING RESULTS

##### 4.1 *Moisture Probes and Tensiometers*

Figures 2 and 3 show the variations of the volumetric water content and the matric suction of Borehole M3 at the crest of the sliding slope from November 2011 to June 2012. By examining the volumetric water content and the matric suction records and their comparison with daily rainfall in borehole M3 at the crest of the sliding slope during the above period (Figures 2 and 3), the following observations can be made:

(1) The volumetric water content increased due to rainfall infiltration in the wet season and decreased due to evaporation in the dry season. The matric suction decreased due to rainfall infiltration in the wet season and increased due to evaporation in the dry season.

(2) The volumetric water content at different depths was not uniform. Generally, the volumetric water content at a shallow depth was lower than that at greater depths during the dry season, while the volumetric water content at a shallow depth was higher than that at greater depths during the wet season. The matric suction at different depths was not uniform too. Generally, the matric suction at a shallow depth was higher than that at greater depths during the dry season, while the matric suction at a shallow depth was lower than that at greater depths during the wet season.

Figure 2. Variations of volumetric water content and daily rainfall from November 2011 to June 2012 in borehole M3 at the crest of the sliding slope.

Figure 3. Variations of matric suction and daily rainfall from November 2011 to June 2012 in borehole M3 at the crest of the sliding slope.

##### 4.2 *Open Standpipes and Piezometers*

The monitoring of the three open standpipes was carried out by using a dipmeter. The monitoring of the open standpipes was to check the monitoring data of nearby installed piezometers. Figure 4 shows the variations of the ground water levels in Borehole P1 at the toe of the sliding slope from November 2011 to June 2012. By examining the ground water level records and comparing them with the daily rainfall data during the above period, the following observations can be made:

(1) The pore water pressure at P1-A was higher than that at P1-B. It probably implies that there was a perched water level in

the sliding slope and the permeability of the residual soil is higher than that of CDG.

(2) The groundwater level decreased around 6.0 m at both P1-A and P1-B.

(3) The rise of the groundwater level was sensitive to rainfall, and it was more sensitive at shallow depth. Furthermore, there was a time lag for monitoring the highest ground water level due to rainfall.

(4) The highest groundwater levels monitored in November, 2011 was probably due to the heavy rainfall during the wet season in 2011, which caused the landslide.

Figure 4. Variations of ground water level and daily rainfall from November 2011 to June 2012 in borehole P1 at the toe of the sliding slope

##### 4.3 *Inclinometers*

Figure 5 shows the monitored horizontal displacements from November 2011 to June 2012 in borehole IN1 at the toe of the sliding slope. By examining the monitored horizontal displacements during the above period, the following observations can be made:

(1) The maximum horizontal displacement from June 2011 to July 2012 in borehole IN1 at the toe of the sliding slope was about 10.0 mm (Figure 25).

(2) The monitored sliding slope was sliding slowly. It is believed that with rainfall infiltration, the matric suction in soils at shallow depth partially disappeared, which decreased the stability of this sliding soil slope.

(3) The decrease of groundwater level was up to 6.0 m during the dry season, however, the increase of groundwater level due to the heavy rainfall on April 7 was less than 1.0 m, therefore, the maximum horizontal displacement was insignificant.

Figure 5. Horizontal displacements from November 2011 to June 2012 in borehole IN1 at the toe of the sliding slope

## 5 THE FAILURE OF THE MONITORING SLIDING SLOPE

As the client started the stabilization of the sliding slope using man-dug piles and anchors, it was found that it was very difficult to protect the monitored system. Therefore, automatic monitoring system for the sliding slope has to be given up. Instead, the sliding slope was being monitored manually during the stabilization of the sliding slope.

There are several rows of piles needed to be constructed during the stabilization and furthermore, there are a lot of excavations before the stabilization. Though many warning letters had been issued to the Contractor by the Consultant, before the completion of the stabilization works, due to a heavy rainfall on November 4, part of the sliding slope had completely collapsed, which caused the fifth landslide for the site.

The investigation of the fifth landslides was carried out later. It was found that the main reason for the landslide was the improper excavation. Some of the excavation has an angle of 45° to 50°. As the Contractor believed that the wet season would end and there would be no heavy rainfall in November 2012 just as in November 2011, improper excavation was carried out for the sliding slope.

Another very important reason for the failure of the improper excavated sliding slope may be due to the significant increase of the volumetric water content and the dramatic decrease of the matric suction of the sliding slope. It may be proved that negative pore-water pressure (or matric suction) plays a crucial role in the stability of unsaturated soil slope. With rainfall infiltration, the matric suction in soils at shallow depth would partially or completely disappear. Consequently, a slope failure may occur.

It is a pity that the automatic monitored system has to be abandoned due to the construction.

Figure 5. Failure of the sliding slope during a heavy rainfall on November 4, 2012.

## 6 CONCLUSIONS

From the study of the field monitoring of a monitoring sliding slope in Hainan, China and the failure of the sliding slope at last, the following conclusions can be made:

(1) The volumetric water content increased in the wet season and decreased in the dry season. Correspondingly, the matric suction decreased in the wet season and increased in the dry season.

(2) The variations of the volumetric water content and matric suction with time at different depths were different. Maximum variations often occurred near the ground surface. The large variations of volumetric water content and matric suction during rainy season at shallow depth may explain the

reason why so many slope failures occurred in this region during heavy rainstorms.

(3) The ground water level generally rose during the wet season and fell during the dry season. The rise of the ground water level occurred during heavy rainfall or long after the rainfall. The ground water level also decreased temporarily after the heavy rainfall.

(4) As the volumetric water content increased during the rainfall, the monitored slope was sliding slowly, though insignificantly. Furthermore, the monitored horizontal displacement during the monitored period was not significant, which is probably due to insignificant rise of the groundwater level in the sliding slope.

(5) It is believed that the main reason for the failure of the sliding slope was the improper excavation. It could also be due to the loss of the matric suction, which plays a crucial role in the stability of unsaturated soil slope.

## 7 ACKNOWLEDGEMENTS

The authors would like to thank China Resources Hainan Shimei Bay Tourism & Development Co., Ltd. for their providence of the site and especially their kind assistance during the installation of the instruments and the monitoring of the sliding slope in the field.

# Estimation and Prediction of Debris Flow Potential Using Discrimination Analysis

## Estimation et prédiction du potentiel d'écoulement de boue utilisant une analyse discriminante

Lin M.L., Lin Y.S.

*Department of Civil Engineering, National Taiwan University, Taiwan*

**ABSTRACT:** Taiwan is situated at the juncture of tectonic plates, which caused complex and fragile geological condition with steep mountain terrain. Being frequently struck by typhoons and earthquakes, the landslide and debris flow hazard occurs frequently. In this research, the estimation model of regional debris flow potential was constructed based on the geo-morphological and hydrological conditions of the research area. For constructing the estimation model of debris flow potential, the Fisher's discrimination analysis was used. A study area of Nantou County in Central Taiwan was selected. Influence factors were identified and a database for both debris flow torrents and non-debris flow torrents were constructed. Estimation model was constructed using the Fisher's analysis by random sampling of the debris flow and non-debris flow torrents. The estimation model is validated and then used for prediction of debris flow potential. The final model can be determined by evaluating the estimation stability and prediction rate with each additional influence factor. The resulting potential estimation of the study area appears to be satisfactory. The influence factor stability of the Fisher's discriminant model and the prediction rate associated with the differences in influence factors were discussed.

**RÉSUMÉ :** Taiwan est situé à la jonction de plaques tectoniques, ce qui engendre un terrain escarpé avec des situations complexes et des conditions géologiques fragiles. L'île étant régulièrement frappée par des typhons et des tremblements de terre, des glissements de terrain et des écoulements de boue se produisent fréquemment. Pour cette étude, le modèle d'estimation des coulées de boue régionale potentiel a été construit sur la base des conditions géomorphologiques et hydrologiques de la zone de recherche. Pour la construction de celui-ci, l'analyse discriminante de Fisher a été utilisée. Une zone d'étude du comté de Nantou qui se situe au centre de Taiwan a été choisie. Les facteurs d'influence ont été identifiés et des bases de données pour les torrents d'écoulement de boue et torrents d'écoulement de non-boue ont été construites. Le modèle d'estimation a été construit en utilisant une analyse de Fisher par échantillonnage aléatoire des torrents d'écoulement de boue et des torrents d'écoulement de non-boue. Le modèle d'estimation est validé, puis utilisé pour la prédiction de potentiels écoulements de boue. Le modèle final peut être déterminé en évaluant l'estimation de la stabilité et la fréquence prédite avec chaque facteur d'influence additionnel. L'estimation résultante potentielle de la zone d'étude semble être satisfaisante. Le facteur d'influence de stabilité du modèle discriminant de Fisher et la fréquence prédite associée aux différences des facteurs d'influence ont été discutés.

**KEYWORDS:** debris flow, potential estimation, Fisher's discriminaton analysis, influence factor, prediction model.

## 1 INTRODUCTION

More than 70 percent of areas in Taiwan are in mountain region and with steep and fragile slopes. The earthquakes and heavy rainfall introduced by typhoons often induced significant landslide and debris flow hazards in Taiwan, which lead to significant loss of properties and lives. For effective mitigation of the debris flow hazards, it is important to evaluate the potential of debris flow torrents, which supports decision on mitigation measures and priority.

This research is based on the data of the 1,420 debris flow torrents published by Soil and Water Conservation Bureau in 2003. The fundamental data of the debris flow torrents for the study area of Nantou County in Central Taiwan were collected, and the basic database along with the related influence factors were established utilizing the geographic information system software, Arcview. The influence factors database included watershed area, stream length, hypsometric integral, stream mean slope, form factor, slope distribution, slope aspect and geology category, were extracted from the fundamental data. The statistic analysis was performed on all influence factors to discuss their significances. The multi-variant discrimination analysis was used to discriminate debris flows and non-debris flows. The analysis model was verified, and accordingly the potential of debris flow torrents in Nantou County was evaluated.

## 2 STUDY AREA AND FUNDAMENTAL DATABASE

The Nantou County located in central Taiwan is selected as the study area in this research, which has a large area with high mountains and rugged topography. The debris flow hazard in Nantou County came into great concern since 1996, when Typhoon Herb caused severe losses of properties and lives. In addition, severe debris flow hazard struck this area frequently after the Chi-Chi earthquake, 1999. According to the data published by Soil and Water Conservation Bureau (2003), the number of debris flow torrents reaches 199 in Nantou County, which are for the potential analysis. The distribution of the debris flow torrents and the study area are as shown in Figure 1. The fundamental database used for construction of related database for analysis include: the digital elevation model published in 1989 with a resolution of 40m x 40m, 1/500,000 Taiwan geology map produced by the Central Geological Survey in 1986, aerial photographs, topographical map. The primary geologic formations of the study area include slate, phyllite, sandstone, and shale. According to the engineering geology zonation proposed by Hung in 1997, the research area contents C zone (metamorphic rocks, metamorphic sandstone, shale, slate, phyllite), D zone (sedimentary rocks), E zone (lateritic tableland), and G zone (basin and plain). As shown in Figure 1. Study area and distribution of Debris Flow Torrents and Non-Debris Flow Torrents

Figure 1, most of the debris flow torrents in Nantou County distribute in C zone and D zone.

In order to perform the discriminant analysis, database for both debris flow torrents and non-debris flow torrents are constructed as discussed in the followings:

a. Debris flow torrents: the debris flow torrents in research area are based on the debris flow torrents published by Soil and Water Conservation Bureau in 2003 in 1/5,000-scale. The total number of debris flow torrents in the research area is 199. The watershed of each debris flow torrent was generated using DEM accordingly.

b. Non-debris flow torrents: The procedures for establishing the non-debris flow torrents are to establish watersheds and streams based on the 1/25,000 topographic map and DEM, and are not debris flow torrents by SWCB (Lin, et al. 2003). The non-debris flow should be in the neighboring area of debris flow torrents and with similar geologic traits and watershed size. Accordingly, a total number of 175 non-debris flow torrents was generated in the research area. Cross examination of these torrents were performed by comparing the torrent distribution to the aerial photograph. The results appeared to be consistent, and the distribution of the non-debris flow torrents is as shown in Figure1.

### 3 INFLUENCE FACTORS AND THEIR SIGNIFICANCES

The necessary conditions for triggering debris flow include affluent debris materials, sufficient water supply, and appropriate geomorphological conditions. For evaluation of debris flow potential, the influence factors were selected based on the three conditions, and the database were generated. Based on previous researches (Lin, et al. 2003, Lin and Chen, 2005, and Lin and Wen, 2006), eight influence factors are selected as: watershed area, streams length, hypsometric integral, form factor of basin, stream mean slope, slope angle, slope aspect, and geology formation, respectively.

1. Watershed area: BA, in hectare. The watershed with larger area usually contributes more water, which is regarded as a factor related to the water supply.

2. Stream length: SL, in meter. Stream length means the largest length of the stream in the related watershed. The longer the stream length is, the larger the watershed area is. Stream length is also regarded as another factor of sufficient water supply.

3. Hypsometric Integral: HI, dimensionless. The hypsometric integral is determined from the integral of the basin's height versus area percentage curve, which is a characteristic of geomorphic evolution of the watershed. It also stands for terrain ruggedness and is regarded as a factor related to the abundance of debris material.

4. Form factor: Form factor, FF (dimensionless), is proposed by Horton in 1920, and is defined as the basin area divided by the square of stream length. A higher form factor suggests broader basin shape, and different basin shapes affect flow hydrograph of the stream (Robet and Raymond, 1978).

5. Stream mean slope: SMS, in degree. Stream slope is an important factor related to flow velocity; the steeper the slope is, the faster the stream flow. The stream mean slope serves as an indicator of appropriate slope conditions.

6. Slope aspect: N, NE, E, ES, S, SW, W, WN, in percentage of area ratio. Most debris flow disasters were triggered by typhoon or heavy rainfall. According to the landing path of typhoons, rain falls concentrated more on windward side. Strong wind also influences the weathering process. Slope aspect serves as an indicator of geomorphological condition.

7. Slope distribution: SD10(0°~10°), SD15(10°~15°), SD20(15°~20°), SD30(20°~30°), SD45(30°~45°), SD90(45°~90°), in percentage of area ratio. Steeper slope has a higher tendency of slope failure and leads to more debris material.

8. Geological formation: E1, E2, EO, Mj, Ml, MS, My, O1, O2, O3, P1, P2, Q2, Q3, Q0, as listed in Table 1, in area ratio percentage. Weak rock quality, complicated geologic structure, highly developed fault and fold, and intensive tectonic activity zone tend to provide abundant debris material. Different geological formation contributes to different material strength, degree of fracture, and soil type.

The influence factors were derived from fundamental data through performing spatial and hydrological analysis using GIS and the related database were established. The distributions and characteristics of the influence factors of debris flow torrents and non-debris flow torrents are compared and discussed.

Table 1. Geological formations of the study area

Category	Symbol	Rock Type
Metamorphic Rock (C Zone)	E1	Slate, interlaminations of slate and sandstone
	E2	Indurate sandstone with carbonaceous slate interbeds
	EO	Slate, phyllite, with sandstone interbeds
	Mj	Sandstone, shale
	Ml	Argillite slate phyllite sandstone interbeds
	MS	Sandstone, shale
	O1	Quartzitic sandstone, slate, graphitic shale
	O2	Argillite, indurate sandstone, slate
	Q2	Gravel, laterite, clay, sand
	Q3	Clay, sand, gravel
Sedimentary Rock (D Zone)	My	Sandstone, shale
	O3	Sandstone, shale
	P1	Shale, sandy shale, mudstone
	P2	Sandstone, mudstone, shale
	Q0	Sandstone, mudstone, shale, conglomerate (limestone)

During the analysis, it was found that the distribution of factors for different engineering geological region had different characteristics with significant effects on triggering of the debris flow; the potential analysis of the study area was conducted on whole area with combined geological zones, Zone C, and Zone D, respectively. The number of debris flow and non-debris flow torrents in Zone C are 99 and 95, and 54 and 54 in Zone D as shown in Figure 1. In order to conduct the statical analysis, the independency and significance level of each influence factor was checked using analysis of covariances and Pearson Test. A significance level of 0.1 with 90% of confidence was chosen, and it appeared that the influence factors selected were independent of each other. The resulting significant influence factors for the whole area, Zone C, and Zone D are listed in order of level of significance in Table 2. Due to the complexity of the geological characteristics when the whole area was

analyzed, the principal component analysis was performed on slope distribution and aspect distribution. In Table 2, the PS2 factor indicated a resulting principal component of slope for the whole area. As shown in Table 2, the significant factors are quite different for the whole area, Zone C, and Zone D except with the Hypsometric Integral, HI. This justified that the debris flow potential would be better understood if separate analysis were conducted for regions of different geological properties.

Table 2 The significant influence factors for different geological zones

Order of significance	Whole area	Zone C	Zone D
1	HI	HI	HI
2	PS2	E1	Mj
3	Q0	O1	FF
4	NE	WN	Q0
5	ES	MI	ES
6	My	SD10	O3
7	MI	-	SD10

#### 4 ESTIMATION MODEL OF DEBRIS FLOW POTENTIAL

In this research the multi-variant variables discrimination analysis is used to establish the differential function for debris flow torrents and non-debris flow torrents. The discrimination analysis is to form a linear combination of variables for each associated group to provide estimation values, where the coefficient of each individual variable represents its contribution to the associated group. The differential function of discrimination analysis defines the line which differentiates two groups, and its coefficients help to discriminate properties of each group. This research uses the commercial statistic software, SPSS, with Fisher's discrimination analysis, and analyses are performed for the whole area, Zone C and Zone D. Random sampling of the debris flow and non-debris flow torrents were used assuming normal distribution of each factor. For each analysis, the contributing influence factor was added following the order of significance, and the improvement of the rate of accuracy was checked with each additional factor. The definition of accuracy rate is expressed as the sum of accurately estimated debris flow torrents and non-debris flow torrents divided by the total number of torrents.

1. Whole area with combined geological zones: The analysis was performed over the whole area using 87 sets randomly sampled out of 199 and 175 debris and non-debris flow torrents. It was found that the HI appeared to be the most significant factor; the additional factors were added following the significant sequence of PS2, Q0, NE, ES, My, and MI, with accuracy rate of 78.9%, 81%, 82.2%, 82.2%, 83.3%, 84.5%, and 85.1%. The resulting discrimination function,  $y$ , is:

$$y = 5.108(HI) + 0.090(PS2) - 0.020(Q0) - 0.027(NE) - 0.065(ES) - 0.018(My) + 0.003(MI) - 1.911 \quad (1)$$

The accuracy rate increases more or less steadily with the additional parameters, but the trend is not significant with addition of NE, and the amount of increase in accuracy was not steady, suggesting different contribution of the parameters compared to their significance level.

2. Zone C: The analysis was performed for the Zone C using 40 sets randomly sampled out of 80 sets debris and non-debris flow torrents. It was found that the HI appeared to be the most significant factor; the additional factors were added following the significant sequence of E1, O1, WN, MI, SD10, with accuracy rate of 82.5%, 83.8%, 85.0%, 85.0%, 83.8%, and 83.8%. The resulting discrimination function,  $y$ , is:

$$y = 19.050(HI) + 0.018(E1) - 0.016(O1) + 0.009(WN) - 0.025(MI) + 0.082(SD10) - 11.388 \quad (2)$$

The accuracy rate increases with the additional parameters up till O1, and then remains the same and decreases. Thus, the amount of increase in accuracy does not increase beyond parameter O1. Although the rest of the parameters appear to be significant, they do not contribute to the estimation model

3. Zone D: The analysis was performed for the Zone D using 40 sets randomly sampled out of 54 sets debris and non-debris flow torrents. It was found that the HI appeared to be the most significant factor; the additional factors were added following the significant sequence of Mj, FF, Q0, ES, O3, and SD10, with accuracy rate of 61.3%, 70%, 68.8%, 75%, 80%, 80%, and 80%. The resulting discrimination function,  $y$ , is:

$$y = -5.070(HI) + 0.036(Mj) - 1.516(FF) - 0.015(Q0) - 0.083(ES) + 0.024(O3) + 0.009(SD10) + 4.731 \quad (3)$$

The accuracy rate increases with the additional parameters till ES and then remains the same. It suggests that the addition of O3 and SD10 parameters does not improve the accuracy rate, although both parameters are significant.

Observing the estimation models for the three regional analyses, the accuracy rate has a tendency to increase with the additional factors, and the HI factor appears to be the most effective factor in all three models. For all three models, the coefficient of each parameter indicates the contribution of the parameter, and is consistent with the variation in accuracy rate. However, the effectiveness of the influence factors is not fully in accord with the order of factor significance shown in Table 2. Therefore, the level of significance of the parameter could not be correlated to the contribution of the parameter to the estimation model.

#### 5 VALIDATION AND PREDICTION

In order to verify the feasibilities of the potential estimation model discussed previously, the data sets of debris flow torrents and non-debris flow torrents not used in developing the estimation models were used for validation and prediction. A total of 112 debris flow torrents and 87 non-debris flow torrents were used for the prediction of the whole area using Eq.1. A total of 40 sets of debris flow and non-debris flow torrents were used for the Zone C, and a total of 14 sets of debris flow and non-debris flow torrents were used for prediction using Eqs. 2, and 3, respectively. The prediction accuracy rates were compared to the estimation accuracy rates for whole area with combined geological zones, Zone C, and Zone D, as shown in Figure 2, Figure 3, and Figure 4, respectively.

From Figure 2, it was found that the accuracy rate for prediction increased steadily up to ES but then decreased with additional factor for whole area with combined geological zones compared to the estimation model. Therefore, the factors used for the model are only up to ES, and the model is rectified as:

$$y = 4.955(HI) + 0.090(PS2) - 0.0205(Q0) - 0.027(NE) - 0.065(ES) - 1.741 \quad (4)$$

Figure 2. Accuracy rates of estimation and prediction for whole area

Figure 3. Accuracy rates of estimation and prediction for Zone C

The estimation accuracy rate is 83.3%, and the prediction accuracy rate is 82.4% with a difference of 0.9%.

From Figure 3, it was found that the accuracy rates for both estimation and prediction increased steadily with additional factor up to O1 but then varied for Zone C. It appears that the accuracy rate would become stable only with factors up to O1, and the model is rectified as:

$$y = 15.531(HI) + 0.019(E1) - 0.007(O1) - 9.255 \quad (5)$$

The estimation accuracy rate is 85.0%, and prediction accuracy rate is 81.3% with a difference of 3.7%.

From Figure 4, the accuracy rates varied for both estimation and prediction, but the accuracy rates increased steadily with additional factor up to ES for Zone D. It appears that the accuracy rate would become stable with the factors up to ES only, and the model is rectified as:

$$y = -5.685(HI) + 0.032(Mj) - 1.504(FF) - 0.015(Qo) - 0.085(ES) + 5.380 \quad (6)$$

The estimation accuracy rate is 80.0%, and the prediction accuracy rate is 78.6% with a difference of 1.4%.

For all three analyses, the prediction curves appear to be quite stable and approach the estimation curves with the similar trends. The resulting accuracy rates are satisfactory and the differences between prediction accuracy rate and estimation accuracy rate of all three models are all within 4%. Thus the discrimination functions used is good for differentiating debris flow torrents from non-debris flow torrents with satisfactory results. Comparing the three modified function equations, not all factors contributed effectively to the model for all three models. The prediction accuracy rate actually reduced if all the factors were included, which suggested over-fitting of the estimation models. Observing the number of factors used for the whole area prediction model is higher than the Zone C and Zone D, it may do to the complexity of multi-geological zones included. The accuracy rate of the Zone D analysis appeared to be lower than the other two analyses, which might due to less samples were available for estimation and prediction compared to number of samples in whole area and Zone C.

Based on the analysis results, the potential of debris flow torrent can be evaluated using distribution of the calculated discrimination function. The accumulated distribution density

Figure 4. Accuracy rates of estimation and prediction for Zone D

of 30% and 70% values are selected as the boundary indicators for low-moderate and moderate-high potential. For the whole area analysis, the discrimination function value for 30% is 0.506 and 3.092 for 70%. Thus the debris flow torrents with discrimination values greater than 3.092 are classified as high potential and moderate potential when discrimination values range within 0.506 to 3.092. The debris flow torrents are considered as low potential when the values are less than 0.506. Similar procedures were applied to Zones C and D. For Zone C the discrimination value for 30% accumulation is 0.765, and 3.143 for 70% accumulation. The discrimination value for 30% accumulation is 0.325 and for 70% is -1.720 for Zone D. Thus the potential of debris flow torrents can be evaluated in all three analysis models.

## 6 CONCLUSIONS

In this research, the potential analysis of the debris flow torrents in Nantou County was performed using discrimination analysis. The influence factors included: watershed area, stream length, form factor, hypsometric integral, stream mean slope, slope distribution, slope aspect, and geological formation. Base on the previous discussions, most influence factors selected are within significance level. Among the factors used, the hypsometric integral appears to be the most important factor, which is a characteristic of geomorphic evolution of the watershed. The second most important factor is the geological properties of the analysis area. For all three models, the accuracy rates are about 80%, which suggests that the discrimination analysis provide satisfactory results. The accuracy rate for Zone D is slightly smaller than the accuracy rates for both the whole area and Zone C, which might due to smaller sample sizes in both estimation and prediction compared to the sample sizes of the whole area and Zone C. The final model could be determined based on the stability of accuracy rates in both estimation and prediction. However, not all the significant factors are contributing to the model effectively. The final potential of the debris flow torrents can be evaluated based on the values of discrimination function in all three models properly.

# Value of Landslide Investigation to Geotechnical Engineering Practice in Hong Kong

## Ingénierie des glissements de terrain à Hong Kong

Lo D.O.K., Lam H.W.K.

*Geotechnical Engineering Office, Civil Engineering and Development Department, Government of the Hong Kong SAR*

**ABSTRACT:** On average, about 300 landslides were reported to the Geotechnical Engineering Office (GEO) of the Civil Engineering and Development (CEDD) in Hong Kong each year. Over the years, GEO conducted landslide investigations to advance knowledge on slope performance and improve understanding of the causes and mechanisms of landslides. Landslide investigations have become an integral part of the Government's Slope Safety System in Hong Kong. Studies on notable landslides on man-made slopes have led to the use of more robust stabilisation measures for cut slopes, improved rock slope engineering practices, enhanced practices in the monitoring and maintenance of water-carrying services affecting slopes and improvement to drainage detailing. Studies on natural terrain landslides have allowed better understanding on the modes and mechanisms of failure. This also enables advancement in debris mobility assessment which is critical to natural terrain risk management. This paper highlights some key lessons learnt and observations made from selected landslide investigations and how this knowledge helps advance the geotechnical engineering practice in dealing with man-made slopes and natural terrain landslide hazards in Hong Kong.

**RÉSUMÉ:** En moyenne, environ 300 glissements de terrain sont signalés au Bureau Géotechnique (GEO) chaque année. Au fil des années, les enquêtes de glissements de terrain sont menées par le GEO et jouent un rôle clé dans l'avancement des connaissances sur la stabilité des pentes et la compréhension des causes et des mécanismes de glissements de terrain et sont devenus une partie intégrante du système de sécurisation des pentes à Hong Kong. Les études sur les glissements de terrain sur les pentes anthropiques ont conduit à l'utilisation de mesures plus robustes pour la stabilisation des pentes artificielles, l'amélioration des pratiques d'ingénieurs pour les pentes dans les matériaux rocheux et l'amélioration des pratiques de suivi. Les études sur les glissements de terrains naturels ont permis de mieux comprendre le mode et les mécanismes de défaillance. Cela permet également l'amélioration de l'évaluation des déplacements des boues, ce qui constitue un point essentiel dans la gestion des risques naturels. Ce document met en lumière certains des principaux enseignements tirés des observations faites à partir des enquêtes de glissements de terrain sélectionnés et comment cette connaissance contribue à l'avancement de la pratique de la géotechnique dans le traitement des pentes artificielles et naturelles à Hong Kong.

**KEYWORDS :** landslides, investigation, geotechnical engineering practice

### 1. INTRODUCTION

The rapid population growth in Hong Kong since the 1960s and substantial economic expansion has been accompanied by extensive civil engineering and building works, resulting in the formation of a considerable number of man-made slopes and retaining walls over the hilly territory. However, as there was very limited geotechnical control of slope formation in the old days, the stability of many of these slopes is therefore in doubt. Coupled with severe rainstorms and dense hillside development, Hong Kong is prone to landslide risk.

Following a number of landslide disasters in 1970s, the Hong Kong Government established the Geotechnical Control Office in 1977 (renamed as the Geotechnical Engineering Office (GEO) in 1991) to regulate geotechnical engineering works and slope safety in Hong Kong. This paper gives an overall review of the slope engineering practices that have been enhanced as a result of the landslide investigation (LI) findings.

### 2. GEOTECHNICAL STANDARDS AND PRACTICE

Setting geotechnical standards has been one of the GEO's functions. To date, some 300 guidance documents have been published covering standards of good practice for the investigation, design, construction and maintenance of slopes.

For public development projects, the prevailing Government policy stipulates that all permanent geotechnical works involving slopes and retaining walls as well as related activities, including investigations, designs and construction should be carried out in accordance with the prevailing standards. Details of the geotechnical works are required to be

submitted to the GEO for checking. In general, the standards for public development projects are also adopted for private building and civil engineering works in Hong Kong.

### 3. LANDSLIDE INVESTIGATION

Figure 1: The Kwun Lung Lau Landslide in July 1994

On average, about 300 landslides are reported to the GEO each year. Most of these occurred at man-made slopes affecting buildings, roads or pedestrian walkways. Many landslides which occurred in remote areas or in natural terrain were not reported. Prior to mid-1990s, the GEO conducted LI on few selected cases of technical interest or having significant consequence. The occurrence of a number of fatal landslides in the mid-1990s has highlighted the need to further enhance the landslide risk management strategy in

Hong Kong. Following the Kwun Lung Lau landslide of 23 July 1994 (Figure 1), which killed five people and seriously injured three others (Morgenstern & GEO 2000), the GEO introduced a number of new enhancement initiatives including a systematic LI programme. The scope of landslide investigations includes examination of all reported landslide incidents and in-depth studies of selected landslides to identify the causes of failure and necessary follow-up actions. The objectives of the systematic LI are to identify those slopes in need of early attention, and undertake forensic investigation of landslides that involve coroner inquests, legal actions or financial disputes. Through landslide investigations, the performance of the Government's slope safety system will be reviewed and areas for improvement identified. Landslide investigations help advance the understanding of causes and mechanisms of landslides and enhance slope engineering practices and the reliability of landslide preventive or remedial works.

The annual expenditure of the LI programme is about US\$3 million. Based on observations from LI, new guidelines are promulgated to improve the prevailing geotechnical practice. Some salient LI observations and improvements for soil cut slopes, rock slopes, retaining walls, fill slopes and natural hillside are described below.

#### 4. SOIL CUT SLOPES

Soil cut slopes formed or treated prior to 1990s typically involved trimming back to a less steep gradient without the provision of reinforcement or structural support. They are prone to degradation and vulnerable to the presence of local weaknesses in the groundmass. Large scale landslides involving such unsupported cut slopes are not uncommon. Notable examples are the Ching Cheung Road landslide in 1997 (Figure 2) and Shek Kip Mei failure in 1999 (Figure 3). The 1997 Ching Cheung Road landslide involved a failure volume of over 2,000 m<sup>3</sup>, resulting in the trapping of a motor car and temporary closure of a major route connecting east and west Kowloon for two months. The Shek Kip Mei failure involved a distressed volume of 6,000 m<sup>3</sup>, resulting in permanent evacuation of three housing blocks. Findings from investigation of such failures highlight the vulnerability of unsupported cut slopes to adverse geological features and hydrogeological conditions, which may be difficult to detect. A pragmatic approach of adopting more robust design solutions, such as the use of soil nailing was called for. A soil nailed slope tends to behave as an integral mass and is less sensitive to local adverse conditions as compared with an unsupported cut. The use of soil nailing has been widely adopted for upgrading of slopes in Hong Kong since mid 1990s.

Figure 2: The Ching Cheung Road Landslide in 1997

So far, there are 40 failures among some 7000 slopes installed with soil nails. None of these are major landslides

(volume  $\geq 50$  m<sup>3</sup>). This indicates that the use of soil nails is effective in averting large scale failure. These minor failures were mostly involved surface erosion or minor local detachment in the groundmass between soil nail heads. Lessons learnt from investigation of soil-nailed slope failures have led to enhanced understanding of the behaviour of soil-nailed slopes (e.g. the importance of soil-nail head), improved detailing of surface drainage provisions (e.g. provision of intersecting drains for long sloping grounds), and enhanced surface protection details. Advances have also been made in the design of soil nails, as promulgated in the Geoguide 7 (GEO 2008).

Figure 3: Laterally-persistent discontinuity infilled with slickensided kaolin and manganese oxide deposits at the 1999 Shek Kip Mei failure

#### 5. ROCK SLOPES

Major failures (volume  $\geq 50$  m<sup>3</sup>) involving rock slopes are not very common. Most of the landslides were rain-induced and structurally-controlled, involving build-up of cleft water pressure in rock joints. Other contributory factors such as presence of soft infill along discontinuities, slope deterioration, root wedging effect, etc were also noted. These failures highlight the importance of identifying adversely-orientated jointing system which could have implication to the stability of slopes in the design. With respect to minor rock slope failures such as rockfalls, the primary causes were due to presence of local adverse groundwater regimes and/or loose or unstable blocks. Many of the rockfalls were initiated by tree-root actions. Given the scale of the failure and the consequence of the failure in the urbanized setting in Hong Kong, rockfalls are difficult to guard against in design. A pragmatic approach is to provide suitable protective and mitigation measures such as rock mesh netting, rock fall fence and buffer zone where practicable. LI findings are incorporated in the relevant manuals and guidelines to enhance the rock slope engineering practice (GEO 2009).

#### 6. RETAINING WALLS

A few major landslides involving retaining wall failures had occurred in the past, the most notable one being the 1994 Kwun Lung Lau landslide. The landslide involved the a brittle collapse of a 100-year old masonry wall (Morgenstern & GEO 2000) releasing 1000 m<sup>3</sup> of debris causing 5 fatalities. No tell-tale sign was reported prior to the failure. The failure was triggered by saturation of the soil behind the masonry wall as a result of leakage from nearby defective buried water-carrying services. The incident highlighted the importance of regular inspection and maintenance of water-carrying services affecting slopes. Following the incident, a guidance document entitled "Code of Practice on Inspection and Maintenance of Water Carrying Services Affecting Slopes" was issued by the Government, setting out the recommended good practice for regular inspection and maintenance of water-carrying services affecting slopes.

Furthermore, the landslide investigation findings indicated that the failed wall was 10 m high but only about 0.8 m thick. The wall thickness is much less than that indicated in the record available. This incident highlighted the danger of slender masonry walls that are liable to fail in a brittle manner without any prior signs of distress, and the importance of verifying the wall thickness in stability assessment. This lesson learnt was incorporated in the guideline for stability assessment of old masonry walls (GEO 2004a).

## 7. FILL SLOPES

Following the disastrous failure of a fill slope at Sau Mau Ping in 1976, the Government appointed an Independent Review Panel to review the landslide problem and make recommendations on the design of fill slopes in Hong Kong. The Panel recommended, amongst others, that the minimum treatment of existing loose fill slopes should consist of removing the loose surface soil by excavating to a vertical depth of not less than 3 m and recompacting to an adequate standard, together with the provision of subsurface drainage behind the recompacted fill layer at the toe of the slope. Technical guidance on the treatment of existing loose fill slopes is given in relevant manual and technical circular (GCO 1984, GEO 2004b).

Up to 2012, about 260 loose fill slopes have been upgraded using the recompaction approach by the GEO. Between 1997 and 2012, a total of 18 landslides occurred on recompacted fill slopes. The primary causes of landslides of these incidents are:

- (a) Surface flow concentration
- (b) Leakage or bursting of water-carrying services
- (c) Inadequate subsurface drainage provisions

Discounting washout failures due to concentrated surface water flow or leakage of water-carrying services, landslides on recompacted fill slopes were generally ductile in nature and did not involve sudden and fast-moving debris as in liquefaction failure.

Enhancement measures have been implemented with reference to the lessons learnt from these landslides. For instance, the Code of Practice on Monitoring and Maintenance of Water Carrying Services Affecting Slopes, which was first issued in 1996, has been updated taking into account lessons learnt from landslides triggered by leakage or bursting of water-carrying services (ETWB 2006).

Detailing of slope drainage provisions has also been improved. Areas for improvement include provision of adequate movement joints for surface drainage channels and provision of filter pipes at upstream end of the subsurface drainage blankets behind the recompacted fill etc. The improvement measures were promulgated in the GEO Report Nos. 210 and 225 (Hui et al. 2007, Fugro 2008)

## 8. NATURAL HILLSIDE

Hong Kong has a land areas of about 1,100 km<sup>2</sup>. About 60% is natural terrain, over 30% of which has a slope gradient over 30°. Natural terrain landslides in Hong Kong are mainly rain-induced. Most of them occurred in remote areas while some affects developments. The GEO has been undertaking technical development works based on the study of natural terrain landslides since the early 1990s.

Based on observed runout distance of landslide debris, a set of simple and suitably conservative guidelines has been developed (Wong 2003) for initial screening purposes to assist planners, land administrators, project managers, etc. to review whether or not a given site is subject to natural terrain

landslide hazards. Where a site is shown to be potentially affected by landslide hazards, more refined criteria are then used to examine whether the proposed development meets the 'in-principle objection' criterion (i.e. relocate the proposed development or amend development layout), or the 'alert criteria' (i.e. carry out natural terrain hazard study and appropriate mitigation measures as part of the development).

In June 2008, Hong Kong was hit by a severe rainstorm. The short-duration rainfall intensity had a return period of about 1,000 years. The rainstorm triggered over 2,400 natural terrain landslides mainly on Lantau Island. Some of them affected developed areas and caused significant social disruption such as evacuation of houses and temporary closure of road sections. The GEO carried out systematic studies on some of these landslides. Detailed field mappings and in-depth landslide investigation provided valuable insights into the characteristics of natural terrain landslides.

Comparing the June 2008 landslides with past landslide records revealed that the 2008 landslides seem to 'cluster' around old ones. Up to 92% of the 2008 landslides occurred within 50 m of at least one past landslide, and 80% within two or more past landslides (Wong 2009). Although further work is needed to interpret this phenomenon, this sheds light on the prediction of regions of natural terrain that is more prone to failure and has implications in the determination of natural hillsides that warrant priority for the mitigation of landslide hazards.

Figure 4: Landslide on the hillside behind the Hong Kong University

Detailed landslide investigations on selected June 2008 landslides showed that past failures could have a significant implication to the scale of the landslides. Past failures could lead to extensive colluvial accumulations on hillside, which are susceptible to give rise to a laterally extensive and a much larger scale failure during heavy rainstorm than those in the past (Figure 4) (Maunsell 2009). If the debris of previous failures deposited along the drainage line, it could become 'entrainable', giving rise to a larger scale of a channelized debris flow (CDF) event (Figure 5) (AECOM 2009). In the 2008 rainstorm, significant entrainment was noted in many of the long runout CDFs with entrainment ratio up to 10 or higher (the entrainment ratio is the volume of additional material that has been entrained by a landslide expressed as a proportion of the source volume). The amount of the pre-existing 'entrainable' materials in a drainage line is dynamic and may change significantly after a rainstorm. This highlights the implications of the deposition of debris from past failures on occurrence of some large-scale failures in natural hillsides.

Figure 5: Yu Tung Road channelized debris flow

In general, the June 2008 landslide debris was found to be more mobile when compared with the previous historical natural terrain landslides in Hong Kong (Figure 6). About 20% of the June 2008 landslides have runout distances over 100 m, as compared with about 10% in past landslides that are observed from old aerial photographs.

Figure 6: Distribution of landslide runout distance

Detailed studies on selected CDFs revealed that some of the CDFs with long runout generally involved debris with high water content, e.g. the failure near Yu Tung Road (Figure 5). After detaching from the source of failure, the debris mixes with a large amount of water along the drainage line, and results in higher debris mobility. LI revealed that a number of circumstances may lead to such ‘watery debris’, such as:

- (a) debris flows along a major drainage line with a large catchment and a long flow path;
- (b) debris flows occurring during heavy rain; and
- (c) debris flows along a main drainage line into which many tributaries of drainage lines are feeding.

To facilitate the modeling of debris mobility under such circumstances for natural terrain hazard studies, systematic back analyses were carried out on some selected long runout CDFs that occurred in June 2008 using a 2-D dynamic modelling algorithm, known as ‘debris mobility modeller’ (2d-DMM) program, as well as 3d-DMM in some cases, to refine the modeling parameters. Improved guidance on debris mobility modeling was promulgated by the GEO (2011).

## 9. CONCLUSIONS

The landslide investigations have brought insights into the causes, mechanisms and characteristics of landslides. The investigations enhance the understanding of the behaviour of man-made slopes and natural hillside under severe rainstorm

and the findings have helped to advance geotechnical engineering practices, and improve standards and design guidelines for enhancing the robustness of slope upgrading and landslide mitigation works.

# Analyses of Seismic Slope Stability and Subsequent Debris Flow Modeling

Analysis de stabilité de pente sous sollicitation sismique et modélisation des écoulements de boues induits

Long X., Tjok K.-M.  
Fugro GeoConsulting Inc., Houston, Tx

**ABSTRACT:** Earthquake-triggered slope failures and subsequent submarine debris mass flow can cause severe consequences and jeopardize the integrity of offshore structures in the proximity. In this paper, a two-dimensional seismic slope stability analysis for an offshore liquefied slope site located in American Petroleum Institute (API) seismic zone 4 with layered stratigraphy is addressed. A nonlinear dynamic analysis using the stress-strain law of “hysteretic modeling” allowing for soil weakening under large strains was adopted to study flow failure instability. Laboratory tests were performed for the derivation of soil dynamic parameters and calibration of hysteretic soil model. Using “Constant-volume” constraints, the run-out distance of subsequent debris flow was also estimated.

**RÉSUMÉ :** Lors de séismes, les ruptures de pentes et les écoulements (de boue) sous-marin qui s’en suivent peuvent avoir des conséquences graves et compromettre l’intégrité des structures « offshore » voisines. Dans cet article, on présente une étude (2D) de stabilité d’une pente dans un site « offshore » liquéfiable, dans un zone sismique de niveau 4 (référentiel de l’American Petroleum Institute). Une analyse dynamique non-linéaire utilisant la loi « hysteretic modeling » (loi permettant la modélisation du radoucissement en grande déformation) a été adoptée pour étudier la rupture des pentes et les écoulements induits. Des tests de laboratoire ont été effectués afin d’identifier et de déterminer les paramètres numériques de la loi de comportement. En se plaçant dans le cadre des déformations à volume constant, la modélisation a permis d’estimer la distance parcourue par les écoulements de boues.

**KEYWORDS:** earthquake slope debris flow non-linear dynamic.

## 1 INTRODUCTION

Earthquakes are one of the major causes of submarine slides. Large shear stresses and deformations may be generated due to seismic vibrations and irrecoverable volume changes are accumulated accompanied by the rise of pore water pressure (i.e., decrease of effective stress) and cyclic degradation of shear strength. Liquefaction occurs when the effective stress equals zero and soil behaves as a liquid. The submarine debris mass flow following the onset of liquefaction and instability of liquefied slope can pose significant impact force and thus jeopardize the integrity of offshore structures in the flow path.

In this paper, a two-dimensional seismic submarine slope stability analysis is performed using commercial computer program FLAC (*Fast Lagrangian Analysis of Continua*) (Itasca, FLAC 7.0, an explicit finite difference program operating in the time domain. It simulates the behavior of soils which may subject to plastic flow when their yield limits are reached. The Finn Model- Byrne Formulation is implemented in the analysis to assess dynamic pore pressure generation and liquefaction potential. Based on “constant-volume” constraints, the run-out distance of subsequent debris flow was predicted using the one-dimensional subaqueous debris flow model BING (Imran and Parker, 2001).

## 2 TWO-DIMENSIONAL NON-LINEAR DYNAMIC ANALYSIS

The slope stability and liquefaction potential for a project site under seismic loading is assessed using FLAC for a two-dimensional non-linear dynamic analysis. The dynamic stress-strain behavior for the soil layers are simulated using a hysteretic model by means of a non-linear stress-strain backbone curve and the associated stress-strain loops that represent

the energy dissipated in the soil during seismic loading. Strain-controlled cyclic simple shear tests have been performed to determine dynamic soil parameters and calibration of hysteretic soil model.

### 2.1 Site Condition

The site is located in International Organization for Standardization (ISO) seismic zone 4 (ISO 2004). Soil stratigraphy consists of soft to firm clay layers overlying dense fine sand. Based on the in situ suspension P (compression wave velocity)-S (shear wave velocity) logging and cone penetration test (CPT) data, the upper 33m (100ft) of the effective seabed is around 160 m/s (525 ft/s) and the site is classified as either American Petroleum Institute (API) criteria Type C or ISO criteria Type E.

Figure 1 below illustrates the soil stratigraphy at the study site. The subsurface conditions comprise of 50 m (160 ft) soft to firm clay underlain by a layer of dense to very dense fine sand down to 105 m (350 ft). The mean sea level is 61.0 m (200 ft) above seafloor. Due to soil erosion, a 20° slope is formed as detected from the geophysical multibeam bathymetric data. In light of variations of material parameters, three soil Strata, i.e., Stratum I, II and III, respectively, are defined within the clay sediment. For the study of effective stress analysis, four Strata with Stratum I, II and III for cohesive materials and Stratum IV for cohesionless sediment, are used. The soil parameters including submerged unit weight  $\gamma$ , average shear wave velocity  $V_s$ , cohesion  $c$ , and friction  $\phi$  for each stratum are also provided on the figure.

The laboratory test data from cyclic direct simple shear (CDSS) along with the generic curves of similar soil types (Seed & Idriss for sand) were used as guidance to develop hysteretic model for the analysis. Figure 2 presents the dynamic

soil characteristics used in the model as defined by the shear modulus degradation ( $G/G_{max}$ ) and damping ratio ( $D$ ) curves.

Stratum	Soil Parameters for Effective Stress Analysis
I (4.3m (14ft) thick)	$\gamma=726 \text{ kg/m}^3, V_s=122 \text{ m/s}, c=4.8 \text{ kPa}, \phi=15^\circ$
II (21.3m (70ft) thick )	$\gamma=807 \text{ kg/m}^3, V_s=186 \text{ m/s}, c=5.8 \text{ kPa}, \phi=20^\circ$
III (23.5m (76ft) thick)	$\gamma=888 \text{ kg/m}^3, V_s=300 \text{ m/s}, c=5.8 \text{ kPa}, \phi=20^\circ$
IV (58.0m (190ft) thick)	$\gamma=1000 \text{ kg/m}^3, V_s=335 \text{ m/s}, \phi=35^\circ$

Figure 1. Soil stratigraphy for the study site (Not to scale).

Figure 2. Soil dynamic characteristic curves

### 2.2 Characteristic of Earthquake Input Motion

The peak ground acceleration (PGA) of the earthquake motion is 0.48 g with a duration time of 40 sec. As indicated from the

power spectra of input velocity and input acceleration as shown on Figure 3, the highest frequency component of the input motion is less than 10 Hz with the majority of the frequencies are less than 6 Hz. The input motion is applied at the depth of 105m (350ft).

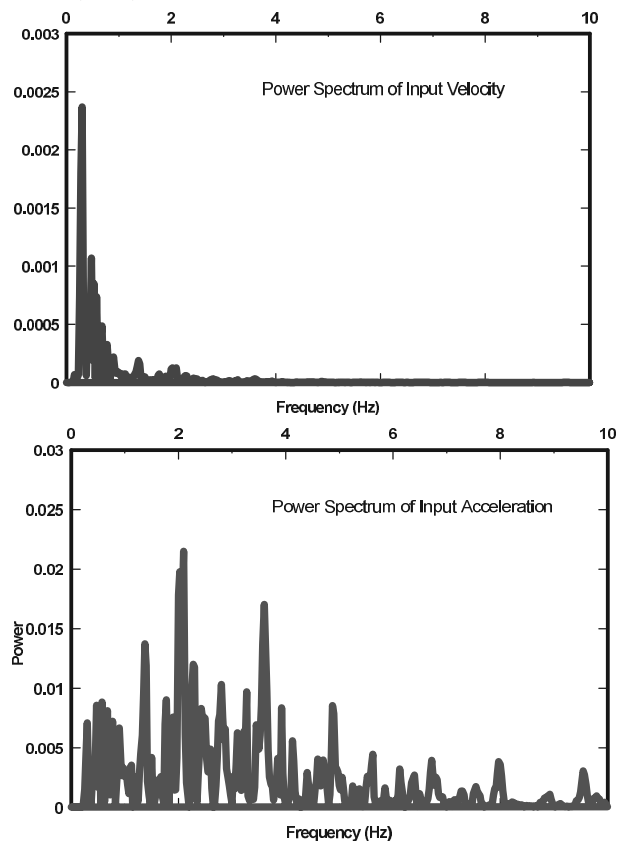

Figure 3. Acceleration time history and power spectrum of input motion.

### 2.3 Two-Dimensional Numerical Modeling

Kuhlemeyer and Lysmer (1973) state that for accurate representation of wave transmission through a model, the spatial element size,  $\Delta l$ , must be smaller than approximately one-tenth to one-eighth of the wavelength associated with the highest frequency component of the input wave, i.e.,  $\Delta l \leq \lambda/10$ , or  $\leq C_s/(10\Delta l)$ , where  $\lambda$  is the wavelength associated with the highest frequency component that contains appreciable energy; and  $C_s$  is speed of propagation associated with the mode of oscillation. Since the majority of the frequencies of input motion are less than 6.0 Hz, a 1.83m (6ft) x 1.83m (6ft) mesh size is selected for the modeling. The maximum frequency that can be modeled accurately for this element size is 6.7 Hz. The frequency of Dynamic excitation to the FLAC model was specified using the compliant-base deconvolution procedure (Mejia and Dawson, 2006). The input excitation was specified as a stress time history at the base of the model as a function of mass density  $\rho$ , shear wave velocity  $V_s$  at the half-space depth (105 m (350 ft) below seafloor) and input shear particle velocity  $v$ . Figure 4 demonstrates the FLAC mesh with rectangular and triangle shapes for this two-dimensional analysis. The free-field on vertical sides and quiet boundary conditions at the bottom are applied in the soil domain.

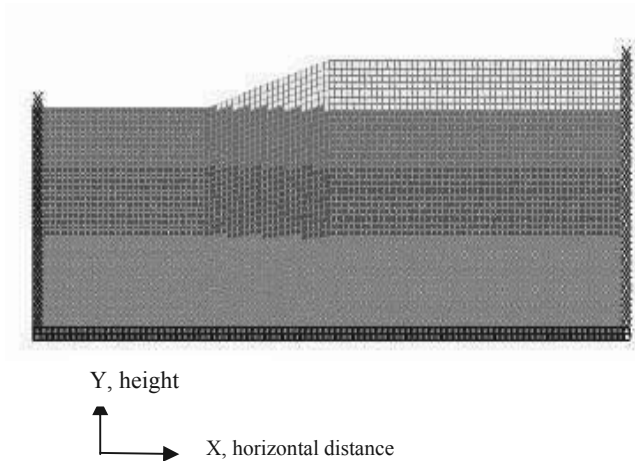

Figure 4. FLAC model for the modeling

The static equilibrium state at the time of the earthquake event is established to obtain the initial shear-stress distribution of the soil mass. The preliminary analysis, assuming undamped elastic-material, was performed to estimate maximum levels of cyclic shear strains and velocity levels throughout the model during the dynamic excitation. The maximum shear strain contour from the preliminary run is shown on Figure 5 indicating that the maximum elastic shear strains are smaller than 0.7 % throughout almost the entire modeled area. This range of shear strains is considered appropriate for inclusion of hysteretic damping based upon the dynamic characteristics of the soils as illustrated on Figure 2. The frequency range for the natural response of the elastic materials is calculated to be relatively uniform throughout the model, with a dominant frequency of approximately 3 Hz.

A fully coupled nonlinear seismic analysis is performed using the Mohr-Coulomb model to represent the soil layers, with additional hysteretic damping applied to simulate the non-linear soil dynamic behavior. Due to the fact that hysteretic damping does not completely damp high frequency component, a small amount of stiffness-proportional Rayleigh damping is also employed in the analysis.

The Finn-Byrne model is used for the liquefaction simulation by considering Strata I and II as liquefiable materials. Based on CPT/SPT correlations from in-situ CPT data and fine contents (Kulhawy and Mayne, 1990), the equivalent normalized SPT blow counts are assigned for the two strata. The automatic rezoning logic is applied in the analysis to correct for severely distorted mesh conditions developed during the simulation of earthquake shaking. The onset of liquefaction is identified by the cyclic pore-pressure ratio,  $u_e/\sigma'_c$ , where  $u_e$  is the excess pore pressure and  $\sigma'_c$  is the initial in-situ effective confining pressure. After the liquefaction, the soil shear strength is reduced to residual strength which is 30% of the original value.

The numerical analysis indicates the development of liquefaction and failure surface in the slope. Figure 6 displays the contours of maximum shear strain at the end of earthquake excitation (40 seconds). The contour of excess pore pressure ratio equaling 1 (onset of liquefaction) at 40 seconds is also marked in green line on Figure 6. Figure 7 shows the vertical and horizontal displacement histories at the slope crest. The negative sign for X and Y axes indicate the left direction and downward direction, respectively. the slope moves horizontally approximately 8.5m.

Figure 5. Maximum shear strain contours from undamped elastic analysis

Figure 6. Shear strain contours and excess pore pressure ratio=1 contour at 40 seconds

Figure 7. Horizontal (x) and vertical (y) displacement histories at crest of the slope

### 3 DEBRIS FLOW RUN-OUT DISTANCE

After the development of liquefaction and failure surface in the slope, debris flow can be triggered and the remolded mass during initial failure travels further downslope until the initial stored potential energy is dissipated by friction.

The debris flow run-out distance can be estimated using one- or two- dimensional numerical modeling of sediment-laden submarine flow. For this study, the one-dimensional (1-D) model *BING* assuming one phase flow and “constant volume” constraint. The required input for the simulation includes the bed profile over which the debris mass flow, the initial configuration of the pile of debris slurry, rheological parameters describing the debris slurry and numerical parameters to describe spatial and temporal discretization, run duration and

soil viscosity (Imran and Parker, 2001& 2001). The Herschel-Bulkley rheological model is used for the run-out distance prediction. In the absence of laboratory test data, the yield strength  $\tau_y$  of 1.5 kPa (30 psf) and reference strain rate  $\dot{\gamma}_r$  of 1/s were adopted using published relationships as shown on Figure 8 based on soil liquidity index LI (Locat and Lee, 2002).

Figure 8. Relationship between yield strength, dynamic viscosity, and soil liquidity index (Reproduced from Locat and Lee, 2002)

Considering debris flow originated at the bottom of the slope and the flow origination mass length of around one-half of the sliding mass length, the estimated run-out distance is around 25 m from the toe of the liquefied slope. These mobilized debris flow mass may pose significant impact force against subsea infrastructure in the flow path, even lead to loss of foundation support.

#### 4 CONCLUSIONS

Dynamic slope instability due to earthquake excitation and subsequent submarine slides can cause mass gravity flow which may cause significant impact force or the loss of foundation support and thus pose great risk for the integrity of offshore structure along the flow path. This paper demonstrated the ability of using a fully coupled nonlinear effective stress analysis to simulate the development of liquefaction and the instability of liquefied slope. The prediction of run-out distance of subsequent debris flow was also discussed here. For practical application, it should be emphasized that the numerical model for assessing the run-out distance should be tested and calibrated with identified historic mass transport deposits (MTD) and geomorphologic conditions along study site.

# Quantitative risk assessment for earthquake-triggered landslides using Bayesian network

## Évaluation quantitative du risque associé aux glissements de terrain déclenchés par séisme en utilisant un réseau Bayésien

Nadim F., Liu Z.Q.

Norwegian Geotechnical Institute (NGI) / International Centre for Geohazards (ICG), Norway

**ABSTRACT:** Strong earthquakes in mountainous regions usually trigger many landslides that lead to damage and destruction. Separate investigations of single hazard processes (earthquake and landslide) might lead to a misjudgement of the risks associated with this type of cascading hazards. The assessment and mitigation of the risks require a multi-risk analysis approach that can account for the interactions among the threats and among the vulnerabilities to these threats. In this paper, a quantitative risk assessment model using Bayesian network is proposed to estimate the risk for the buildings exposed to the threat of earthquake-triggered landslides. A sensitivity analysis was done to identify the optimum and appropriate risk reduction strategy in a multi-hazard perspective.

**RÉSUMÉ :** De forts séismes dans les régions montagneuses déclenchent habituellement des nombreux glissements de terrain qui mènent à dommages et destruction. Si l'on traite les aléas singuliers séparément, par exemple un tremblement de terre et un glissement de terrain, une estimation erronée des risques associés à ce type d'aléas cascades peut être obtenue. L'évaluation et l'atténuation des risques nécessitent une approche multi-risques qui doit tenir compte des interactions entre les dangers et les vulnérabilités à ces dangers. L'article propose un modèle d'évaluation quantitative des risques en utilisant un réseau Bayésien pour estimer le risque aux bâtiments exposés aux glissements de terrain déclenchés par un séisme. Une analyse paramétrique a été réalisée pour identifier une stratégie optimale et appropriée pour réduire le risque dans une perspective multi-aléas.

**KEYWORDS:** Landslides, Earthquake, Quantitative risk assessment, Bayesian network

### 1 INTRODUCTION

Earthquake-triggered landslides are one of the most common secondary disasters caused by earthquake in mountainous areas. In the Wenchuan earthquake of May 2008, more than 15 000 landslides of various types were triggered in the steep mountain slopes (Huang 2008). The landslides caused more than 20 000 fatalities (Yin *et al* 2009) and caused extensive damage to housing settlements and irrigation channels (Tang *et al* 2011).

In earthquake-triggered landslide risk assessment, complex interactions are present between the earthquake and landslide threats. The vulnerabilities of the elements at risk are sometimes also correlated to the threats. Amplified risk resulting from hazard and vulnerability interactions has to be considered. Unfortunately, to date, the risk assessment involving multiple hazards is commonly done with independent analyses neglecting possible cascade effects (Marzocchi *et al* 2012) and standard approaches for dealing with the multi-risk situations are not available (Kappes *et al* 2012). In this paper, a quantitative risk assessment model using Bayesian network is proposed to estimate the risk for the buildings exposed to the threat of earthquake-triggered landslides.

### 2 BAYESIAN NETWORKS

A Bayesian network (BN), also called a belief network, Bayes net or casual network, is an increasingly popular method for reasoning under conditions of uncertainty and modelling uncertain domains. It has been applied to a number of civil and environmental engineering problems, ranging from avalanche risk assessment (Grêt-Regamey and Straub 2006), dam risk analysis (Smith 2006), earthquake risk management (Bayraktarli *et al* 2005; Bensi *et al* 2011), design of early warning system for landslide hazard mitigation (Medina-Cetina *et al* 2007) and environmental modelling and management (Aguilera *et al* 2011).

A BN is a probabilistic model based on directed acyclic graph

$$B_s = G(Z, E) \quad (1)$$

where  $B_s$  represents the structure of the network,  $Z$  is the set of random variables ( $Z_1, Z_2, \dots, Z_n$ ), and  $E \in Z \times Z$  is the set of directed arcs, representing the probabilistically conditional dependency relationships among random variables. Each variable  $Z_i$  can be defined in a discrete and finite outcome space (discrete random variable) or as a continuous outcome space (continuous random variable).

One important property of the Bayesian network is that the joint probability function of all random variables in the network can be factorized into conditional and unconditional probabilities implied in the network (Jensen 2007). Thus, the joint distribution can be expressed in the compact form as

$$P(z_1, z_2, \dots, z_n) = \prod_{i=1}^n P(z_i | pa(Z_i)) \quad (2)$$

where  $pa(Z_i)$  is the parent set of  $z_i$ . It should be noted that if child node  $z_i$  has no parents, then the equation reduces to the unconditional probability of  $p(z_i)$ .

A simple Bayesian network with five nodes and five arcs is illustrated in Fig.1. These nodes are: Magnitude ( $M$ ), Distance ( $D$ ), Seismic severity ( $S$ ), Landslide severity ( $L$ ), and Building damage ( $B$ ). These nodes are connected via the arcs:  $M-S$ ,  $D-S$ ,  $S-L$ ,  $S-B$  and  $L-B$ . The prior probability of  $B$ ,  $P(B = B_j)$  can be calculated by

$$P(B = B_j) = \sum_{i=1}^2 \sum_{j=1}^2 \sum_{k=1}^2 \sum_{m=1}^2 P(B = B_j, M = M_i, D = D_j, S = S_k, L = L_m) \quad (3)$$

where  $P$  = probability,  $B_j$  = no damage,  $M_1$  = small magnitude,  $M_2$  = large magnitude,  $D_1$  = small distance,  $D_2$  = large distance,  $S_1$  = low seismic severity,  $S_2$  = high seismic severity,  $L_1$  = low landslide severity,  $L_2$  = high landslide severity.

In this case, as both  $M$  and  $D$  are the parents of  $S$ ,  $S$  is the parent of  $L$ , and both  $S$  and  $L$  are the parents of  $B$ , the joint probability can be derived according to Eq. 2:

$$\begin{aligned}
 P(B = B_i, M = M_i, D = D_j, S = S_k, L = L_m) \\
 = P(M = M_i) \times P(D = D_j) \times P(S = S_k | M = M_i, D = D_j) \\
 \times P(L = L_m | S = S_k) \times P(B = B_i | S = S_k, L = L_m) \quad (4)
 \end{aligned}$$

where the (conditional) probabilities on the right hand side of the equation are quantified with available information (e.g., statistical data, expert knowledge, and physical approaches).

Fig. 1 A simple Bayesian network.

The BN allows one to enter evidence as input, meaning that probabilities in the network are updated when new information is made available, for instance, a case with a small magnitude and large distance. This information will propagate through the network and the posterior probabilities of  $B$ ,  $P(B = B_i)$  can be calculated as:

$$\begin{aligned}
 P(B = B_i | M = M_1, D = D_2) &= \frac{P(B = B_i | M = M_1, D = D_2)}{P(M = M_1, D = D_2)} \quad (5) \\
 &= \frac{\sum_{j=1}^2 \sum_{i=1}^2 P(B = B_i, S = S_j, L = L_i, M = M_1, D = D_2)}{\sum_{k=1}^3 \sum_{j=1}^2 \sum_{i=1}^2 P(B = B_k, S = S_j, L = L_i, M = M_1, D = D_2)}
 \end{aligned}$$

where the joint probabilities in the above equation are calculated with Eq. 3 on the basis of Baye’s theorem (Ang and Tang 2007).

### 3 BAYESIAN NETWORK FOR EARTHQUAKE-TRIGGERED LANDSLIDE RISK ASSESSMENT

According to the ISSMGE Glossary of Risk Assessment Terms, ‘Risk’ is the measure of the probability and severity of an adverse effect to life, health, property, or the environment. Quantitatively risk is the product of the threat times the potential worth of loss and can be expressed as:

$$Risk = Probability\ of\ Threat \times Worth\ of\ Loss \quad (6)$$

Otherwise expressed (e.g. Einstein 1997):

$$Risk = P(T) \times P(E|T) \times U(E) \quad (7)$$

where  $P(T)$  is probability of threat,  $P(E|T)$  is conditional probability of damage of the element(s) at risk exposed to threat, i.e. vulnerability, and  $U(E)$  is utility of element(s) at risk.

A comprehensive Bayesian network (modified after Einstein *et al* 2010) for estimating the risk of buildings in an assumed earthquake-triggered landslide case was built with an open-source MATLAB package BNT (Bayes Net Toolbox) (Murphy 2001) as shown in Fig. 2. There are 11 nodes and 16 arcs in the network. Each node is characterized by several discrete states as shown in Table 1.

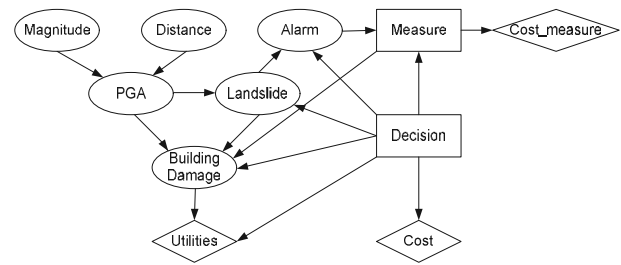

Fig. 2 Bayesian network for earthquake-triggered landslide risk assessment with possible decisions (modified after Einstein *et al* 2010).

Table 1 Nodes and their states of the Bayesian network in Fig. 2

Nodes	No. of states	States
Magnitude ( $M_w$ )	6	4.0-4.5-5.0-5.5-6.0-6.5-7.0
Distance (km)	6	22-25-28-31-34-37-40

## 4 QUANTIFYING THE NETWORK

### 4.1 Seismic hazard

The seismic source is assumed as a line source in this study. Using the geometric characteristics of the source, the distribution of distances can be calculated as shown in Fig. 3.

Fig. 3 Specification of the discrete probabilities of distance.

The annual probabilities for each range of  $M_w$  are calculated using the Gutenberg-Richter magnitude recurrence relationship (Gutenberg and Richter 1994), as shown in Fig. 4.

Fig. 4 Specification of the discrete probabilities of magnitude.

The conditional probabilities of PGA given the magnitude and distance to epicenter are calculated with the ground motion equation proposed by Ambraseys *et al* (2005), using Monte Carlo simulation in Microsoft Excel. The joint probabilities of

PGA are obtained based on inference of Bayesian network, as shown in Fig. 5

Fig. 5 Specification of the discrete probabilities of PGA.

#### 4.2 Landslide hazard

Approaches developed to assess the stability of slopes during earthquake fall into three general categories: (1) pseudo-static analysis, (2) stress-deformation analysis, and (3) permanent displacement analysis. In this paper, dynamic performance of slopes is modelled using permanent displacement analysis developed by Newmark (1965). The critical acceleration of a landslide block can be calculated by

$$a_c = (FS-1) g \sin \alpha \quad (8)$$

where  $FS$  is the static factor of safety;  $g$  is the acceleration of Earth's gravity; and  $\alpha$  is the angle of the sliding surface, which can generally be approximated as the slope angle.

The static factor of safety ( $FS$ ) for an infinite slope is

$$FS = c' / (\gamma z \sin \alpha \cos \alpha) + (1 - m \gamma_w / \gamma) \tan \phi' / \tan \alpha \quad (9)$$

where  $c'$  and  $\phi'$  are the effective cohesion and friction angle of the soil;  $z$  is the depth of the failure surface;  $\alpha$  is the slope angle;  $\gamma$  is the soil unit weight; and  $\gamma_w$  is the specific weight of water.

In the present study, the Newmark displacement is estimated using Eq. 10 reported by Ambraseys and Menu (1998):

$$\log D_n = 0.9 + \log [(1 - a_c / a_{max})^{2.53} (a_c / a_{max})^{-1.09}] \quad (10)$$

where  $D_n$  is the Newmark displacement in centimeters,  $a_c$  and  $a_{max}$  are critical acceleration and peak ground acceleration in  $g$ 's respectively.

The probability of slope failure as a function of Newmark displacement, as described by Jibson *et al* (2000) is estimated using the following equation

$$P(f) = 0.335 \times [1 - \exp(-0.048 \times D_n^{1.565})] \quad (11)$$

The soil and slope properties used in this study are shown in Table 2.

Table 2. Soil and slope properties.

Variable	Mean	St. Dev
$c'$ (N/m <sup>2</sup> )	10 000	2 000
$\phi'$ (degree)	30	2
$z$ (m)	2.5	0
$\alpha$ (degree)	35	0
$\gamma$ (N/m <sup>3</sup> )	27 500	0
$\gamma_w$ (N/m <sup>3</sup> )	10 000	0
$m$	0.4	0

The probabilities of slope failure computed by Eq. 11 for various ranges of PGA are listed in Table 3. Countermeasures made to landslide could reduce risk. Specifically, active actions can reduce the probability of slope failure, passive actions and warning system can reduce the vulnerability of element(s) at risk. The assumed probability of slope failure when active actions are taken is shown in Table 4.

Table 3. The probability of slope failure

PGA (10 <sup>-2</sup> g)	0-8	8-16	16-24	24-32	32-40	40-48
$P(f)$	0.124	0.256	0.305	0.328	0.339	0.346

Table 4. The probability of slope failure when active actions are taken

PGA (10 <sup>-2</sup> g)	0-8	8-16	16-24	24-32	32-40	40-48
$P(f)$	0.025	0.03	0.035	0.04	0.045	0.05

#### 4.3 Other nodes

In the case of a building subjected to a multi-hazard situation involving additive load effects (e.g. earthquake + landslide), the damage will be increased. Herein, the conditional probabilities of building damage are modified from Einstein *et al* (2010). For other nodes, we adopt from Einstein *et al* (2010). These probabilities (conditional probabilities) are shown in Tables 5-11.

Table 5. Four combinations of conditional probabilities of Building damage

Parent nodes	PGA		0-0.08		
	Measure		Yes		
	Decision	Passive	Does not Happens	Happens	Does not
Building damage	No damage	0.4	0.1	0.52	0.1
	Some damage	0.3	0.1	0.43	0.1
	Collapse	0.3	0.8	0.05	0.8

Table 6. Four combinations of conditional probabilities of Measure

Parent nodes	Alarm		Yes

Cost measure	-1000	0		

## 5 RESULTS

The results obtained using the described Bayesian network of the entire risk assessment and decision are shown in Fig. 6. Different mitigation measures result in different utilities. The warning system, showing the lowest (negative) utility is the optimal mitigation measure.

Fig. 6 Comparison of results for Passive countermeasure, No action, Active countermeasure, and Warning system.

This result is based on many parameters that can vary, for instance, the costs; the probability of slope failure or the reliability of the warning system. Therefore, sensitivity analyses were conducted to assess the effects of these variations on the results. Fig. 7 investigates the effect of changing the probability of landslide occurrence against different measures. As expected, for very low failure probabilities, no action is preferred; otherwise a warning system is the best choice, except for very high probabilities where active countermeasures are preferred. It is worth noting that this is only one example, and the sensitivity of the decision to other factors needs to be similarly investigated.

Fig. 7 Sensitivity analysis of the resulting risk arising from varying the probability of slope failure while employing different mitigation actions.

## 6 CONCLUSIONS

This paper presents a new model for evaluating the risks associated with earthquake-triggered landslides using a Bayesian network. The model considered the interactions between different threats in a systematic structure, and accounted for the uncertainties and expert judgments, which are always present in risk analysis. The results obtained in this study are a preliminary step in furthering the earthquake-triggered landslide risk assessment and similar multi-hazard risk assessments. Some of the subjective and empirical parameters in the model need to be further calibrated with the addition of objective data, experience and observations.

## 7 ACKNOWLEDGEMENTS

The research leading to these results has received funding from the European Community's Seventh Framework Programme [FP7/2007-2013] under Grant Agreement n° 265138 New Multi-Hazard and Multi-Risk Assessment MethodS for Europe (MATRIX).

# Collapse behavior of slope due to change in pore water pressure

## Effondrement d'une pente à cause d'une variation de la pression interstitielle

Nakata Y., Kajiwara T., Yoshimoto N.  
Yamaguchi University, Ube, Japan

**ABSTRACT:** In 2010, a slope failure occurred due to heavy rain following an elevation in ground water level. Although a significant rainfall was experienced at the site in the previous year, there was no deformation with a similar elevation. In the past several collapses were recorded at the site due to heavy rain. Thus tests were performed using a plane strain compression apparatus to understand the deformation behavior of sand subjected to cyclic loadings in pore water pressure which were simulated the observed data on the collapsed slope. Rainfall records and data obtained from the observation well and extensometer were also shown. Finally lessons learned from the data were outlined.

**RÉSUMÉ :** En 2010, un glissement de terrain eu lieu après une élévation du niveau de la nappe phréatique à cause de fortes pluies. L'année précédente, bien que des précipitations légèrement plus fortes aient été enregistrées sur le site, il n'y eu pas de mouvement de terrain avec un niveau similaire de la nappe. Dans le passé, plusieurs effondrements ont été enregistrés à cause de fortes pluies. Des essais ont été effectués en utilisant un appareil de compression en déformation plane pour comprendre le comportement en déformation d'un sable soumis à des pressions interstitielles cycliques qui expliquent les données observées sur la pente effondrée en 2009-2011. Les relevés pluviométriques et les données obtenues dans un puits d'observation et à partir d'extensomètres sont également indiqués. Enfin on souligne les leçons tirées de l'ensemble de ces données .

**KEYWORDS:** slope stability, heavy rain, ground water level, pore water pressure, monitoring system, .

### 1 INTRODUCTION

Slope failures induced by heavy rainfall are one of the most destructive natural hazards and these have claimed untold numbers of lives and millions of dollars in infrastructure losses every year in many parts of the world. The rapid progress of global warming is already leading to changes in climate and related environmental problems. In line with global trends, temperatures in Japan are rising. At the same time active seasonal weather fronts carrying heavy clouds are resulting in increasingly heavy local downpours. As a result of these local downpours of torrential rain there is a national increase in geotechnical failures including slope failure and debris flows. These notable tendencies due to climate change have been increasingly recognized since the beginning of the 21st century.

In 2010, a slope failure due to heavy rain occurred at Hagi city in Yamaguchi Prefecture, which has been known as an unstable landslide area. In 2009, rainfall of significant intensity was experienced at the site, but there was no evident the deformation at that time. Additionally in the past, several collapses occurred at the site due to heavy rain. This means that several cycles of rise-and-fall of the ground water level have occurred at the site. The cycle could be linked to the cyclic changes of pore water pressure.

This paper firstly focuses on the cyclic change of pore water pressure. So far, there has been little research work done on cyclic loading of pore water pressure using triaxial compression apparatus (Ohtsuka & Miyata, 2001, and Orense et al., 2004). Therefore, in order to understand the deformation behavior of soil subjected to cyclic loading of pore water pressure, an experimental research using plane strain compression apparatus was carried out for sand specimens and the results are presented. Subsequently, the observed data on the collapsed slope in 2009-2011 is explained. Especially rainfall records and the data obtained from the observation well and extensometer

are shown. Finally, the lessons learned from the data are described.

### 2 DEFORMATION BEHAVIOR SUBJECTED TO CYCLIC CHANGE OF PORE WATER PRESSURE

#### 2.1 Plane strain compression test

In order to simulate the cyclic rise-and-fall of ground water level, experimental tests were performed by applying the cyclic change of pore water pressure in the specimen. In past researchers (Ohtsuka & Miyata, 2001, and Orense et al., 2004), tests were carried out using triaxial compression test apparatus applying monotonic loading of the pore water pressure. Thus, plane strain compression tests were adopted to reproduce stress condition closer to the site.

Each specimen was approximately 60mm wide, 160mm high and 80mm deep. Axial loading was applied through an electric motor from the top pedestal of the specimen. Confining and pore water pressures were applied by E/P transducers. All the external forces were controlled by a developed computer program. Grease was painted on the front and back planes of specimen in the direction of zero strain to minimize the friction. Note that the intermediate principal stress could not be measured in this study. Photos of the front plane of the specimen in the direction of zero strain were taken during the shearing process to observe local deformations.

The material used was Toyoura sand which has a higher permeability to propagate the quick change in pore water pressure and to keep the homogeneity of the effective stress condition. The material can be considered to show the relatively small compression deformation component. The specimens were prepared by air pluviation method with a constant falling height of 125mm. The specimen was formed in 5 layers with the falling height kept constant for each layer. As a result, the

initial relative density of specimens produced were 80%±3%. To saturate the specimen, de-aired water was flushed through the specimen and then a back pressure of 50 kN/m<sup>2</sup> was applied. All specimens were isotropically consolidated for 1 hour and then were sheared to reach maximum and minimum principal stress ratio of about 4.0. The cyclic change in pore water pressure was applied to the anisotropically consolidated specimen with constant amplitude. The principal stress difference was also kept constant by moving the top pedestal with constant axial deformation rate of 0.1%/min. The loading and unloading of the pore water pressure was conducted through a constant pressure increment of 1 kPa/min. After cyclic loading, monotonic loading of pore water pressure was applied to understand the strength of the specimen.

2.2 Cyclic deformation behavior due to pore water pressure

Figure 1 Deformation behavior due to cyclic and monotonic loadings of pore water pressure

Figure 2 Effect of N and ( $\sigma_1/\sigma_3$ ) on the deformation behavior

Figure 1 shows the pore water pressure and axial strain relationship for the cyclic test under 100 kN/m<sup>2</sup> of the lateral pressure. The principal stress difference ( $\sigma_1 - \sigma_3$ ) was kept constant at 320 kN/m<sup>2</sup>. This value corresponded to the residual stress obtained from plane strain compression (PSC) test under 100 kN/m<sup>2</sup> of lateral pressure. The cyclic change in pore water pressure,  $u_{cyc}$  was the amplitude of 34 kN/m<sup>2</sup>. The maximum principal stress ratio reached corresponded to that of PSC test result at 100 kN/m<sup>2</sup>. The sand specimen generated 0.40% of axial distortion from 0.75% (A) to 1.15% (B) during the 1st loading of pore water pressure. After this, the specimen showed 0.15% of axial strain during the rest of the cyclic loading. For comparison, monotonic pore water pressure loading was applied as shown in the figure. The specimen subjected to cyclic pore pressure loading showed rigid-plastic behavior and reached a higher pore water pressure level than the monotonically-loaded specimen without any cyclic loading.

Figure 2 shows the cyclic loading test results with 100 kN/m<sup>2</sup> of lateral pressure. As the number of cycles increase, the axial deformation becomes larger during the cyclic loading.

Also, as the principal stress difference ( $\sigma_1 - \sigma_3$ ) is kept higher, the peak pore water pressure during the monotonic loading after the  $u_{cyc}$  process becomes lower. This is because the higher stress difference ( $\sigma_1 - \sigma_3$ ) is closer to the failure stress condition. After first loading, relatively small axial deformations were obtained irrespective of the amount of  $u_{cyc}$  and number of cycles N. This indicates that the cyclic loading of pore water pressure never lead to any larger deformation and failure.

2.3 Failure after cyclic change of pore water pressure

Figure 3 Stress-strain behavior from monotonic and cyclic loading of pore water pressure

Figure 3 shows the principal stress ratio  $\sigma_1/\sigma_3$  and axial strain relationship for the test results shown in Figure 1. The stress-strain curves before  $u_{cyc}$  loading are the same indicating good reproducibility of the specimen. Then, cyclic loading was initiated from the residual stress condition as described earlier. The sand subjected to the loading with  $u_{cyc} = 34$  kN/m<sup>2</sup> reaches a higher maximum stress ratio  $(\sigma_1/\sigma_3)_{max} = 7.5$  compared with  $(\sigma_1/\sigma_3)_{max} = 6.0$  for the conventional PSC test. The volume change during the cyclic loading is relatively small.

Figure 4 Stress dependency on peak stress ratio

Figure 4 shows the maximum stress ratio  $(\sigma_1/\sigma_3)_{max}$  plotted against the minimum principal stress at the peak stress condition. It can be seen that the value of  $(\sigma_1/\sigma_3)_{max}$  decreases as  $\sigma_3$  at peak increases. As generally well known the stress dependency on the peak stress has been observed. In addition, the results of the cyclic loading of pore water pressure shows a higher  $(\sigma_1/\sigma_3)_{max}$  than PSC tests. The results of the monotonic tests were similar with those of PSC test results. It can be recognized that the cyclic loading may induce the hardening and strengthening of the soil.

3 COLLAPSE BEHAVIOR OF SLOPE DUE TO GWL

The Kiyō District of Hagi City, Yamaguchi Prefecture has been known to be an unstable landslide area. The slope has geologic profile consisting of rhyolite and granite with a lower

permeability. Previous failures have occurred at the site in 1973, 1981, 1991 and 1994. In 2000, a landslide occurred as far as the lower debris flow barrier. In 2002 ground surface movements were observed without any apparent flow of soil mass. In order to monitor the stability of the slope, a monitoring system was installed since 1988 as shown in Figures 5 and 6. The main parameters measured were rainfall, ground water level (GWL) and slope movements using extensometers. The data were recorded remotely at the National Highways Bureau in Hagi. The system was upgraded in 2004 by installing inclinometers in the slope and debris barrier. In addition, a strain-gauged tell-tale system was installed across a crack in the barrier. The data logging and communications system was updated with wireless technology. The data has been automatically updated on a website. Moreover a mailing notification system has been installed in case of unusual conditions developing at the site.

Figure 5 Plane view with failure blocks and measurement points (“C” represents failure block, “S” and “EG” are extensometers, “B” and “BV” are observation wells and “K” are for inclinometers)

Figure 6 Cross section with failure block and measurement points

Three types of countermeasures were implemented to mitigate slope failure. Firstly the top third of the slope was covered with rubber sheeting to prevent inflow of rainwater. Secondly, water head relief tubes were installed below the area covered by the rubber sheets. And thirdly, a debris flow protection gallery was built over the road in front of the collapsed slope. This gallery was designed to resist an overburden of 4m thick of debris.

#### 4 RAINFALL RECORD AND FAILURE PROCESS

As shown in Figure 7, the rainfall commenced at 22:00 on 10/7/10 with a maximum recorded intensity of 25 mm/hr. At the time of failure, i.e. 5:00 on 10/7/14, the rainfall rate of 18 mm/hr on 7/12 led to a cumulative rainfall of 269mm. By 10:00 on 7/15 the accumulated rainfall was 351mm. The first failure occurred at 5:00 on 7/14 at the lower slope area C-1-2 over a slope length of 80m, width of 50m and depth of 2m. The total volume of the slip was 1600m<sup>3</sup>. The second failure occurred between 15:00 on 7/14 and 10:00 on 7/15 at Block C-2-1 over a slope length of 30m, width of 35m and depth of 2m. With these failures, the lower part of the slope was covered by a 2m to 3m

thick layer of debris. This layer was unstable and was liable to flow failure under future heavy rainfall. The upper part of the debris deposit had a vertical slope face. Also a visible continuous crack on the topside of block C-3 was discovered. This means higher potential for further movement of this block under the next heavy rainfall. So the stability of blocks C-2-2 and C-3 was worsened by the rainfall in July 2010.

Figure 7 Variation of ground water level in July 2010

#### 5 GROUND WATER LEVEL RECORD

B1 and B2 were located in Block C-1-2. The elevation of GWL firstly occurred in B1 following the rainfall as shown in Figure 7. The GWL rose to within 0.51m below ground level (BGL). In the case of B2 the GWL rose to 18.54m BGL before the first failure, which represented a rise of 3m from the dry period. In previous failures in 1991 and 1994 similar GWL observations were made. It is therefore thought that the GWL was the trigger for the series of failures. The GWL in C3 had not apparently risen above normal levels.

BV-5 was located at the top of the slope and recorded a significant rise in GWL which correlated to the failure of C-3. During the dry period the GWL was at a depth of 29m. The GWL rose from 12:00 on 7/13 reaching a depth of 17.35m BGL at the initiation of failure and started to fall slowly again after 17:00 on 7/14. From 7/14 to 7/21 the rate of decrease was between 0.3m and 0.8m/day and from 7/22 to 7/25 the rate was 1.85m/day, finally reaching 29m BGL on 7/25. The movement of the extensometers stabilised when the ground water level dropped to 20m BGL. B4 was located at the top of the C-2-1 block. The GWL rose to 2.03m BGL which was a 3.5m rise. The rate of decrease was more than BV5 and on 7/17 it fell to 5m BGL. The major movement of Block C3 was considered to be the result of the earlier failure of C1-2 and C2-1 which effectively unloaded the toe of C3.

#### 6 GROUND MOVEMENT

Before the rainfall there were no indications of movement from the monitoring system located in Block C-3. However after the second failure, movement of the C-3 block was observed with rising GWL. After the first failure the monitoring system failed to work for a temporary period of time and was reinstated at 15:00 on 7/14. At this time it was noted that Block C-3 was moving at a rate of 30 mm/hr. This movement was monitored by the inclinometers at K-3. According to the inclinometer data, the slip surface was located at a depth of 20m. The movement at the surface was the same as that at depth, indicating that Block C-3 was moving as a single mass. From 7/15 the rate of movement decreased from 15 mm/hr to 1 mm/hr on 7/19, coming to a virtual halt on 7/22. This decrease correlated with the decrease in GWL. The S-3 extensometer became inactive due to the failure. No movement was observed by the extensometers EG1 and EG2 as shown in Figure 8. Movement was measured by EG3, EG4, EG5 and EG6 after 17:00 on 7/14 with greater than full-scale readings.

From 7/14 to 7/15 the rate of deformation was 5 mm/hr to 15 mm/hr and on 7/16 to 7/18 it reduced to 1 to 5 mm/hr. From 7/18 it gradually decreased. From 7/19 it reduced to 1mm/hr ceasing on the 7/22. The S-4 extensometer was set up on 7/17 because of the failure of C-2-1 and the enhanced risk of failure of the RHS of the slope. During the time the ground water level was going up, progression of displacement was not seen at all. Moreover, displacement between -17m and -20 m of the groundwater level was very remarkable. Furthermore, if the groundwater level falls lower than -23m, it can be considered that the movement of the block stopped in general.

Figure 8 Data of extensometers observed in July 2010

6.1 Rainfall record in 2009

Figure 9 Rainfall record between 2009 – 2010

In 2009, a significant rainfall had been experienced at the same site as shown in Figure 9 with a maximum intensity of 62 mm/hr and cumulative intensity of 289mm over 3 days. However there was no evident of deformation at that time. The evidence indicates that it is difficult to predict the collapse solely by the rainfall forecast. The GWL in B1 in 2009 was 10m BGL compared to 3m BGL in 2010. The potential for slope failure in 2010 was therefore higher. The general tendency over the period 2009 to 2010 was for the GWL to be above normal.

6.2 Collapse behavior in 2011

Deformation of the slope was observed in 2011 due to the smaller rainfall shown in Figure 10. The rainfall in 2011 started on 6/27 and continued intermittently to 7/17. For 21 days, 4 major daily rainfall events were recorded; 60mm on 6/27, 40mm on 7/1, 30mm on 7/4 and 50mm on 7/8. The extensometer began to act on 7/1 before the GWL for BV5 elevated on 7/3. From this date, the deformation increased gradually and accelerated on 7/7, rising with the rapid increase in the GWL. During the ground water level rise and descent, the displacement of the C-3 block was recorded. The maximum displacement rate appeared during the water level rise while in 2010 it was during water level descent. This implies that the

timing of the warning official announcement would be earlier more for the next heavy rainfall.

Figure 10 Data of extensometers observed at July in 2011

7 CONCLUSIONS

The paper focused on the evidence of collapse behavior for a slope due to heavy rain in 2010. In the past the site had experienced several collapses. An experimental research was performed to understand the deformation behavior of sand subjected to cyclic loading of pore water pressure using plane strain compression apparatus. Then the observed data on the collapsed slope in 2009-2011 was explained. Finally the lessons from the data were discussed.

- 1) The experimental test results showed that cyclic loading of pore water pressure never lead to any larger deformation and failure except the first loading. The rigid-perfectly plastic type behavior was observed for the sand specimen subjected to the cyclic changes in pore water pressure.
- 2) In 2009, a significant rainfall fell at the same site. However, there was no evidence of deformation at that time. This indicated that it was difficult to predict the collapse by the rainfall forecast only and a monitoring system is needed to predict any deformation.
- 3) The collapse behavior started at the surface layer of the toe part of the slope and then the movement of the major slip block correlated with the rise of ground water level behind the block. Therefore it is important to monitor the ground water level at the appropriate points to understand the collapse behavior.

8 ACKNOWLEDGEMENTS

The author gratefully acknowledges Mr. S. Yamada (Chugoku Regional Development Bureau, MLIT) for providing the monitoring data. This work was supported by Japan Society for the Promotion of Science KAKENHI, Grant-in-Aid for Scientific Research (B) 22360187.

**ABSTRACT:** In this paper, the SPH (Smoothed Particle Hydrodynamics) method is applied to slope stability problems. This method can handle large deformation problems because it is based on the free mesh system. In addition, the constitutive models of geomaterials can be used directly. First, a simulation of a simple shear test is carried out to validate the SPH method. Then, slope stability analysis considering countermeasures is carried out. The numerical results are compared with results of the safety factors calculated by the Fellenius method. Based on the obtained results, the effectiveness of the SPH method for slope stability analysis is discussed.

**RÉSUMÉ :** Dans cet article, la méthode SPH (hydrodynamique des particules lissées) est appliquée à des problèmes de stabilité des pentes. La méthode peut traiter des problèmes de grandes déformations parce qu'elle est basée sur le système de maillage libre. En outre, les modèles de comportement des géomatériaux peuvent être utilisés directement. Dans un premier temps, une simulation d'essai de cisaillement simple a été réalisée afin de valider la méthode SPH. Ensuite, une analyse de stabilité des pentes considérant des contre-mesures a été réalisée. Les résultats numériques ont été comparés avec les résultats des facteurs de sécurité calculés par la méthode Fellenius. Sur la base des résultats obtenus, l'efficacité de la méthode SPH pour l'analyse de la stabilité des pentes a été discutée.

**KEYWORDS:** slope stability analysis, meshfree method, constitutive model

### 1 INTRODUCTION

In terms of the slope stability problems, design of structures and evaluation of countermeasures are carried out using a safety factor of slope obtained from circular slippage calculations at the practical level. In this approach, the safety factor of the slope is easily obtained from equilibrium of force. However, it is not possible to take into account of the deformation of slope. If it is possible to predict the deformation of slope, more detailed design of structures and evaluation of countermeasures can be facilitated. A lot of deformation analyses using the Finite Element Method (FEM) with developed constitutive models have been reported. It is, however, still difficult to solve large deformation problems using the FEM due to the distortion of the mesh. On the other hand, to solve such problems, various numerical approaches have been proposed, such as a modeling based on the computational fluid dynamics (CFD) and the discrete modeling (Cundall and Strack 1979). In the method based on CFD, it is not necessary to pay attention to mesh distortion, because the mesh is fixed in space. However, soils are assumed to be a kind of non-Newtonian fluids (Moriguchi 2005). Thus this modeling is an effective tool for flow problems, but is difficult to apply to static deformation problems. In addition, it is difficult to use constitutive models based on solid mechanics, because they cannot easily handle the history information of soils during deformation. The discrete modeling uses an assembly of discrete elements, and is inappropriate for dealing with constitutive models based on a continuum approximation.

Against these backgrounds, the purpose of this research is to express the large deformation behavior of geomaterials in the framework of continuum mechanics. The smoothed particle hydrodynamics (SPH) method, proposed by Lucy (1977) and Gingold and Monaghan (1977), is based on a mesh-free Lagrangian scheme, and is one of the effective numerical methods. The method can solve large deformation problems

without mesh distortion. Moreover, it can handle the governing equations and existing constitutive models for geomaterials, since it is based on a continuum approximation. The method has already been used to solve many types of geotechnical problems, and a number of interesting achievements have been published (e.g., Maeda et al. 2004, Bui 2007). From these achievements, it is shown that the SPH is applicable to geotechnical problems. However, as far as the introduction of the constitutive models of geomaterial into the SPH method, detailed discussions have not been carried out.

In this paper, the SPH method was applied to slope stability problems. In order to validate the method, a simulation of the simple shear test for elasto-plastic materials is carried out. Then, a slope stability analysis considering countermeasures is carried out. The numerical results are compared with the results of the Fellenius method. Based on the obtained results, the effectiveness of the SPH method for slope stability analysis is discussed.

### 2 NUMERICAL METHOD

#### 2.1 Basic theory of SPH method

In the SPH method, an object is expressed as an assembly of particles. If the motions of the particles are solved individually, the deformation behavior of the continuum cannot be represented by this technique. In order to treat an object as a continuum, a unique interpolation theory is used. This interpolation theory includes two key approximations: a kernel approximation and a particle approximation. The first step is a kernel approximation of the field functions. The kernel approximations are based on neighboring particles  $\beta$  located at points  $x^\beta$  within the support domain  $\kappa^d h$  of a smoothing function  $W$  for a reference particle  $\alpha$  located at point  $x^\alpha$ , as shown in Fig. 1. In the first step of the interpolation, we define a smoothed

physical quantity  $\langle f(x^\alpha) \rangle$  for the physical quantity  $f(x^\alpha)$  at the reference particle  $\alpha$  as follows:

$$\langle f(x^\alpha) \rangle = \int_{\Omega} f(x^\beta) W(r, h) dx^\beta \quad (1)$$

where  $r = |x^\alpha - x^\beta|$ ,  $h$  is the radius of the influence domain, and  $\Omega$  is the volume of the integral that contains  $x^\alpha$  and  $x^\beta$ .

In the second step of the interpolation, the physical quantity  $\langle f(x^\alpha) \rangle$  for the reference particle  $\alpha$  is expressed as the summation of the distribution of the assumed physical quantities  $f(x^\beta)$  for each particle. Thus, the physical quantity can be expressed in terms of  $N$  discrete points:

$$\langle f(x^\alpha) \rangle = \sum_{\beta} \frac{m^\beta}{\rho^\beta} f(x^\beta) W^{\alpha\beta} \quad (2)$$

where  $m^\beta$  is the mass, and  $\rho^\beta$  is the density of neighboring particles  $\beta$ .  $N$  is the numbers of neighboring particles in the support domain, and  $W^{\alpha\beta}$  is the smoothing function that expressed the contribution from the neighboring particles  $\beta$  to the reference particle  $\alpha$ . In this study, Cubic spline function (Swegle 1994) is used as the smoothing function. Equation (2) is a formula for evaluating a physical quantity via the SPH method. It is also possible to approximate the spatial gradient of a physical quantity in a similar way, using the spatial derivative of the smoothing function. The spatial derivative of Eq. (2) can be written as

$$\frac{\partial \langle f(x^\alpha) \rangle}{\partial x_i} = \sum_{\beta} \frac{m^\beta}{\rho^\beta} f(x^\beta) \frac{\partial W^{\alpha\beta}}{\partial x_i} \quad (3)$$

Based on the two-step interpolation procedure, it is possible to calculate any physical quantity and its special derivative of a physical quantity.

Figure 1. An image of basic concept of SPH method

## 2.2 SPH method based on the solid mechanics

The governing equations used in this study are based on solid mechanics. The equation of continuity and the equation of motion can be defined as follows,

$$\frac{d\rho}{dt} = -\rho \frac{\partial u_i}{\partial x_i} \quad (4)$$

$$\frac{du_i}{dt} = \frac{1}{\rho} \frac{\partial \sigma_{ij}}{\partial x_j} + F_i \quad (5)$$

where  $u_i$  is the velocity vector,  $\rho$  is the density,  $\sigma_{ij}$  is the stress tensor and  $F_i$  is the external force vector. Applying the SPH interpolation theories, the equations are expressed as follows:

$$\frac{d\rho^\alpha}{dt} = -\sum_{\beta} m^\beta (u_i^\beta - u_i^\alpha) \frac{\partial W^{\alpha\beta}}{\partial x_i} \quad (6)$$

$$\frac{du_i^\alpha}{dt} = \sum_{\beta} m^\beta \left( \frac{\sigma_{ij}^\alpha}{(\rho^\alpha)^2} + \frac{\sigma_{ij}^\beta}{(\rho^\beta)^2} + C_{ij}^{\alpha\beta} \right) \frac{\partial W^{\alpha\beta}}{\partial x_j} + F_i^\alpha \quad (7)$$

where  $C_{ij}$  is the summation of the artificial viscosity term (Monaghan and Gingold 1983) and the artificial stress term (Monaghan 2000; Gray et al. 2001). In order to introduce the artificial viscosity and the artificial stress, the numerical instability and the tensile instability are decreased (Swegle et al. 1995). Tensile instability, specifically the instability of the solution for tension deformation, is one of the problems with the SPH method for solid mechanics. In this study, the Drucker-Prager model (Drucker and Prager 1952) and the Super-subloading Yield Surface Modified Cam-clay model (Asaoka et al. 2000; 2002) are used in the deformation analysis of geomaterial to validate potential of the SPH method.

## 3 SIMULATION OF SIMPLE SHEAR TEST

In the validations of the SPH method for solid mechanics, a simulation of simple shear test under plane strain condition is carried out using Drucker-Prager model and Super-subloading Yield Surface Modified Cam-clay model. Calculated stress strain relation and stress paths are compared with the theoretical solution at the center of specimen. Figure 2 illustrates the numerical model used in the simulation. As the figure indicates, the specimen is a square object (10 cm by 10 cm). In the SPH method, numerical instabilities and errors tend to arise due to lack of calculation points. Therefore, a virtual area surrounded the specimen was used in this simulation. The solid line denotes the initial configuration of the specimen, and the dashed line denotes the configuration after deformation. In the simulation, the virtual area is forcibly deformed with a constant displacement to represent simple shear conditions, and the deformation of the specimen is calculated. Since a virtual area surrounded the specimen, only the scheme is employed in this validation. The parameters used in this simulation are summarized in Tables 1. As Table 1 indicates, seven different cases are considered in this simulation. In Cases 1, cohesive frictional material is used. In Cases 2 and 3, parameters of typical clay under two different values of the initial mean stress and initial overconsolidation ratio are used. In Cases 4 to 7, parameters of typical sand under three different values of the initial mean stress and degree of structure are utilized.

Figure 2. Numerical model

Figures 3 to 5 shows calculated stress-strain relation and stress paths at the center of the specimen. The theoretical solutions are also described in these figures for comparison. The solid line denotes the theoretical solutions, and plotted points indicate the obtained results. Based on the comparison, the results from the SPH scheme are in good agreement with the theoretical solution. Also, by introducing the Super-subloading Yield Surface Modified Cam-clay model (Asaoka et al. 2000; 2002) into the method, the softening with plastic compression behavior of structured soil and rewinding behavior of overconsolidated clay (Fig. 4) are expressed. Also, the softening behaviors with plastic compression of medium-dense sand and subsequent hardening behavior with plastic expansion (Fig. 5)

are expressed. It is summarized that the high performance elasto-plastic constitutive model can be introduced into the SPH method. Also, it is possible to simulate the various state of geomaterial, such as the clay and sand, using the SPH method.

Table 1. Material parameters

(a)Drucker-Prager model

Case		1
Young's modulus	$E$ [kPa]	1000.0

4 SLOPE STABILITY ANALYSIS CONSIDERING COUNTERMEASURES

A slope stability analysis considering countermeasures is carried out, using the Drucker-Prager model. Two types of countermeasures, such as top soil removal work and counterweight fill, are considered into these simulations. The numerical results are compared with results obtained using the safety factors calculated by the Fellenius method. Figure 6 illustrates the numerical models in Cases 1 to 8. The slope angle is 45 degrees and the model ground is cohesive. Also, as the figure shows, the displacements at the top of the slope are checked. The parameters used in this simulation are listed in Table 2. For the boundary conditions, the horizontal direction at the side wall of the slope was fixed, and the vertical direction is free. The horizontal and vertical directions at the bottom of the embankment are fixed. Fixed boundary particles are used to describe the walls. In order to take into account the effect of surface compaction, the internal friction angle of the counterweight fill material is set to 30 degrees. The effect of pore water pressure is not taken into account. The isotropic stress corresponding to static earth pressure is used as the initial stress.

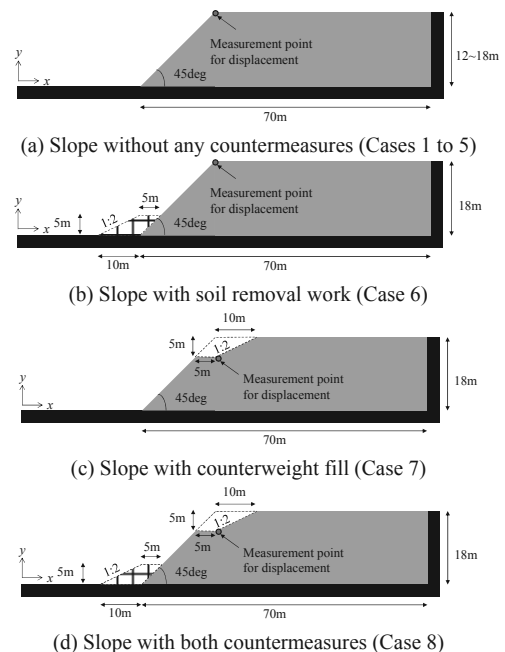

Figure 6. Numerical models.

Table 2. Material parameters.

Young's modulus	$E$ [MPa]	100.0
Poisson's ratio	$\nu$	0.30
cohesion	$c$ [kPa]	50
internal friction angle	$\phi$ [deg]	0.0
unit weight	$\gamma$ [kN/m <sup>3</sup> ]	19.6

Table 3. Safety factors obtained from the Fellenius method for each case.

Case	Countermeasures	Height of slope $H$ [m]	safety factor $F_s$
1	Without any countermeasures	12	1.24
2		14	1.01
3		15	0.91
4		16	0.86
5			0.75
6	Soil removal work	18	0.87
7	Counterweight fill		0.90
8	Both countermeasures		1.02

The safety factors obtained from the Fellenius method are listed in Table 3. As Table 3 indicates, the safety factors rise according to the order of case without any countermeasures,

case with soil removal work, case with counterweight fill, and case with both soil removal work and counterweight fill.

The distributions of accumulation of the maximum shear strain are shown in Fig. 7. As explained in above, boundary particles are used for the wall, but are not shown in these figures. Figure 8 shows the relationship between the safety factor and the value obtained by dividing the displacement  $\delta$  at the top of the slope by the height of the slope  $H$ . When the safety factor is larger than 1.0 (Cases 1 and 2), shear strain does not appear in the figures. However, when the safety factor is less than 1.0 (Cases 3 to 5), a distribution of circular shear strain can be seen. When the safety factor is close to 0.9, shear strain is observed but still large deformation cannot be observed. In particular, a crack forms at the crown of the slope, and block slippage is confirmed in the cases with the lowest safety factors. In the case without any countermeasures (Case 5), the shear strain is conspicuous and the slope is largely deformed. On the other hand, in the cases with countermeasures (Cases 6 to 8), the shear strain does not become more prominent and the displacements can be controlled as the safety factor increased. Thus, similar tendencies are observed in the results from the SPH method and the Fellenius method. In addition, while conventional circular slippage calculations are used to estimate the occurrence of rigid block slippage, the SPH method can estimate not only the stability, but also the effects of deformation. In Cases 3 and 7, the slope is not deformed, although the safety factor is less than 1.0. On the boundary between stable and unstable states, we consider that the slope is stabilized due to the redistribution of stress following an initial small deformation. The SPH method can estimate deformation and stability simultaneously. Moreover, it is capable of continuously predicting the deformation, even in a large deformation region. In other words, the SPH method can predict the entire deformation process of a geomaterial. Therefore, one may conclude that a variety of useful information about slope stability problems can be obtained via the SPH method.

Figure 7. Distributions of accumulation of the maximum shear strain

Figure 8. Relationship between safety factor and displacement at the top of slope.

## 5 CONCLUSION

In this study, introducing the constitutive model into the SPH method, deformation analyses of geomaterials were carried out. Firstly, in order to validate the method, the simulation of simple shear test of elasto-plastic material was simulated using two kinds of constitutive models of geomaterials. The numerical results were compared with the theoretical solutions. Then, a slope stability analysis considering countermeasures was carried out. The conclusions can be summarized as follows:

- The simulation of a simple shear test demonstrated that the SPH method could calculate the appropriate stress state of geomaterials using high performance elasto-plastic constitutive models.
- The SPH method was applied to slope stability analysis. The results indicated that the method was able to express the same safety factor tendencies obtained from the conventional circular slippage calculations. At the same time, the SPH method can simultaneously estimate both the deformation and stability. From the results of a slope stability analysis considering countermeasures, it can be inferred that the SPH method was capable of predicting the deformation and stability of slopes even in complex situations, such as simulations that include countermeasures.
- From a series of the numerical results, the SPH method was found to be applicable to slope stability analysis. Also, the SPH method has the potential to describe the deformation of geomaterials from the initial state to subsequent large deformations.

# Slope stability along a new road "Drisht –Drisht castle"

## Stabilité de pente le long de la nouvelle route "Drisht-Drisht castle"

Paçi E., Cullufi H., Dervishaj A.  
*Polytechnic University of Tirana, Albania*

**ABSTRACT:** Some slopes along the new road from the village Drisht center to the medieval castle entrance are located in a very disturbed tectonic zone. Due to overthrust geological processes the rock quality are extremely poor. In surface there are different active slides that due to water circulations especially during seismic events are very unstable and slide towards road pavements or cause side channel and culvert fills.

This article describes the numerical calculation concerning frequent normal conditions during construction and use of road and accidental condition during seismic events. Based in these calculations design solution are given. The calculations will be controlled by a back analysis algorithm. We have decided the upper and lower boundaries for the main results and we have made a sensitivity analysis that will show the influence of each parameter to the predicted results. So during maintenance time with same site tests results we can correct numerical parameters used in the model and predict long time behavior of the slope. In this manner we can also correct the future rehabilitation measures (if necessary) for the above mention road slope and other road slopes in similar conditions.

**RÉSUMÉ :** Certaines pentes le long de la nouvelle route allant du centre du village de Drisht à l'entrée du château médiéval sont situées dans une zone tectonique très perturbée. En raison de différents processus géologiques, la qualité de la roche est extrêmement médiocre. En surface, il existe différents glissements actifs qui, en raison de circulations d'eau lors d'événements sismiques, sont très instables et glissent vers chaussées et remplissent le canal longitudinal.

Cet article présente un calcul numérique (en conditions fréquentes – normales) pendant la construction et l'utilisation de la route. Les conditions accidentelles correspondant à des événements sismiques sont aussi traitées. Sur les bases des calculs effectués, des solutions techniques sont proposées. Les calculs sont contrôlés par un algorithme de "back analysis". Nous avons décidé les limites supérieure et inférieure pour les principaux résultats et nous avons fait une analyse de sensibilité qui montre l'influence de chaque paramètre. Ainsi, pendant le temps d'entretien du site, nous pouvons déterminer les paramètres numériques à utiliser dans le modèle pour prédire le comportement de la pente à long terme. Nous pouvons aussi proposer des mesures de réhabilitation futures (si nécessaire) pour la pente.

**KEYWORDS:** Slope stability, seismic events, weathering.

### 1 INTRODUCTION

The new road links the center of the village with a very famous medieval castle. It pass through a mauntainous area and need a lot of structures such as retaining walls, culverts, small bridges etc. The last part of the roads pass in a very steep slope where a year after the construction ware seen local slope failures.

Figure 1. Photo of local slope failures

The road width is 6m with 0.5 shoulders and a longitudinal concrete paved channel on the side of the mauntain. The road body is partly in filling and partly in cutting. The zone is one of

the wettest zone in Albania with a average rainfall of 1750mm/year. Due to lack of budget during the construction phase for finishing all the engineering measures and maintenance problems during exploitation phase local slope slides have occured after a period of 3 years.

#### 1.1 *Geological and geotechnical aspects*

The road to Drisht castle pass through a very disturbed tectonic zone. The study area takes part in subzone Cukali which, in the west and northwest is overthrust from the Albanian Alps zone , and in the southeast area is overthrust from Mirdita zone. Slope of the right side of the road represented by mainly constrained dark color old clays. Inside the clay mass can be meet compact sandstone layers bodies with dimensions up to 1 m in length, and up to 30 cm thickness and sandstone pieces measuring 5 to 10 cm with rounded shape and often alienated. These deposits are turbidits with a clayey - sandy cementation. They are too weak and are divided into small pieces. The above mention formation can be classified as very heterogonous flysch. Within the clay mass at the bottom of the slope (on the right side of the road) can be meet limestones olistolite size 5 to 10 meters above which are placed massive limestone rocks of Triassic geologic time.

Figure 2. Schematic representation of the geological aspects of the slope

### 1.1.1 Geotechnical parameters

As given above we have identified two main type of terrain. The limestone rock formations with very good mechanical characteristics and flysch formations that are very weak rocks to soils.

These last rocks are described as rocks with relatively low strength and high deformability. They can be easily eroded by water, have a plastic behavior and poor stability on the slopes. Volume weight ranges from 2.2 - 2.6 g/cm<sup>3</sup>, porosity up to 35%, elasticity module  $2 \cdot 10^3 - 10^4$  daN/cm<sup>2</sup>, compression strength 5 - 25 daN/cm<sup>2</sup>, intact rock cohesion 20 - 100 kPa, internal friction angle <15°.

Based upon the lab test and empirical evaluation the main geotechnical parameters for unweathered formations used in the design are as follows

Table 1. Geotechnical main parameters

Layer	$\gamma_s$	$c$	$F$
Flysch/Clay	23	20-100	15
Limestone	26	400	45

## 2 MODELING OF THE SLOPE

### 2.1 FE 2D model

The slope stability analysis is made with finite element software Plaxis. The geometry and the layers are given in figure 3. For the calculation of sliding slopes should be distinguish the existing slides as well as those caused by changes in loading, reduction of parameters so first time slides. In finite element numerical calculations for the new slide slopes can not predefined a critical surface along its length the strength mobilized parameters progressively softened. The problem must pass in two stages, initially determining a critical sliding plan (if any) and then to give the soil strength mobilized parameters of this plan the residual parameters.

Through the first model we can determine the stability of the slope for a long time while the second model we can define the engineering measures (walls, piles, anchored wires, nails, etc.) and make the their design.

Figure 3. FE model of the slope

The soil is modeled as elasto-plastic material with yield criterion of Mohr-Coulomb. Advanced models with softening behavior would be more appropriate, but for lack of data (as well as the impossibility of accurate assessment of softening process) in our case can not be used. Weathering processes have been taken into account by dividing a surface layer in which the strength parameters gradually increase in depth until intact rock/soil values. In each analysis we took into account the initial natural stages as well as the following stages during the construction and the final stage during exploitation.

Influence of time, the accumulation of deformation, creep, brittle behavior that manifest same old overconsolidated clays, the formation of shear bands, influence of existing fissures, change of resistant parameters along the extent of the critical sliding surface, etc. in our model can not be taken in consideration. However, this modeling by taking the average parameters gives us practical results for the controls of the slope stability and dimensioning of retaining structures in the final limit state of the slope.

The fillings for road widening are reinforced with geogrids. Slope nailed wire mesh, anchors are simulated by applying a surface pressure perpendicular to the slope. The value of the pressure is taken such that the safety coefficient of the second model after application of this pressure to be 1.25. Plaxis program allows a sensivity analysis to see the influence of each parameter to the stability of the slope.

### 2.2 Water influence

The zone is one of the wettest zone in Albania with a average rainfall of 1750mm/year. It is well known that the rainfall precipitation degrade the soil properties due to progressive weathering. The weathered soil material has filled the longitudinal channel blocking the dewatering. The water infiltrate through existing fissures reducing significantly the soil parameters. The flysch/old clay formation have been separated into two soil layers. Upper surface layer that has been weakened as a result of rain water infiltrations and bottom layer of the terrain representing the intact formation. We haven't used an underground water level and thus a seepage calculation because in this type of formation we can not speak for a real water level. The water influence is taken into account only between the reduction of surface layer parameters and increase of the thickness of this layer at the end of the excavated slope, toe of the slope. For the surface layer geotechnical parameters that are used are the residual parameters  $c_r, F_r$ .

### 2.3 Seismic input

One of the reasons of slope instabilities are seismic events. So for the long term stability in the seismic zones is necessary to do also slope seismic loads analysis. Seismic input can be considered from time history of acceleration. These time

histories can be produced artificially or taken from records. In every case the accelerograms must be compatible with the acceleration spectra required by the codes.

For seismological and geotechnical applications real accelerograms are preferred because they are more realistic for frequency content, number of cycles, correct correlation between the vertical and horizontal components of ground motion and for the energy content in relation to the seismogenic parameters. In our case the site is near the zone of a seismic source that can generate earthquakes so we need to consider also near fault influence. However, in order to use a real accelerogram in near-fault conditions it is required for the time histories to include directivity effects and fling step, in other words they should refer to real, near-field earthquakes. So just for comparing the results we have also generated an artificial accelerogram taking account the near source effects.

Considering that we have been interested for the design of slope retaining structures the chosen accelerogram according to EC8 spectra is multiply by  $2 \cdot 1.4 / 1.146 \approx 2.45$  for being compatible with PGA taken from PSH analysis for  $T_R \approx 475$  years. The ground motion parameters are given below:

Figure 4. Acceleration response spectras

Figure 5. Time history of acceleration

PGA : 1.146m/sec<sup>2</sup> in t=10.790sec  
 PGV : 0.082m/sec in t=16.590sec  
 PGD : 0.020m in t=47.880sec  
 Vmax / Amax: 0.071sec. Predominant Period (Tp): 0.300sec

## 2.4 Results

From the analysis is seen that local instabilities occur before global instabilities. To overcome this problem the filling reinforcement with geogrids have been activated from the first stage of excavation before defining the critical sliding surface. In figure 6 are given the displacement of the road body fillings.

Figure 6. Local displacement

After that stage of local stabilization is done the global stability analysis. From analysis of the displacement and displacement incrementations we receive critical sliding surface shape and position as shown in Figure 7.

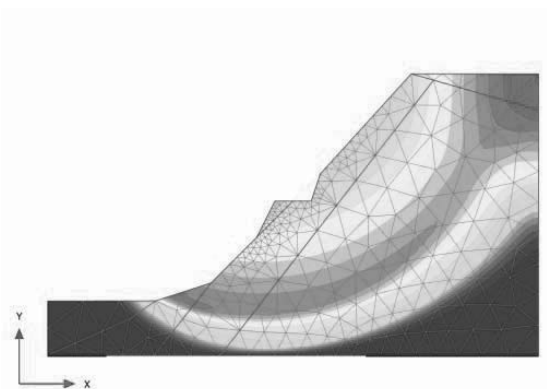

Figure 7. Total displacement

To simulate the critical sliding surface the "interface" element is activated with residual mechanical characteristics,  $c_r = 5 \text{ kPa}$ ,  $F_r = 10^\circ$

Since in site are not observed existing deep slides that affect the global stability of the slope conditioning the preexisting sliding surfaces the value of cohesion is not taken zero, thus improving also the numerical calculations. The displacement rate effect on residual strength parameters especially for seismic loading aren't taken in consideration.

In the case of application of a seismic load the safety coefficient for the second model decrease and wire anchored mesh of the slope should be strengthened, although for this case the coefficient of security can be taken close to 1. By sensitivity analysis of the parameters the cohesion changes are within small limits and their small changes doesn't affect the stability of the slope. The friction angle changes from peak values in those residual gives the greatest impact. These assessments we think correspond with the real monitored cases referred in literature. Since in the site is not implemented the wire anchored mesh the monitoring of weathering processes of slope materials in the future will give us the opportunity to correct resistance parameters values taken in the first analysis and reanalyze the slope stability.

## 3 CONCLUSIONS

Although the lack of data and the inability of finite element software with elasto-plastic modeling with Mohr-Coulomb yield criteria or softening criteria, to take into account the

numerous elements that affect the stability of slopes in soft rock / old clay the simulation of processes by means of two modeling even in the case of application of simple models of yield criteria gives practical good results for first time slides ultimate stage or when we have a reactivation of an existing surface of non-brutal slide. This modeling does not provide intermediate data for the developed process, giving the possibility to correct in time the analysis parameters, and provide in time appropriate engineering measures. In any case when it will be used it will be referred only to the final phase with residual parameters.

#### 4 ACKNOWLEDGEMENTS

The authors are very grateful for the help of Dr. Shkelqim Daja for the preparation of geological study.

**ABSTRACT:** The consideration of multiple hazards and their interaction to achieve risk reduction is a necessity since many regions are prone to different types of threats. However, this is neither simple and straightforward nor commonly undertaken at present since different natural hazards are usually analyzed individually and managed separately. A common example of this is the alteration of the density and locations of rainfall-induced landslides after an earthquake due to the extensive disturbance of surface strata. That implies an influence of the earthquake on the soil structure that alters the disposition towards landslides. Taking this into consideration, a model was developed that could give a rough spatial and temporal prediction of expected change in landslide hazard in an area following an earthquake. The model is able to describe the reduced impact of earthquakes with distance from epicentre as well as how the soil gradually regains its strength with time. These reductions are then applied to an equilibrium stability analysis in order to compute new Factors of Safety. Although analysis schemes can be proposed and software tools can be provided to facilitate many steps, a well-conceived and reflective approach to multi-hazard settings is still essential.

**RÉSUMÉ :** Etant donné que différentes régions sont sujettes à différents types de menace, l'étude de multiples facteurs de risque et de leur interaction est nécessaire afin de réduire le risque. Ce genre d'études est néanmoins rarement entrepris de nos jours puisque chaque risque naturel est usuellement analysé et traité séparément. Un exemple courant est l'évolution de la densité et de la localisation des glissements de terrain induits par des précipitations suite à un tremblement de terre en raison de l'importante perturbation des couches superficielles. Cela implique que l'influence des tremblements de terre sur la structure du sous-sol modifie la prédisposition aux glissements de terrain. Compte tenu de cela, un modèle de prédiction spatio-temporelle de la variation du risque de glissement de terrain dans une région donnée suite à un tremblement de terre a été développé. Le modèle est capable de décrire la diminution de l'impact des tremblements de terre en fonction de la distance à l'épicentre ainsi que la manière dont le sous-sol retrouve sa résistance initiale. Ces diminutions sont ensuite appliquées à une analyse de stabilité de façon à calculer de nouveaux facteurs de sécurité. Bien que des programmes d'analyses puissent être proposés et que des logiciels peuvent être fournis afin de faciliter de nombreuses étapes, une approche réfléchie et bien conçue des environnements à dangers multiples reste indispensable.

## 1 INTRODUCTION

A multi-hazard analysis refers to the implementation of methodologies and approaches aimed at assessing and mapping the potential occurrence of different types of natural hazards in a given area. Analytical methods and mapping have to take into account the characteristics of the single hazardous events as well as their mutual interactions and interrelations (Delmonaco et al. 2006). The existence of relations between natural hazards and the potentially resulting consequences is an issue of increasing importance in multi-hazard studies (Kappes et al. 2010). The specific methods to deal with related hazards are as diverse as the terms and the phenomena falling into this category. However, a general approach can be applied where the investigation of the individual chain of one hazard triggering the next is performed (so-called cascading events).

Evidently, performing multi-hazard risk analysis is not a simple operation. Apart from the data requirements and time-consuming conduction of single-hazard risk studies that require know-how from different disciplines, many further aspects have to be considered. One important source of difficulty is the contrast in hazard characteristics. Hazards differ with respect to their properties such as time of onset, duration, physical properties and extent. As a result, the modelling approaches adjusted to the hazard specifics also contrast strongly (Bovolo et al 2009).

## 2 MODEL DESCRIPTION

The proposed model aims to compute and estimate the associated alteration in the landslide hazard following an earthquake event. The model describes the reduced impact of earthquakes with distance from epicentre as well as how the soil gradually regains its strength with time. This was achieved by analyzing the collected data on how seismic activity influences the critical rainfall intensity and duration needed to trigger landslides in the area impacted by the earthquake. Based on the gathered information the modelling objective was met by constructing three sub-models: A) Use empirical data to construct a sub-model linking rainfall threshold reduction as function of time after earthquake impact; B) Use empirical data to construct a sub-model linking rainfall threshold reduction as function of distance from epicentre and earthquake magnitude, C) Use an analytical hydrological model to link rainfall threshold reduction to changes in soil shear strength.

Sub-models A and B together form an empirical model for rainfall threshold reduction as a function of magnitude, distance and time after the earthquake. The model is based on the following assumptions:

- The effect of earthquake on the rainfall threshold reduction decays with distance from and time after the earthquake.
- The maximum rainfall threshold reduction (i.e. rainfall threshold reduction immediately after and at epicenter) is assumed to be a function of earthquake magnitude only.

- The temporal and spatial effects are independent and thus the spatial and temporal variations are treated separately in two different functions and multiplied to find the actual rainfall threshold reduction.
- The earthquake effect is included into the spatial model. The temporal model is a normalized model representing the remaining threshold reduction as a function of time after the earthquake.

According to the assumptions above, the threshold reduction for a given point in time and space is a product of the spatial model and the temporal model (Eq. 1):

$$\text{Threshold reduction (X, T, M)} = f_{\text{spatial}}(X, M) \cdot f_t(T) \tag{Eq.1}$$

In this model, X is the distance to the epicenter, T is the time after the earthquake and M is the earthquake magnitude. The purpose of the model is to relate the post-earthquake rainfall threshold to the pre-earthquake threshold using the derived threshold reduction function (Eq. 2):

$$\text{Post-earthquake threshold} = (1 - \text{Threshold reduction}(X, T, M)) \cdot \text{Pre-earthquake threshold} \tag{Eq.2}$$

The rainfall threshold changes referred to in the model is the numerical value of the mean rainfall intensity for a duration of one hour, i.e.  $\alpha$  in Eq. 3 below:

$$I = \alpha D^\beta \tag{Eq.3}$$

In this equation, I is the mean rainfall threshold intensity, D is the rainfall duration in hours and  $\beta$  is the slope of the threshold curve in log-log space.

### 2.1 Rainfall threshold reduction as function of time

Shou et al. (2011) modelled the effect of earthquake on the rainfall threshold reduction by an exponentially decaying function with time. The model parameter could be transferred to cumulative precipitation by using the annual mean precipitation. In the proposed model, the variations caused by other relevant parameters, such as slope angle and actual precipitation, are not treated explicitly; but model uncertainty is added to account for such variations. Shou et al. (2011) provided some data on the temporal effect of the Chi-Chi earthquake. No such data exist for the Wenchuan earthquake. From the available data it appears that the temporal behavior is site-dependent. However, Shou et al. (2011) used a model representing the average of three sites in Taiwan. Model uncertainty was introduced by two curves representing uncertainty bands. The uncertainty bands represent deviations of  $\pm 50\%$  from the average curve in a semi-log coordinate system.

Figure 1 shows the variation of the normalized rainfall threshold reduction with time for three different locations in Taiwan together with the average curve and uncertainty bands. The figure illustrates the long-term effects after the Chi-chi earthquake.

Fig. 1 Remaining rainfall threshold reduction (i.e. rainfall threshold reduction factor) as a function of time for three locations in Taiwan (colored curves) as well as an average curve and curves representing model uncertainty (black curves).

### 2.2 Rainfall threshold reduction as function of distance and earthquake magnitude

The rainfall threshold reduction as a function of earthquake magnitude and distance from the epicenter is based on the following relations and assumptions:

- For the spatial variation, the effect of earthquake on the rainfall threshold reduction is assumed to decay exponentially with distance from the epicenter/fault. This assumption is based on observations after the Chi-Chi earthquake by Khazai & Sitar (2003).
- The maximum “influence radius” of an earthquake is a function of the magnitude. The function described by Keefer (1984) is applied. This function describes the maximum distance from epicenter for seismically induced landslides as a function of earthquake magnitude. It was further assumed that at for a distance equal to the influence distance of the earthquake, the rainfall threshold reduction was 1/100 of the rainfall threshold reduction at distance 0.
- The model for maximum rainfall threshold reduction as a function of magnitude is assumed to increase with increasing magnitude.

Based on the above mentioned relations, a conceptual model for rainfall threshold reduction as a function of earthquake magnitude and distance from epicenter may be established as illustrated in Figure 2.

Fig. 2 Reduction of rainfall threshold caused by earthquake as a function of magnitude and distance

### 2.3 Linking rainfall threshold reduction and reduction of soil shear strength

Post-earthquake soil strengths may be lower than pre-earthquake (static) strengths for zones that are susceptible to

strength loss. As time passes, the progression of soil self-healing will result in increased shear strength compared to shortly after the earthquake. Temporal changes of soil properties are known to have an effect on the rainfall thresholds required to trigger landslides (Tang et al. 2009). Due to the decreased soil strength, landslide-triggering rainfall thresholds decrease compared with their pre-earthquake values (Lin et al. 2004).

A proposed methodology is presented for estimating temporal changes in soil strength related to landslide-triggering rainfall thresholds after an earthquake over a wide area (a few square kilometers). This methodology is based on response analysis with a deterministic, spatially distributed model that combines a 1-D transient infiltration model with a safety-factor analysis for calculating rainfall threshold.

After an earthquake, an abundance of loose landslide debris can be present on the hillslopes. The potential failure surface typically lies at or near the contact between the relatively permeable colluvium and the relatively impermeable underlying bedrock. The thickness of the soil cover is small compared with the length of slope, thus the infinite slope stability model can be performed to evaluate slope stability. Limit equilibrium conditions are reached at a certain depth when the mobilized shear stress (a function of soil unit weight, failure surface depth and slope angle) equals the soil shear strength, given by the Mohr-Coulomb failure criterion (Eq. 4):

$$\frac{\tan \phi'}{\tan \alpha} + \frac{c' - \gamma_w \psi \tan \phi'}{\gamma_s d_b \sin \alpha \cos \alpha} = 1 \quad \text{Eq.(4)}$$

where  $c'$  and  $\phi'$  are the effective cohesion and friction angle of the soil,  $d_b$  is the depth of the failure surface,  $\alpha$  is the slope angle,  $\gamma_s$  is the soil unit weight,  $\gamma_w$  is the specific weight of water, and  $\psi$  is the pressure head at the failure surface.

The limiting value of the pressure head which leads a slope with given geometrical characteristics and soil properties to limit equilibrium conditions can be calculated from Equation 5 as:

$$\psi_{lim} = \frac{c'}{\gamma_w \tan \phi'} + \frac{\gamma_s}{\gamma_w} d_b \cos^2 \alpha \left( 1 - \frac{\tan \alpha}{\tan \phi'} \right) \quad \text{Eq.(5)}$$

For a saturated soil cover, the evolution of the pressure head with time and depth inside the slope is governed by the following one-dimensional conservation equation (Eq. 6) (Iverson 2000):

$$\frac{\partial \psi}{\partial t} = D \frac{\partial^2 \psi}{\partial Z^2} \quad \text{Eq.(6)}$$

where  $Z$  is the depth of the point considered with respect to an horizontal reference plane;  $D = D_0 / \cos^2 \alpha$  and  $D_0$  is the hydraulic diffusivity of the soil.

Two factors,  $f_s$  and  $f_i$ , which are respectively reduction factors of soil shear strength and critical rainfall intensity, are now introduced. It is assumed that the effective cohesion and tangent of effective internal friction angle have the same reduction factor  $f_s$ . The reduction factor of critical rainfall intensity is calculated by dividing the reduced rainfall intensity  $I_{reducrit}$  due to soil shear strength reduction by the original critical rainfall intensity  $I_{critic}$  (Eq. 7):

$$f_i = \frac{I_{reducrit}}{I_{crit}} \quad \text{Eq.(7)}$$

For sandy soil, where the cohesion is zero, i.e.  $c = 0$ , an approximation solution is given by Eq. 8:

$$f_i = \frac{\frac{\gamma_s}{\gamma_w} d_b \left( 1 - \frac{\tan \alpha}{f_s \tan \phi'} \right) - (d_b - d_w)}{\frac{\gamma_s}{\gamma_w} d_b \left( 1 - \frac{\tan \alpha}{\tan \phi'} \right) - (d_b - d_w)} \quad \text{Eq.(8)}$$

### 3 RESULTS

#### 3.1 Study area: MATRIX virtual region

The case presented below is used to demonstrate the capabilities of the model in terms of hazard assessment. It is not a validation of the performance of the model. The case partly makes use of artificial data (including the digital elevation model) and partly typical engineering values (as for the soil parameters and rainfall intensity). A digital elevation model (DEM) has been developed for demonstration of the landslide hazard model (Fig. 3)

Fig. 3 3D representation of digital elevation model (DEM) for the case study region.

#### 3.2 Reduction factor for critical rainfall intensity

Figure 4 shows the results of the reduction factor inside the virtual region for a sandy soil where the earthquake event has a magnitude of 6.98 with a fault length of 3.08 km. The time span after the earthquake is assumed to be 45 days.

Fig. 4 Rainfall threshold reduction factor ( $f_i$ ) as a function of time, magnitude and distance to the fault.

The temporal model represents the remaining threshold reduction as a function of time after the earthquake. The remaining threshold reduction is represented by a normalized function with values between 0 and 1. Value 1 corresponds to the maximum rainfall threshold reduction (i.e. the rainfall threshold reduction immediately after the earthquake) and value 0 corresponds to no remaining rainfall threshold reduction (i.e. after long time, when the occurrence of the earthquake has no effect on the rainfall threshold.) The effect from the earthquake on the rainfall threshold reduction is included in the spatial model.

### 3.3 Reduction factor of the soil shear strength

A quantitative assessment of the relationships between different factors (i.e. slope angle, failure depth and water table depth) and reduction factor of soil shear strength due to earthquake was performed. Figure 5 shows the areal distribution of the reduction factor of the soil shear strength considering a rainfall intensity of 120 mm a day. The bedrock is assumed to be much less permeable than the soil cover. Soil depth varies from 4 to 7 m depending on the type of soil and topographic characteristics inside the virtual region.

Fig. 5 Spatial distribution of the soil shear strength reduction factor ( $f_r$ ).

### 3.4 Slope stability assessment including the reduction factors

A two dimensional equilibrium stability analysis based on the infinite slope model was carried out in order to compute the new factors of safety that included the reduction factors. The mean values of the logarithmic distributions functions of the input parameters were applied in the analyses. A constant porosity of 42% and an evapotranspiration of 5 mm/day were selected throughout the area. Five different friction angles were used for the different soil types: 30, 32, 34, 36, 38°. Figure 6 shows the results of the stability analysis considering the reduction of the soil strength after an earthquake.

Fig. 6 Stability analysis considering the loss of strength of soil due to the perturbations caused by a magnitude 6.98 earthquake.

## 4 CONCLUSIONS

A natural system is not just the sum of its components but is the result of many interacting parts. Hence, a multi-hazard assessment should address evolving characteristics in space and time. These characteristics can, for analysis purposes, be analyzed as the alteration of the susceptibility and the triggering mechanism. A multi-hazard assessment offers the advantage to consider a slightly larger part of the overall system. The major challenge is to identify the relationships among the interacting factors and establish the respective links.

For this reason, a model that includes the reduction of the soil strength parameters induced by the strong motion of an earthquake was developed and implemented. A virtual case study was performed to assess the behavior of the model and its parameters. This was achieved by calculating two reduction factors that represented the reduction of rainfall threshold in space and time, and the reduction of the soil strength due to prevailing conditions.

There are still some limitations regarding the model and further validation needs to be done. A thorough calibration of the reduction factors should be done locally and the possibility of using real events that are well documented should be considered. However, despite its limitations, the model provides a practical approach to assess the prospective outcomes of future hazards and their interactions. Thus the model contributes to increasing the knowledge required for the protection of the people at risk and their assets.

**RÉSUMÉ:** Des glissements de terrains importants ont eu lieu au pays du cèdre. La topographie montagneuse du Liban, la présence des aquifères et les fouilles réalisées pour les travaux de construction sont à l'origine du risque élevé de glissements de terrains. Un objectif principal visé par cette étude est de comprendre les facteurs causant ces instabilités. Deux études de cas bien documentés sont analysées. Les glissements ont lieu dans des formations argileuses à l'interface au-dessus de formations plus rigides composées de marne argileuse ou de roche calcaire. On observe aussi les glissements dans des alternances de banc calcaire fracturé et couche d'argile intercalée. Des conclusions intéressantes sur le comportement des sols à la rupture sont avancées. Les résultats escomptés devront compléter une cartographie éventuelle des cas de glissement à travers le Liban.

**ABSTRACT:** Important landslides took place in the land of cedar. Lebanon's mountainous topography, the presence of aquifers and excavations for construction are at the origin of the high risk of landslides. A main objective of this study is to understand the factors causing these instabilities. Two well-documented case studies are analyzed. Landslides occur in clay formations at the interface over more rigid formations composed of clayey marl or limestone. There are also landslides in alternating fractured limestone bench and intercalated clay layer. Interesting conclusions on the behavior of soil at failure are proposed. The expected results should help in achieving a possible landslide cases mapping throughout Lebanon.

**MOTS-CLÉS:** glissement de terrains, argile marneuse, schiste argileux

## 1 INTRODUCTION

Le Liban a connu ces dernières années des hivers avec des pluies particulièrement abondantes. Ces intempéries sont à l'origine de plusieurs cas d'instabilité des terrains surtout en régions montagneuses parfois très proches du littoral densément habité. La densité moyenne de la population libanaise est de 450 habitants par km<sup>2</sup>, ce chiffre étant beaucoup plus élevé sur la côte méditerranéenne et diminuant en altitude. L'urbanisation couvre donc aujourd'hui une grande superficie du pays du cèdre. En janvier 2013, la tempête qui a frappé le pays a laissé des dégâts énormes avec des glissements menaçant des habitations dans plusieurs régions. Mais l'activité humaine due à l'urbanisation se manifestant par les fouilles réalisées pour les travaux de construction vient aussi se conjuguer aux facteurs naturels déclenchant les glissements.

La répartition spatiale des mouvements relève de la topographie et de la géologie (Carrara et al. 1995). Leur occurrence est très marquée par les variations climatiques mais peut aussi être liée à des secousses sismiques ou encore être induite par les activités humaines. Le glissement est défini par le déplacement de terrains meubles ou rocheux et peut être identifié par un état d'activité (Cruden et Couture 2011). Selon la géométrie de la surface de rupture, deux types principaux de glissements sont distingués: d'abord, le glissement plan où la ligne de rupture suit généralement une couche mince ayant de mauvaises caractéristiques mécaniques et sur laquelle s'exerce souvent l'action de l'eau (couche savon). Ensuite, le glissement plutôt rotationnel où la surface de glissement est plus ou moins circulaire; ce mouvement étant caractérisé par l'existence d'une zone de départ (Abramson et al. 2002). Le passage de l'état de stabilité à l'état d'instabilité (Dikau et al. 1996) relève de causes nombreuses: externes (l'érosion, les séismes, les surcharges

d'un ouvrage); et internes (l'augmentation de la pression interstitielle, l'altération d'une roche). Souvent aussi, les causes sont conjuguées. Les matériaux affectés sont très variés (Fletcher et al. 2002), mais globalement la présence d'argile en forte proportion est toujours un élément défavorable. Au Liban, le rôle de l'eau est reconnu comme le facteur déclenchant des glissements en l'absence du facteur tectonique. Il y a aussi les excavations réalisées qui deviennent un facteur déstabilisant. Beaucoup de techniques ont été développées afin de minimiser l'impact des glissements de terrains (Popescu 2002). Une analyse des facteurs causant les instabilités de pentes au Liban a été réalisée (Rahhal et al. 2003). Un travail de cartographie des mouvements de terrains a aussi été entrepris (Rahhal et al. 2004). Enfin, des études probabilistes sont aussi conduites dans le but de comprendre la sensibilité des paramètres géotechniques dans l'évaluation de la stabilité des pentes. (Rahhal and Abou Rached 2005; Rahhal 2006; Benarroch et al. 2011).

Cet article présente une analyse étoffée de deux glissements, survenus au nord de Beyrouth dans deux régions densément peuplées. La compréhension du comportement des sols est une étape fondamentale lors de l'analyse d'un glissement de terrain.

## 2 CAS DU GLISSEMENT DE ESSFIRÉ

### 2.1 Localisation et contexte

Essfiré est une bourgade au nord du Liban, d'altitude moyenne 1100 mètres. Elle est située à 120 km de la ville de Beyrouth. En mars 1998, le sol à Essfiré a glissé, suite à la fonte de la neige accumulée. Ce glissement montré dans la Figure 1 sera l'objet de cette étude. La région a déjà connu dans son

histoire plusieurs glissements depuis les années soixante. La zone glissée a 70m de largeur, et 835m de longueur. Le profil de la pente a été tracé entre les cotes 960 et 1170 mètres. La pente à la cote 960m a un angle de 18°, elle commence à s'atténuer peu à peu, pour atteindre 12° au milieu du glissement, et arrive enfin à 10° au sommet, aux alentours de la cote 1170m.

Figure 1. Vue globale du glissement dans le centre de la bourgade Essfiré. Le mouvement entre les maisons est indiqué par la flèche.

## 2.2 Données géotechniques

Pour pouvoir identifier les différentes couches de sol constituant la région glissée, une analyse détaillée des forages réalisés s'avère être indispensable. Le profil du sol qui a glissé peut être représenté par 3 couches principales: une première couche en surface constituée d'une argile sableuse avec du gravier; une seconde couche en profondeur formée d'une argile marneuse; et enfin, une troisième couche constituant le substratum rocheux. Les propriétés géotechniques minimales et maximales des deux couches argileuses sont présentées dans le Tableau 1.

Tableau 1. Plage de valeurs pour les propriétés des couches d'argile sableuse et d'argile marneuse.

Propriété	Argile sableuse	Argile marneuse
Limite de liquidité (%)	30-52	21-67
Limite de plasticité (%)	12-24	7-35
Pourcentage de fines (%)	31-96	42-83
Pourcentage d'argile (%)	9-42	9-52

La couche superficielle du sol est formée principalement d'une argile sableuse d'épaisseur variable allant de 1 à 13m. Les essais de cisaillement direct réalisés permettent d'attribuer à cette couche d'argile sableuse les valeurs moyennes de cohésion et d'angle de frottement suivantes:  $c = 20 \text{ kN/m}^2$  et  $\phi = 22^\circ$ . Par ailleurs sa perméabilité mesurée est  $k = 8 \times 10^{-5} \text{ cm/s}$ . En dessous de la couche d'argile sableuse, se trouve une couche d'argile marneuse d'épaisseur variant entre 1.5 m et 8 m. Les essais de cisaillement direct réalisés sur cette argile marneuse donnent les valeurs moyennes de cohésion et d'angle de frottement suivantes:  $c = 46 \text{ kN/m}^2$  et  $\phi = 18.5^\circ$ . Une perméabilité représentative de cette couche d'argile marneuse est donnée par  $k = 7 \times 10^{-6} \text{ cm/s}$ . L'indice de plasticité de 22 % laisse supposer un taux et un potentiel de gonflement pour cette argile marneuse assez élevés. En cas de saturation de cette argile, elle pourrait gonfler considérablement, et sa cohésion risquerait de diminuer. Cette couche d'argile jouerait donc en cas de saturation, le rôle d'une couche savon. Sachant que pendant la période des forages, aucune nappe n'a été détectée, cela laisserait supposer que ces valeurs sont «à sec». Enfin, le substratum rocheux a été

trouvé à des profondeurs variant entre 5 m et 17m. Ce rocher est moyennement fracturé et fissuré, et ses fractures sont remplies d'argile. Sous l'effet des pluies et des infiltrations d'eau dans le sol, la saturation d'argile comblant les fissures entraînerait leur gonflement, ce qui exercerait une importante pression latérale dans le rocher, et augmenterait le risque de détachement du rocher de l'argile qui est en dessus.

## 2.3 Calcul et analyse de la stabilité

Une analyse du profil de sol obtenu laisserait présager les causes éventuelles qui ont déclenché le glissement. La couche d'argile marneuse, en cas de saturation pourrait très bien jouer le rôle de couche savon pour cette pente. Le glissement s'étant produit au mois de mars, la fonte des neiges a un rôle à jouer dans la saturation du sol. La nature gonflante de cette argile et son grand potentiel d'effondrement renforcent la théorie de la couche savon; ce qui nous laisse deviner une surface de rupture potentielle qui se trouverait au niveau de l'argile marneuse. Ceci valide l'existence d'un glissement plan dû à une couche saturée aux faibles propriétés mécaniques qui glisserait sur une discontinuité. Le problème serait donc a priori un problème d'eau. Ayant considéré la saturation de la couche d'argile marneuse comme étant la cause du glissement, il a été décidé de répartir le profil en 3 couches: une première couche d'argile sableuse (couche 1), une deuxième couche d'argile marneuse non saturée (couche 2) qui perd de ses propriétés mécaniques, et enfin une dernière couche qui représente le substratum rocheux (couche 3). L'analyse qui suit va considérer donc deux périodes, selon que la couche d'argile marneuse soit non saturée (période sèche) ou saturée (période humide), pour observer l'évolution du coefficient de sécurité entre ces deux périodes de l'année.

### 2.3.1 La période sèche

Cette période est la période d'été en principe, où il n'existe pas d'eau dans le sol. Pendant la période d'été, quand les forages ont été réalisés, l'argile marneuse n'a pas de partie saturée. Les propriétés mécaniques à considérer seront celles trouvées lors de la réalisation des essais sur des échantillons tirés à partir des forages exécutés. La surface de rupture a été prédéfinie à l'avance. Ainsi durant la période sèche, les coefficients de sécurité obtenus suivant quatre méthodes de calcul (Fellenius, Bishop, Janbu, Morgenstern-Price) sont de l'ordre de 3.

### 2.3.2 La période humide

Cette période est normalement caractérisée par les mois d'hiver et du début du printemps, où les fortes pluies, et la fonte des neiges ont un effet sur l'approvisionnement du sol en eau, et la saturation de ses couches. Les propriétés mécaniques à observer pour l'argile marneuse saturée en profondeur sont:  $\phi_u = 0$ , et une valeur réduite de la cohésion  $C_u$  sera considérée. La saturation de l'argile marneuse entraînant son gonflement et une diminution de ses propriétés cohésives, plusieurs itérations seront effectuées sur cette valeur en la diminuant constamment, afin de trouver la valeur critique de la cohésion qui entraînerait la rupture, et la chute du versant. La surface de rupture a été prédéfinie à l'avance, comme étant parallèle à la discontinuité entre le rocher et le sol. Une variation en diminution de la cohésion donne les valeurs de coefficients de sécurité montrés dans le Figure 2. Les cohésions qui induisent la rupture pour les différentes méthodes de calcul varient entre 23 et 29 kPa. Le coefficient de sécurité diminue presque linéairement avec la cohésion tel que montré dans la Figure 2. D'autre part, en considérant une cohésion de 26 kPa pour l'argile marneuse saturée, l'équilibre des forces pour une même tranche a été analysé, et l'évolution des forces sur cette tranche entre période sèche et période humide a été calculée. L'analyse des résultats montre une diminution moyenne de 33 % de la résistance au cisaillement à l'interface roche/sol dans les conditions humides.

Figure 2. Evolution du coefficient de sécurité en fonction de la cohésion en période humide pour différentes méthodes de calcul.

### 3 CAS DU GLISSEMENT DE ANTELIAS

#### 3.1 Localisation et contexte

Le deuxième glissement de terrain analysé est survenu en Avril et Mai 2006 à Antélias, une ville sur le littoral au nord de Beyrouth, emportant une partie de la route Faouar Antélias-Raboueh (Figure 3 et Figure 4). La synthèse des levés géologiques, des sondages de reconnaissance et des constatations sur le site, permet de schématiser le site comme suit. Dans la partie supérieure du glissement (cote 130m) et le sommet de la fouille Mission La Vie (cote 95m), la surface du sol a une pente de 15° dans la direction Ouest-25°-Sud. Dans sa partie inférieure, la surface se poursuit avec une pente 15° dans la direction Ouest-45°-Sud pour arriver sur un plat artificiel ayant servi d'aire de stockage de déchets à la cote 86m. Dans la zone de glissement, le pendage ne peut être mesuré en surface car le rocher n'y affleure pas, mais des sondages indiquent que le toit du rocher a un pendage de 14° dans la direction Nord-78°-Ouest. Les relevés piézométriques montrent que la zone de glissement est imbibée d'eau; Elle est alimentée par un aquifère et par les égouts défailants le long de la route.

Figure 3. Route Faouar Antélias-Raboueh coupée par le glissement.

Figure 4. Le glissement de Antélias vers la fouille Mission la Vie. L'ouverture de la fouille serait un facteur déclenchant

#### 3.2 Données géotechniques

Dans la zone de glissement, on rencontre de haut en bas 3 couches, à savoir: D'abord, à la surface, une couche d'éboulis et de dépôts quaternaires alluviaux formée de silts argilo-sableux et caillouteux. Cette couche s'étend jusqu'à la surface et a une épaisseur moyenne de 7m. Ensuite, une couche d'argile silteuse fortement surconsolidée (schiste argileux ou shale), de couleur brun chocolat. Son épaisseur est variable entre 0,5 et 4m avec une moyenne de 1,5m. L'épaisseur semble croître en allant vers le Nord. Enfin, le substratum rocheux calcaire, altéré et fissuré. Cette roche est relativement perméable (10 à 20 lugeons) et sert de drain aux argiles qui la surmontent. En termes de caractéristiques mécaniques, la couche de surface a un angle de frottement  $\phi=25^\circ$  et une cohésion  $c=20$  kPa. Cette couche n'intéresse pas le glissement. La deuxième couche (schiste argileux) est responsable du glissement. En effet, dans leur état naturel ces schistes argileux sont très résistants, avec une cohésion de plusieurs centaines de kN/m<sup>2</sup>. Cependant, mis en contact prolongé avec l'eau, ils sont fortement absorbants et leurs propriétés mécaniques se dégradent fortement, jusqu'à provoquer un glissement à leur surface. Deux échantillons de ce schiste argileux ont été testés (essais CU) pour en déduire un angle de frottement  $\phi_{cu}$  et une cohésion  $C_{cu}$ . Les résultats sont les suivants: Essai 1 ( $I_c = \text{indice de consistance} = 0,803$ ;  $\phi_{cu} = 15^\circ$ ;  $C_{cu} = 44$  kPa); Essai 2 ( $I_c = \text{indice de consistance} = 0,725$ ;  $\phi_{cu} = 17^\circ$ ;  $C_{cu} = 46$  kPa). Les caractéristiques ci-dessus ne représentent pas en réalité les caractéristiques des schistes argileux lors du glissement et ce, pour deux raisons, à savoir: Premièrement,  $\phi_{cu}$  et  $C_{cu}$  représentent les caractéristiques mesurées à court terme; or quand les sols argileux sont soumis à des contraintes de cisaillement pendant un temps assez long, les particules le long de la ligne de glissement potentielle se réorientent progressivement (fluage); il en résulte un affaiblissement des caractéristiques du sol le long de cette ligne et elles tendent vers les "caractéristiques résiduelles" en grande déformation. Ces dernières sont estimées, aux deux tiers des caractéristiques mesurées ( $IP=17\%$ ), soit:  $\phi_{rcu} = 2/3 \phi_{cu}$  et  $C_{rcu} = 2/3 C_{cu}$ . Deuxièmement, si en plus de l'affaiblissement dû au fluage, on permet au schiste argileux fortement absorbant de se saturer d'eau et de gonfler (gonflement 5,6 et 7,8%), il s'affaiblit encore plus pour tendre vers des caractéristiques minimales  $\phi_{mecu}$  et  $C_{mecu}$  qui sont essentiellement fonction de l'indice de consistance  $I_c$ . Cependant, en surface de la couche de schiste argileux, directement en contact avec l'eau, l'indice de consistance  $I_c$  peut atteindre 0,5 formant ainsi une pellicule de quelques centimètres extrêmement affaiblie (couche savon). En appliquant les deux réductions (caractéristiques résiduelles et

caractéristiques minimales) aux deux échantillons, pour obtenir les caractéristiques des schistes argileux le long de la ligne de glissement, nous obtenons: pour l'essai 1 ( $\phi_{m\text{cu}} = 10^\circ$  et  $C_{m\text{cu}} = 2,8$  kPa) et pour l'essai 2 ( $\phi_{m\text{cu}} = 11^\circ$  et  $C_{m\text{cu}} = 4,8$  kPa).

Pour une couverture de 7m de sol, de densité 2, la résistance au cisaillement au toit de la couche de schiste argileux (shale) serait de 26,3 à 30,7 kPa. Ces valeurs se recoupent assez bien avec celles dans la littérature pour des argiles raides et shales à long terme, soit une résistance au cisaillement de 20 à 40 kPa.

### 3.3 Calcul et analyse de la stabilité

Une estimation des forces dues à la pression de l'eau dans les fissures montre que celles-ci sont très faibles comparées aux forces actives de gravité qui provoquent le glissement et aux forces passives de cohésion qui le freinent (de l'ordre de 4 à 5%). Ces faibles forces de pression d'eau n'ont d'importance pour le glissement que si les forces actives de gravité et les forces passives de cohésion s'équilibrent à peu de chose près, c'est-à-dire si les forces actives de gravité seules sont très légèrement inférieures aux forces passives de cohésion (période sèche stable) mais en y ajoutant les forces actives de poussée d'eau, elles deviennent légèrement supérieures aux forces de cohésion (fortes précipitations).

Le glissement plan se fait sur le toit des shales, qui dans la direction du glissement (Ouest 13° Sud) faisant un angle de 25° avec la ligne de plus grande pente, a une pente de 12°7. En effet, il ne peut se faire dans les couches de surface (éboulis et dépôts quaternaires) car l'angle de frottement  $\phi = 20^\circ$  est supérieur à la pente 12°7 et il ne peut se faire dans la masse des shales ou au contact shale-rocher car dans ces zones, le schiste argileux a un indice de consistance supérieur à 0,725 donc des caractéristiques résiduelles  $\phi_{cu} \geq 10^\circ$  et  $C_{cu} \geq 29,3$  kPa entraînant une résistance au glissement supérieure aux forces actives de gravité. Sur le toit des schistes argileux (couche savon), les contraintes de cisaillement dues au poids des sols de surface, sur un élément de pente 12°7, sont en moyenne de 30 kPa.

Pour équilibrer ces forces actives, le toit des schistes argileux devrait avoir en moyenne une résistance au cisaillement de 30 kPa, or les schistes argileux mis en présence d'eau de façon prolongée, atteignent leur état minimal, c'est-à-dire une résistance au cisaillement de 26,3 à 30,7 kPa. Ce calcul montre que les forces actives et passives s'équilibrent sensiblement (le coefficient de sécurité étant très voisin de 1) et que le glissement peut se produire. Si aux forces actives nous ajoutons les faibles forces dues aux pressions d'eau dans les fissures, il devient alors très probable que le glissement s'active comme il a été constaté après de fortes précipitations. En admettant une résistance moyenne au cisaillement égale 28,5 kPa, les coefficients de sécurité sont: Absence de précipitations,  $F = 28,5/30 = 0,95$ ; incertitude sur le glissement. Fortes précipitations: poussées de l'eau = 1,8 kPa par mètre carré de glissement:  $F = 28,5/31,8 = 0,9$ ; le glissement est presque certain. Le bilan des forces, présenté ci-dessus, néglige les forces de butée au pied du glissement comme cela est effectivement le cas après ouverture de la fouille Mission La Vie.

La question qui se pose naturellement est de savoir si l'ouverture de la fouille a contribué au glissement, sachant que le sol avait été très affaibli par les écoulements d'eaux usées. Pour y répondre nous avons évalué les forces de butée au pied du glissement, avant ouverture de la fouille. Pour une fouille de 7m de hauteur en moyenne et 30m de long environ, la force de butée est de 50000 kN, soit une contrainte moyenne tangentielle sur le plan de glissement (estime à  $10.000\text{m}^2$ ) de 4,75 kPa. En admettant une résistance moyenne au glissement de 28,5 kPa, l'ensemble des forces passives serait égal à  $28,5 + 4,75 = 33,25$  kPa, soit une sécurité  $F = 33,25/30 = 1,1$ ; ce qui signifie que le glissement n'aurait probablement pas eu lieu. Il semblerait donc que l'ouverture de la fouille Mission La Vie ait contribué au glissement bien que faiblement, la raison essentielle étant

l'affaiblissement du sol par les eaux usées. En définitive, nous pouvons affirmer que le glissement est dû à deux causes, l'une majeure et l'autre mineure, à savoir: la cause majeure est due à l'imbibition en surface, et pendant une période prolongée, des schistes argileux qui se situent à 7m sous la surface du sol. Cette imbibition est due aux pertes en continu des égouts vétustes le long de la route Fouar Antélias-Raboueh. Elle réduit très fortement la résistance du sol le ramenant dans un état à la limite du glissement (sécurité  $F = 1.1$ ). Quant à la cause mineure: le sol étant à la limite du glissement, l'ouverture de la fouille qui enlève la faible butée en pied du glissement (15% des forces résistantes) le fragilise encore plus, rendant le glissement possible à la moindre force active supplémentaire.

## 4 CONCLUSION

Les deux glissements sont plans: le sol glissé subit une translation, formant un bloc non ou peu fissuré. Le glissement se fait sur le toit de formations argileuses affaiblies par l'eau et sensiblement parallèles au toit du rocher. Pour le deuxième glissement, l'ouverture de la fouille en aval constitue un élément de déclenchement supplémentaire. L'effet néfaste des propriétés mécaniques affaiblies des argiles est expliqué.

# A smart adaptive multivariable search algorithm applied to slope stability in locating the global optima

Un algorithme adaptatif multivariable de recherche d'optimum global appliqué à la stabilité des pentes

Saha A.

Irrigation & Waterways Department, Govt. of West Bengal, Kolkata, India

**ABSTRACT:** The paper addresses the topic of single objective optimisation of a three dimensional real-world problem and introduces a hybrid technique of an iterative random population search within a geometrically shrinking hypercube and a sort of simplified Design of Experiments (DOE). A 'population' of design variables are generated and augmented with the multivariable objective function, and the design variables pertaining to the local optima are perturbed by a factor ( $\Delta k$ ) sequentially in both positive and negative directions to create  $2(2^N-1)$  offspring in the neighbourhood of local optima to hopefully produce some better progeny. The 'fittest' perturbed offspring decides a new contracted search interval for the consecutive generation according to a geometric decay rule commensurate with the generation number. A 'simple hill-climbing' strategy in Artificial Intelligence context is followed subsequently and the loop is continued to produce fresh generations of refined offspring till the outcome converges to the global optimum. The method is applied in searching the critical slip-surface of a vulnerable soil-slope and it was revealed that the optimum found by this method is superior to that found by traditional and non-traditional (genetic algorithms) optimization techniques while using much less computational resources.

**RÉSUMÉ:** L'article traite de l'optimisation à une seule fonction objectif pour un problème réel tridimensionnel et introduit une technique hybride de recherche itérative à partir d'une population aléatoire au sein d'un hyper cube de taille décroissante, selon une méthode simplifiée de plan d'expérience. Une "population" de variables de design est générée, et étendue grâce à la fonction objectif multi variable. Les variables de design correspondant à l'optimum local sont alors perturbées par un facteur ( $\Delta k$ ) de manière séquentielle dans les directions à la fois positives et négatives pour créer  $2(2^N-1)$  individus de génération suivante dans le voisinage de cet optimum, dans l'espoir de produire une meilleure génération. La génération perturbée la plus satisfaisante selon l'objectif définit un nouvel intervalle de recherche, de taille réduite pour la génération suivante, selon une règle de décroissance géométrique en rapport avec le rang de génération. Une stratégie simple de plus grande pente dans un contexte d'intelligence artificielle est suivie pas à pas et une boucle produit de nouvelles générations améliorées jusqu'à ce que le résultat converge vers l'optimum global, indépendamment de la population initiale. La méthode est appliquée à la recherche de la surface de glissement critique d'un sol en pente vulnérable. Il a été constaté que l'optimum trouvé par cette méthode est plus critique que celui donné par les méthodes traditionnelles et non traditionnelles (algorithmes génétiques) et de plus, cette méthode est moins exigeante en terme de capacité de calcul.

**KEYWORDS:** hybrid technique, random population search, optimization algorithm, slope stability.

## 1 INTRODUCTION

The stability of slopes has received wide attention due to its practical importance in the design of excavations, embankments, and dams. There are numerous methods available for stability analysis and the majority of analyses performed in practice still use traditional limit equilibrium approaches. By the advent of computers, the use of optimization techniques in locating the critical slip surface has been a major topic for the researchers. Duncan (1996) presented a comprehensive review of both limit equilibrium and finite-element analysis of slopes. Malkawi et al (2001) developed an effective approach for locating the critical circular slip surface based on Monte-Carlo techniques. Non-traditional optimization algorithms simulating processes drawn from nature like genetic algorithm (GA) and simulated annealing (SA) have proved to be efficient in locating the global optima. GA mimics the principles of Darwin's natural selection and survival of the fittest rule, in which an optimum solution evolves through a series of generations of population and has the super ability of global convergence and parallel searching. SA is the stochastic evolution of thermodynamic state of slow cooling of molten metals to achieve a crystalline absolute minimum energy state, where a perpetual decreasing sequence of temperature controls the reproduction rate, which is very efficient in neighborhood search. Li et al (2009), Author (2011) proposed hybrid global search procedures combining GA with SA. While summarizing

the state of the art techniques for evolutionary algorithm (EA) parameter tuning, T. Beielstein (2003) exclaims that "*real world optimization problems allow only a few preliminary experiments to find good EA settings. As the commonly used 'one factor at a time approach' is considered as inefficient and ineffective, we recommend DOE methods*". The present paper introduces a new Soft Computing algorithm- a hybrid technique of an iterative *random population based search embedded with simulated annealing (SA) features within a geometrically shrinking hypercube coupled with simplified Design of Experiments (DOE)*.

## 2 APMA-A NOVEL OPTIMIZING TOOL

A smart adaptive population based multivariable function optimization algorithm proposed herein, and referred to as APMA hereinafter, is a simple yet robust optimization procedure basically of heuristic nature. Before plunging into details, a fitness function is defined to maintain uniformity over various problem domains and to map the 'goodness' of the objective function (here FOS) value to a fitness value. The fitness of an individual is calculated as the worst objective function objective function (FOS) value of the whole population subtracted from the individual's objective function value. Hence, this fitness function is computed for the individual as  $F_i = \max. \{f(x)_j | j = 1, 2, \dots, n\} - f(x)_i$ . Where; 'n' is the population

size.  $f(x)_i$  is the objective function (here FOS of  $i^{\text{th}}$  individual). The technique is known as windowing as it eliminates the worst individual (FOS)-the probability comes to zero, and stimulates the better ones.

Within the random generated set of population (n) of design multivariable (N-dimensions or feature vectors),  $f(x_i, y_i, z_i, \dots, w_i)$  within wide deterministic search boundaries for each variable, and subsequent objective function evaluations, the minimum is located. With a view to exploit the search space neighbourhood

the N-multivariable set  $f(x_{i_{\min}}, y_{i_{\min}}, z_{i_{\min}}, \dots, w_{i_{\min}})$  creating this minimum is perturbed by a factor ( $\Delta k$ ) sequentially in both directions (positive as well as negative directions)  $f(x_{i_{\min}} \pm \Delta k), (y_{i_{\min}} \pm \Delta k), (z_{i_{\min}} \pm \Delta k), \dots, (w_{i_{\min}} \pm \Delta k))$  to

$$2 \sum_{i=1}^{i=N} {}^N C_i = 2 \sum_{i=1}^{i=N} \frac{N!}{(i!)(N-i)!} = 2(2^N - 1)$$

create offspring  $\{ \text{Where, } N! = N.(N-1).(N-2) \dots \dots 3.2.1 \}$  in the neighbourhood of the local minimum in an attempt to generate some superior offspring. Hence, for a three variable function (like slope-stability problem)  $f(x_i, y_i, z_i)$ , a population (of n individuals) are randomly generated and their local minimum  $f(x_{i_{\min}}, y_{i_{\min}}, z_{i_{\min}})$  located for the first generation.

Thereafter, this local minimum is perturbed initially in the positive direction and function evaluations are made at  $f(x_{i_{\min}} + \Delta k), (y_{i_{\min}}, z_{i_{\min}}); f(x_{i_{\min}}, (y_{i_{\min}} + \Delta k), z_{i_{\min}}); f(x_{i_{\min}}, y_{i_{\min}}, (z_{i_{\min}} + \Delta k)); f(x_{i_{\min}} + \Delta k), (y_{i_{\min}} + \Delta k), z_{i_{\min}}); f(x_{i_{\min}}, (y_{i_{\min}} + \Delta k), (z_{i_{\min}} + \Delta k)); f(x_{i_{\min}} + \Delta k), (y_{i_{\min}} + \Delta k), (z_{i_{\min}} + \Delta k)); f(x_{i_{\min}} + \Delta k), (y_{i_{\min}} + \Delta k), (z_{i_{\min}} + \Delta k));$

and finally in the negative direction, by changing the sign of  $\Delta k$  in above expressions. Hence, apart from objective function evaluations of all n number of population individuals in each generation, the algorithm requires further function evaluations at  $2(2^N-1)$  points around the local minimum of each generation. Now as fresh generations are produced, often different selection pressures of reproduction are needed at successive generations. Hence, the choice of a value of the sequential perturbing factor ( $\Delta k$ ) becomes of paramount importance, in a sense that if it is too large it will be adequate in the first phase of the search but not in the final phase and vice versa if it is too small. Further, this  $\Delta k$  is likely to be different for different design variables commensurate with their individual feasible search intervals. As such, the situation calls for some sort of normalization of  $\Delta k$  in initial phase for application in various problem domains, and further it should possess the flexibility of shrinking itself automatically in successive generations according some decay rule in compliance with the selection pressure criteria. In this study, this perturbing parameter is defined as  $\Delta k = \kappa.(x_i^U - x_i^L) \Delta_i$ , where,  $\kappa$  is a problem specific constant; to be fixed after some initial trials.  $x_i^U$  and  $x_i^L$  are the upper and lower bounds of a design variable and  $\Delta_i [=G_i(1-r)^{(G_i-1)}]$  is the size reduction parameter, where,  $G_i$  is the generation number and 'r' a constant less than unity. As the number of design variables (N-dimensions) increases, more trials are needed for fixing the value of  $\kappa$ . The 'fittest' perturbed offspring

$f(x_{i_{\min}}^p, y_{i_{\min}}^p, z_{i_{\min}}^p, \dots, w_{i_{\min}}^p)$  of the  $i^{\text{th}}$  generation decides a new contracted search interval for the consecutive generation, wherein the value each design variable corresponding to the fittest perturbed offspring is assigned the central value of the interval. The two new extreme bounds of the fresh search interval is the product of the positive and negative value of this central value and the size reduction parameter,  $\Delta_i$ . Thus, if the local minimum objective function of the previous generation be

$$f(x_{(i-1)_{\min}}^p, y_{(i-1)_{\min}}^p, z_{(i-1)_{\min}}^p, \dots, w_{(i-1)_{\min}}^p), \text{ the current (that is, } i^{\text{th}} \text{ search interval becomes, } \left[ \left\{ x_{(i-1)_{\min}}^p \pm G_i(1-r)^{G_i-1} x_{(i-1)_{\min}}^p \right\}, \left\{ y_{(i-1)_{\min}}^p \pm G_i(1-r)^{G_i-1} y_{(i-1)_{\min}}^p \right\}, \left\{ z_{(i-1)_{\min}}^p \pm G_i(1-r)^{G_i-1} z_{(i-1)_{\min}}^p \right\}, \dots, \left\{ w_{(i-1)_{\min}}^p \pm G_i(1-r)^{G_i-1} w_{(i-1)_{\min}}^p \right\} \right]$$

A new population of random variables (of size n) is again generated from scratch within the new reduced stochastic search interval and again objective function evaluations are made for each set of new random variables so generated. The generated set replaces the initial one and the loop is continued to produce fresh generations of refined offsprings till the outcome converges to the global optima.

### 2.1 APMA efficacy checked with benchmark test functions

With a view to examine the performance of the algorithm, APMA is initially applied to some benchmark unconstrained global optimization test functions like Goldstein-Price's function, Hartman's function, Beale's function, Perm's function, Booth's function, Bohachevsky's function (A. Hedar), Six hump camel's back function and Xin-She-Yang's function (X.-S. Yang, 2010) and promising results were obtained. APMA successfully captured all the four optima of the multimodal Himmelblau function (Deb K., 2000):  $f(x_1, x_2) = (x_1^2 + x_2 - 11)^2 + (x_1 + x_2^2 - 7)^2$ , [the optima being (-2.805, 3.131); (-3.779, -3.283); (3.584, -1.848); (3,2)] in each and every simulation run while finally converging to the global minimum at (3,2) [The simulation runs has been done with  $\kappa=80-90\%$  &  $r=0.10$ ]. The method may be regarded as a basic thrust of 'Artificial Intelligence', that is to get the computer to perform tasks fast and automatically. The method is independent of the initial vector and as no specific search direction is used in this method, this random search method is expected to work efficiently in many classes of problems.

### 3 THE PROBLEM DEFINITION

A problem cited by Spencer (1967) is chosen for analysis. The problem parameters, soil-data and search boundaries are depicted in Fig.1. In the search process, the three independent design variables are the abscissa (CX) and ordinate (CY) of the circle centre and the depth factor ( $N_d$ ) of the circular failure surface. The base width (B) and height (H) of slope are assumed as 60 meters and 30 meters respectively.

Fig.1. Initial variable bounds of the tri-variable & soil data used in search for critical circle-The Slope-Stability problem definition.

The radius  $R=f\{CX, CY, N_dH\}$ . Based on a few trials, the feasible bounds of the design variables, has been identified as: -

$0.25B \leq CX \leq B$ ,  $1.05H \leq CY \leq 3H$ ,  $0.80 \leq N_d \leq 1.25$ . In the widely used limit equilibrium methods of slope analysis, the potential slip surface and the sliding mass are divided into segments or slices. The FOS, (F) is related to the total height of the slope H, the effective subsoil parameters  $c'$ ,  $\phi'$  and  $\gamma$ , the pore pressure ratio  $r_u (= u/\gamma h)$ , the individual slices of width  $b_i$ , height  $h_i$  and  $\alpha_i$ -the inclination of slice on the failure arc with the horizontal, by the following equation (Bishop, 1955):

$$F = \frac{\sum_{i=1}^n \left[ \left\{ \left( \frac{c'}{\gamma H} \right) \left( \frac{b_i}{H} \right) + \left( \frac{b_i}{H} \right) \left( \frac{h_i}{H} \right) (1 - r_u) \tan \phi' \right\} \frac{\sec \alpha_i}{1 + \tan \alpha_i \tan \phi'} \right]}{\sum_{i=1}^n \left( \frac{b_i}{H} \right) \left( \frac{h_i}{H} \right) \sin \alpha_i}$$

A modest population size (n) of 20 is adopted. The design variables of the fittest population genre (local FOS<sub>min</sub>) is perturbed sequentially by a factor  $\Delta k$  in both directions, resulting in  $2(2^3-1)=14$  ‘offsprings’. **Initial value of  $\Delta k$  is fixed at 5% of the search interval** for each variable after some initial trials. Hence,  $\Delta k$  works out to be  $3.75 [= .05x\{(60.00)-(-15.00)\}]$  for  $x_i$ -the abscissa of the slip-circle centre,  $3.225 [= .05x(94.50-30.00)]$  for  $y_i$ -the ordinate of the slip-circle centre and  $0.0225 [= .05x(1.25-0.80)]$  for  $z_i$ -the depth factor of the slide (refer Fig.2). **This  $\Delta k$  is further shrunk in successive generations by multiplying it with the size reduction parameter,  $\Delta_i = G_i(1-r)^{(G_i-1)}$** . Again, the objective function evaluations are made for the perturbed individuals and the minimum of these 14 points is located. This local minimum point (offspring) acts as the ‘mother’ of the next generation, and the corresponding design variables acts as the mean of the search space of next generation.

Fig.2. Search space exploitation in line with Design of Experiments.

Fig.3. Search space exploration analogous to simulated annealing schedule by contraction of search boundary in successive generations.

Fig.4. Initial deterministic search space turns heuristic at 2<sup>nd</sup> Generation—a quick shift towards the best part of search space.

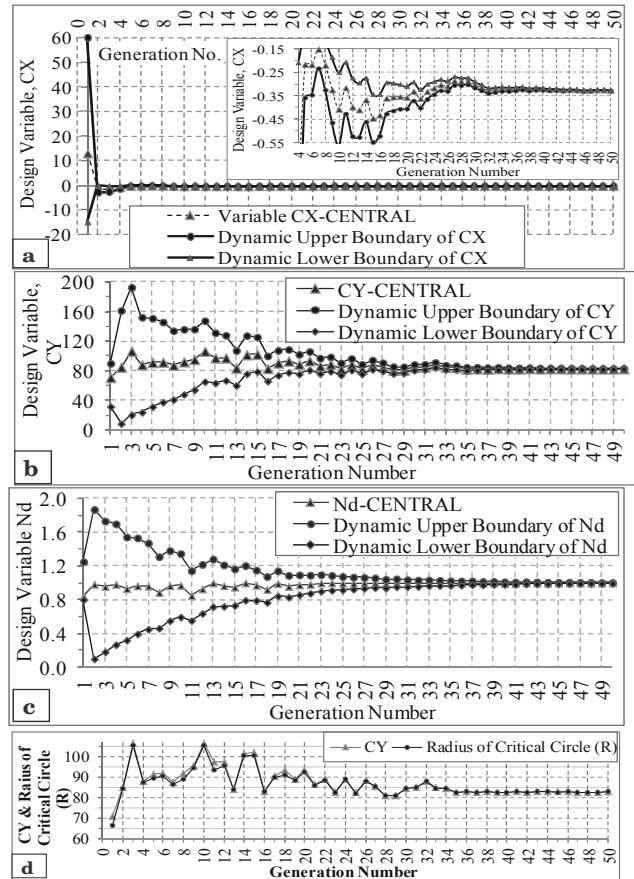

Fig.5. Robust movement of variable bounds along with the central value of tri-variables (CX, CY,  $N_d$ ) shown in (a), (b), (c) respectively. In (a), a further close-up view from 2<sup>nd</sup> generation is shown. From (d) it emerges that  $R \approx CY$  for critical circle.

#### 4 COMPUTER SIMULATION & GRAPHICAL DEPICTION OF THE SMART ADAPTIVE PROCESS

Fig.3 shows how the limit of search boundary shrinks towards the mean (that is, the central value or the best point of the preceding generation) of the search space. Fig.4 shows a typical result of 1<sup>st</sup>, 2<sup>nd</sup> and 50<sup>th</sup> randomly generated population along-with the perturbed population set of 1<sup>st</sup> and 50<sup>th</sup> generations. **It may be noted that initial wide deterministic search space turns heuristic at 2<sup>nd</sup> generation with a quick shift towards the best part of search space.** Fig.5(a) to (c) depict the robust movement of variable bounds along with the central value of the three design variables (CX, CY &  $N_d$ ), illustrating the generate-and-test heuristic search technique that exploit domain-specific knowledge. It emerged that whatever be the initial search bounds specified deterministically, the algorithm adjusts itself to move to the best part of search space in the immediate 2<sup>nd</sup> generation. It is revealed that **the bounds of CX are drastically reduced (Fig.5a), and that of CY &  $N_d$  are radically expanded (Fig.5b&c) in immediate 2<sup>nd</sup> generation**, and thereafter the bounds move steadily with successive generations that are guided by the mean of the search space, while maintaining a heuristic character. It emerged that the value of radius of critical circle (R) almost merges with the ordinate (CY) of the critical slip circle (Fig.5d). Fig.6 depicts the change in average fitness, standard deviation and variance of fitness function of population with successive generations. The variance of fitness decreases steadily with increasing generations maintaining its randomness. Fig.7 shows the maximum fitness of each generation vs. search space size reduction parameter in log-log scale. Fig.8 portrays the stochastic movement of Min. FOS in successive generations to converge to global optimum, wherein results of five simulation runs are superimposed. The inherent

stochastic nature of the algorithm showing value convergence with increasing generations is reflected in all the results.

Fig.6. Change in average fitness, standard deviation & variance of population fitness function with successive generations.

Fig.7. Max<sup>m</sup> fitness of each gen. vs. search space size red. parameter.

Fig.8. Stochastic movement of Min. FOS (obj. func.) in successive gens. to converge to global optimum (Results of five simulation runs).

Fig.9. CX vs. CY & CY vs. N<sub>d</sub>: The artificial intelligent character depiction. Fast random movement of candidate solutions to best part of the search space with increasing generations.

Fig.10. Stochastic decrease of maximum fitness in successive generations (Results of five simulation runs superimposed).

Fig.9 depicts the artificial intelligent character of the algorithm wherein a fast random movement of candidate solutions with increasing generations to best part of the search space is noticed. Fig.10 shows the stochastic decrease of maximum fitness in successive generations in 5 simulation runs. Fig.-11 gives the validation of results against other studies reported in literature.

## 5 CONCLUSIONS

A global population based search procedure (APMA) is developed and successfully applied to slope-stability problem. It does not require problem specific knowledge in searching the critical slip-surface of a soil-slope and is a heuristic technique based on the ‘generate-and-test’ strategy. Diverse aspects are presented to demonstrate its efficiency and robustness. The spectrum of application area of APMA is widespread as it is a direct search method where no specific search direction is used and multivariable functions, both continuous and discontinuous can be handled. Function value evaluations at discrete points only enable it to handle non-differentiable functions at ease. The beauty of the process is that, it handles a number of designs in each simulation run. The result of some simulation runs revealed minimum factor of safety obtained by APMA is less than that found by directed grid search, variational method, GA and GA-SA hybrid.

# Soil slope stability of hydropower reservoirs - from geological site investigation to design of mitigation measures

## La stabilité des talus de réservoirs hydroélectriques - de l'investigation géologique du site à la conception de mesures d'atténuation

Saurer E., Prager C., Marcher T.  
*ILF Consulting Engineers, Rum/Innsbruck, Austria*

**ABSTRACT:** Many reservoir slopes are affected by different types of instabilities during the first impoundment, due to reservoir level fluctuations and due to earthquakes. These potential failure processes are caused by complex hydro-mechanically coupled processes, which in most cases cannot be fully assessed during the design stage due to a limited knowledge of the soil behaviour and properties. Thus, for the site selection and the design of power storage plants, especially for the risk assessment and mitigation of potentially unstable soil slopes, a systematic methodology for the selection of the appropriate stability measures is presented. Based on case studies from both engineering projects and literature, a methodological approach and a decision matrix for the design of appropriate mitigation measures depending on the failure mode and size of the potentially instable slope are proposed.

**RÉSUMÉ :** Un grand nombre de talus à proximité des réservoirs sont affectés par différents types d'instabilités en raison des fluctuations des niveaux de réservoir et en raison de tremblements de terre. Ces procès potentiels de défaillance sont causés par des transformations complexes hydromécaniques, qui dans la plupart des cas, ne peuvent être entièrement évalués au cours de la phase de conception en raison d'une connaissance limitée sur le comportement et des propriétés des sols. Ainsi, pour la sélection des sites et la conception des installations de stockage d'énergie, il est essentiel de tenir compte des expériences antérieures et d'appliquer ces connaissances à la conception de nouvelles installations pour créer une stratégie d'évaluation des risques et d'atténuation. Ici une méthode pour la sélection des mesures de la stabilité appropriées en fonction du mode de défaillance est fournie. Basé sur des études de projets et de la littérature une méthodologie systématique et une matrice de décision pour la conception de mesures d'atténuation appropriées en fonction du mode de défaillance et la taille de la pente potentiellement instables sont proposées.

**KEYWORDS:** soil slope stabilization, mitigation measures, decision matrix

## 1 INTRODUCTION AND FRAMEWORK

### 1.1 *Reservoir slope instabilities (causes, triggers)*

Concerning site selection studies for a water storage reservoir, particular focus has to be placed on the assessment of terrain stability, especially in the dam area but also along the reservoir slopes.

In general, failures are related to changes of stability parameters of natural slopes or artificial cuts. Related to reservoirs, the disturbance may be caused by water level changes (due to first impoundment and/or recurring water level fluctuations during operation) which may cause catastrophic (uncontrollable) slope failures of all sizes. According to Riemer 1995, the causes and triggers of soil displacements include, e.g.

- change of consistency due to saturation (fine soils)
- change of effective stresses (pore pressure)
- groundwater flow (steady and transient flow)
- external erosion, e.g. caused by waves
- internal erosion (suffosion, subrosion)

At the design stage of a reservoir, these processes have to be considered in order to assess the slope stability. Commonly, slope failures are only treated when they affect the serviceability (storage volume loss, operational restrictions, land use along shoreline, water quality) or failure of a reservoir and its surroundings.

### 1.2 *Slope stability assessment and risk management*

Extensive literature reviews of landslides and reservoirs as well as detailed case studies have been carried out by many authors (e.g. in Riemer 1995). In particular deep-seated rock slides have been monitored and investigated intensively, and monitoring

results have been reported over the last decades (Leobacher and Liegler 1998, Tentschert 1998, Jäckli 1996, Watson et al. 2006, Barla et al. 2010).

Moreover, process based investigation methods and monitoring measures have been developed (Keusen 1998, Zangerl et al. 1999, Leobacher and Blauhut 2010).

The issue of slope stability, in particular for dam safety, during rapid drawdown and earthquake loading and has been studied widely (e.g. ICOLD 1980, Casagrande 1937, Sherard 1963, Alonso and Pinyol 2009). Besides the stability assessment, (e.g. according to Casagrande 1937), it is expected that engineers are able to make a statement not only on stability but also on the consequences of potential mass movements.

Following the stability assessment, a risk management plan may be produced. Whereas several research projects on landslide risk management have been undertaken (e.g. ICG 2009 and 2011), only few data concerning slope stability in the vicinity of water reservoirs are publically available.

Here, an overview of a systematic approach to assess the slope stability before and after reservoir impoundment with particular consideration of earthquake and rapid drawdown conditions and a proposal for a customized toolbox for slope stabilization in cohesive and granular soils are provided.

## 2 SLOPE STABILITY ASSESSMENT

A possible flowchart for the slope stability assessment is provided in Figure 1. The individual steps are described in the subchapters below.

### 2.1 Site selection

The site selection process for hydropower reservoirs is driven by the need to optimise decision criteria which are initially mainly of an economic nature.

In the best case, several sites are shortlisted based on economic factors followed by comparisons of options and more detailed feasibility studies including detailed geological and geotechnical investigations and designs.

### 2.2 Geological and hydrogeological model

A geological and hydrogeological model may be developed using the following investigation techniques (selection):

- geological site mapping, incl. structural geological surveys;
- remote sensing and terrain analyses (e.g. optical images, LiDAR, DEMs);
- hydrogeological field surveys (mapping of springs, surface flow systems incl. discharge measurements, recharge and infiltration characteristics);
- groundwater measurements, tests and monitoring (spring parameters e.g. EC, T and discharge, stage-discharge stream gauges, groundwater elevation gauges, piezometers/hydraulic heads, tracer tests, hydrochemical and isotopic analyses, etc.);
- core drillings with in-situ measurements and tests (e.g. core SPTs, geophysical borehole logs, geotechnical and hydraulic tests, e.g. packer tests, water pressure tests, dilatometer tests) and (un)disturbed rock/soil sampling;
- geophysical surveys (surface and borehole seismics);
- slope monitoring (geodetic surveys, inclinometer measurements and others).

Based on these data, a comprehensive rock mass model may be established, which in turn constitutes the basis for the subsequent steps (see Figure 1).

### 2.3 Geotechnical model and assessment of actual slope stability

Based on the geological model (incl. results from lab and field tests), characteristic soil parameters and a geotechnical model are defined. “Characteristic” soil properties may be i) obtained from field and lab tests and/or ii) back calculated from the geological model, (taking into account the soil strata and slope inclinations). In the latter case an assumption on earthquake loads which have already been acting on the slope has to be made and included in the back analyses. When using back calculations it is assumed that the slope is in limit equilibrium. Ideally both approaches should be combined.

These calculations yield values for the assessment of the actual slope stability. However, these assessments are commonly based on geological and geotechnical models of limited accuracy due to a limited number of available results from laboratory and field tests. Therefore, the “real” soil parameters are to be verified at the latest at the stage of the first impoundment of a reservoir.

### 2.4 Assessment of slope stability under changed boundary conditions

The boundary conditions of reservoir slopes may change drastically due to impoundment and rapid drawdown

Therefore the back calculated geotechnical slope model (see above) has to be adapted to these changed boundary conditions and the slope stability has to be reassessed. From this analysis four different scenarios may be obtained (see Figure 1):

In the best case, the slope stability is not affected by the new boundary conditions at all. This is the case when the failure plane is located entirely above the shoreline.

The remaining three cases may be assessed according to i) the size and shape of the potential landslide mass and ii) the acceptance of the consequences of a failure.

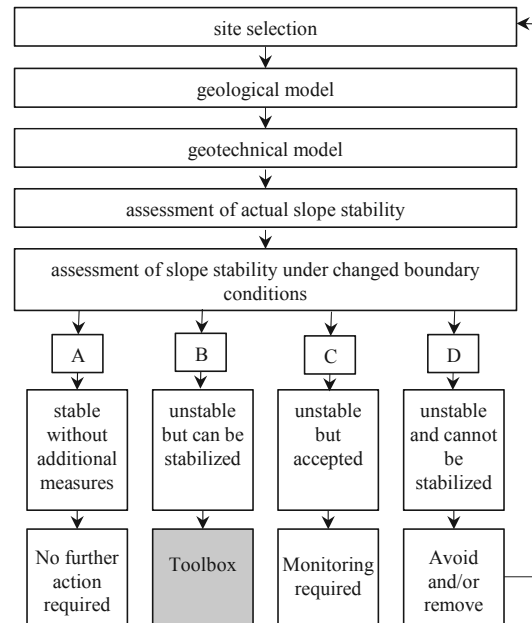

Figure 1: Flow chart for the assessment of slope stability (explanations, see text).

The decision whether a potential slope failure is acceptable depends on various criteria: If the slope stability deteriorates, proof has to be provided that the safety of the dam and its surroundings are not affected. This means that the size and the velocity of potential landslides do not cause critical tsunamis overtopping the dam.

For this proof and the risk assessment, the slope deformation behaviour has to be evaluated according to the types shown in Figure 2. While deformation types 1 and 2 are commonly unproblematic and type 3 requires a sound risk assessment, the stick-slip behaviour of type 4 landslides is much more difficult to predict. Such deformation behaviour requires intensive monitoring and a fundamental knowledge of the soil properties (Barla et al. 2010, Leobacher and Liegler 1998, Zangerl et al. 1999).

Figure 2: slope kinematics (temporal deformation types): (1) decreasing slope velocity; (2) constant velocity; (3) accelerating and failing slope; (4) episodic accelerated slope (after Keusen 1998)

Planning any mitigation measures depends on the geometry and depth of landslides. Concerning this, the classification of landslide thickness (according to BAFU 2009 and ICG 2011) is shown in Table 1.

Table 1: Landslide categories as a function of the depth of movement (acc. to BAFU, 2009 and ICG 2011).

Category	Depth of movement [m]	
	BAFU 2009	ICG 2011

Superficial	0 - 2	< 0.5
Shallow		0.5 - 3
Medium	2 - 10	3 - 8
Deep	> 10	8 - 15
Very deep	> 30	> 15

Depending on the findings from the above mentioned work packages (Ch. 2.1. to 2.4) four possible slope scenarios and respective measures may be differentiated (Figure 1):

- A) stable without additional measures, no further action is required.
- B) unstable due to changed boundary conditions and cannot be stabilized with feasible measures. However, the slope instability may be avoided by flattening the slope by massive earth works.
- C) unstable due to changed boundary conditions but the consequences of the instability do not affect the serviceability of the reservoir and are therefore acceptable and do not affect the serviceability of the facility.
- D) potentially unstable due to changed boundary conditions but can be stabilized with additional stabilization measures: for this case a toolbox is presented in Table 2; depending on the geometry, of the potential slide and its failure mode, the required measures may be chosen.

### 3 MITIGATION MEASURES

#### 3.1 Superficial and shallow landslide mitigation measures

Shallow landslide (i.e. < 3m thick, see table 1) mitigation measures aim to prevent surface erosion and to improve the drainage capacity of the uppermost meters. Appropriate measures comprise, e.g.:

- drainage trenches, to reduce the length of drainage path and hence erosion; they may be lined with geotextiles and combined with drainage tubes;

Figure 3: reservoir slope featuring drainage trenches above the storage level.

- wave protection, to prevent soil from external erosion

Figure 4: Wave protection measure (stone wall) in an impounded reservoir.

- cultivated crib walls;
- geomembranes, along with soil nailing, gabion mattresses and/or blocks as surface erosion protection, especially for fine-grained soils; nails are used primarily to stabilize the geotextile and secondarily to stabilize the soil itself;
- geomembranes, along with flat gabions, as erosion protection measure.

Protection in the vicinity of road cuts above the shoreline comprises gabion walls and soil nailing, used as artificially steepened natural slope measure.

#### 3.2 Medium to deep seated landslide mitigation measures

By installing a defined grid of geotextile wrapped stone columns, the shear strength of the soil may increase and the length of the drainage path in the soil can be shortened. Both effects increase the slope stability. Also, by means of local soil substitution with material of higher shear strength and permeability, the stability and erosion protection are improved.

Supporting embankments may be used to prevent erosion and to stabilize deep seated potential slip circles. Such embankments have already been successfully applied to stabilize unstable slopes of operating hydropower facilities.

If subaquatic soil instabilities (i.e. below the reservoir water level) are accepted, which may be acceptable if they do not influence the serviceability of the reservoir, but the shore above water level has to be protected, a pile wall at the height of the maximum water level may be installed as a protection measure.

#### 3.3 Very deep seated landslide mitigation measures

Very deep seated (i.e. > 15 m thick, see table 1) landslides generally require cost-extensive mitigation and monitoring measures such as drainage drillings and adits (Bonzanigo et al. 2007, Zangerl et al. 2010).

### 4 COMBINATIONS OF MEASURES

In order to find feasible and appropriate combinations of mitigation measures, Table 2 presents a matrix of scenarios (scenarios 1 to 7).

- Scenario 1 represents possible combinations of protection measures below storage level to prevent superficial mass movements and erosion.
- Scenarios 2 to 7 combine mitigation measures against potential superficial instability with medium to deep seated mass movements. Whereas in scenario 2 flattening of the upper part of the slope reduces the driving force of a potential instability, in scenario 3, the increase of the safety level is obtained by increasing the resisting force at the toe of the slope. Note that for scenario 3 the safety against surface erosion is given when using accordingly graded fill material. In contrast, when combining measures as shown in scenario 4, measures for both failure mechanisms have to be designed individually. This may also be the case for scenario 5.
- The most drastic measure is hence the soil replacement depicted as scenario 6, whereas in scenario 7 the goal is that the safety of the slope above the impoundment level remains, without taking into consideration the stability below the measure.

Table 2: Matrix of combinations. +: appropriate measure/combination. ° inappropriate measure/combination.

## 5 RESIDUAL RISK ASSESSMENT

The residual risk from a potential mass movement has to be analysed independently from mitigation measures. This is due to the fact that the mitigation measures are designed for a certain defined load (e.g. design earthquake). However, remaining residual risks may comprise events larger than the design event and resulting slope instabilities. Thus, also the impacts of such instabilities on both the safety of the dam and reservoir (probability and consequences of overtopping) have to be assessed.

For this both empirical approaches (Fritz et al. 2003, Heller 2007) and numerical models (e.g. Grilli and Watts 2005) may be applied.

## 6 MONITORING MEASURES

Slope stability behaviour can be monitored a) pointwise, b) linear and c) areally and can be measured in-situ and/or by remote sensing methods (see Sect. 8 References). Point data can be obtained through triangulation, levelling, GPS surveys, wire extensometer, joint- or crackmeter, laser distance meter and water level gauge measurements. Line data may be obtained from inclinometer, extensometer and Trivec measurements and/or from fibre optic sensing techniques. The deformation field of a surface of a landslide can be obtained by photogrammetry, terrestrial or satellite based radar interferometry and terrestrial or airborne laser scanning. A variety of these monitoring methods has already been successfully applied to some well-documented reservoir slopes (e.g. Leobacher and Liegler 1998, Tentschert 1998, Watson 2006, Zangerl et al. 2009, 2010).

## 7 CONCLUSION

Assessment of slope stability of potential reservoir sites requires interdisciplinary knowhow, comprising intensive field investigations and sound determination of soil characteristics. Data thus obtained enable the assessment of slope stability (due to changed boundary conditions) and the design of appropriate mitigation measures.

For the design phase, possible scenarios of mitigation measures are described and presented in a matrix form. These measures serve as a basis during later design phases and during execution when the stabilization measures are allocated to the appropriate slopes in the reservoir according to the corresponding refined geological model and boundary conditions.

The scenarios 1 to 7 (Table 2) may be applied to different slope conditions (Figure 1: A to D), i.e. areas with acceptable slope stability, areas where near-surface stabilization measures are required, and areas with shallow to deep seated mass movements which have to be stabilized.

On the basis of available geological surface and subsurface data (field survey, geophysics, drillings) representative geological slope cross sections are established in order to illustrate, evaluate and assess the current and future slope stability in the individual regions. These geological sections and geotechnical data are used to for stability calculations.

Due to the repeated water level fluctuations, some areas may experience erosion and landslide processes (landslides, flow processes), especially in areas with large granular or cohesive soil layers. Stability studies including all load cases (including earthquakes) have to be carried out. If the safety calculation without stabilization measures returns an insufficient safety factor, measures required to achieve the required level of safety have to be determined. The goal of constructing mitigation measures is that the slopes for the mentioned load combinations (including earthquake load) remain stable.

For the monitoring of slope stability during the construction and operating phase, instrumental measurements of selected slope areas are required. These include both episodic campaigns and permanent measurements, e.g. geodetic surveys, levelling and inclinometer measurements.

**ABSTRACT:** During the foundation excavation of an industrial plant in Eskişehir, Turkey, a landslide occurred in the neighbouring slope, and consequently, the excavation had to be stopped. The instability occurred in a natural slope which had an average slope angle of 9-13 degrees. The aerial extent of the slide mass was 400 m by 115 m. The material in the slope was 7 to 20 meter-thick colluvium (slide debris), which constitutes a historic landslide mass, underlain by a gravelly sandy silty clay matrix containing limestone blocks, weathered tuff and tuff. Soil profile and location of the slip surface were determined through a site investigation program including nine boreholes and inclinometers. A back analysis was carried out and shear strength parameters of the slope forming materials were determined. Slope stability analyses were carried out, stabilization alternatives were evaluated and slope stabilization by piled retaining walls was considered as the most feasible alternative. The analyses and design procedure for the piles will be presented together with a summary of existing analyses and design methods for landslide stabilizing piles.

**RÉSUMÉ :** Pendant les excavation des fondations d'un site industriel à Eskişehir, en Turquie, un glissement de terrain a eu lieu dans un talus voisin, et par conséquent, les travaux ont été arrêtés. L'instabilité s'est produite dans un terrain naturel présentant une pente moyenne de 9 – 13 degrés. Les dimensions en plan du glissement étaient de 400 m par 115 m. Le matériau du glissement était composé de colluvions, sur 7 à 20 m d'épaisseur, qui constituaient une masse de glissement postérieur. Les colluvions reposaient sur une argile graveleuse et sablo-limoneuse contenant des blocs de calcaire, du tuf sain et du tuf altéré. La coupe géotechnique du site et la localisation de la surface de glissement ont été mises en évidence par une campagne d'investigations incluant neuf forages et inclinomètres. Les paramètres de résistance au cisaillement des terrains en place ont été déterminés par une rétro-analyse. Suite aux études de stabilité des pentes et à l'examen des systèmes de renforcement alternatifs, la solution de stabilisation par une paroi en pieux s'est avérée comme la plus judicieuse. Les analyses et la procédure de dimensionnement pour ces pieux vont être présentées en même temps qu'un résumé des analyses et des méthodes de calcul existantes sur la stabilisation des glissements par pieux.

**KEYWORDS:** landslide, piles, inclinometer.

### 1 INTRODUCTION AND SOILS AT THE SITE

Instability occurred in a natural slope which had an average slope angle of 9-13 degrees, during excavation works near the toe. The aerial extent of the slide mass was 400 m by 115 m. The construction site was located at the toe of this sliding mass (Figure 1). The slope movement had a NW-SE direction. The material in the slope was 7 to 20 meter-thick colluvium (slide debris), which constitutes a historic landslide mass, underlain by gravelly sandy silty clay layers with limestone blocks, weathered tuff and unweathered tuff at different borehole locations. The colluvium was also composed of pieces of limestone cobbles and blocks in a clayey silty matrix.

It was observed that the slide debris lies on tuff. The pliosen age tuffs are approximately 100 m thick and lies on limestone. In the borehole descriptions the tuff layer at the upper levels are weathered to highly weathered condition and can be considered as a transition between rock and soil and identified as a layer of stiff clay. Samples from this weathered tuff had natural water content 19-43% (high natural water content such as 43% was obtained near the shear surface at about 20 m depth at borehole SK9). Since this material can be considered clay-like, Atterberg limits are determined LL=45-49%, PI=11-28% (for the material near the shear surface LL=49-66% and PI=27-36%), fines content=34-74% and clay-size fraction was 23-57%, and the material can be classified as CL, ML, GC and SC. The natural unit weight of samples were 20-21 kN/m<sup>3</sup>. Unconfined compressive strength of this material was 30-240 kPa and UU triaxial tests gave  $c_u$ =13-44 kPa and  $\phi_u$ =11-22°. Since the

residual shear strength will be of interest in this reactivated landslide case, direct shear tests were carried out on limited number of undisturbed samples taken from near the shear surface in order to find the residual friction angle. 46 mm diameter specimens were sheared undrained without submerging in water, then sheared continuously and slowly to reach residual condition. From the lab tests it was concluded that the 100 and 250 kPa undrained shear strength for tuffaceous clay and clayey tuff are reasonable values. Drained friction angle of slope debris/colluvium was 15-20 degrees, and tuffaceous clay taken from near the shear surface had 10.2 degrees residual friction angle.

#### 1.1 Soil Profile and The Mechanism of the Slope Movement

The sliding mass has grown progressively backward into the slope as multistage rupture surfaces from the toe of the landslide developed. First, the tension crack (scarp) C1 has been observed while excavation works were going on. Then, within about 15 days, there were total of four major tension cracks (visible scarps) (C1 to C4 in Figures 1 and 2) and one meter horizontal and vertical movements have been observed at the ground surface. Fifty days after the start of the first scarp, a small road located at the slope was observed to move 15 m downslope and 4 m in vertical direction.

Nine boreholes are opened at a line of NW-SE direction which is also the direction of the movement and inclinometers are also placed in these boreholes. In all boreholes except SK7, SK8 (at the toe) and SK6; the top layer is slope debris and

below that tuffs sometimes in clayey state and sometimes in harder state are encountered.

## 2 ANALYSES AND RESULTS

In this section the types of the analyses, the results of the back-analyses of the landslide movement and then the stabilization works will be presented.

### 2.1 Back-Analyses and the Shear Strength Parameters

In all boreholes inclinometer readings were taken, and the depth of the slip has been determined. As it is a fast movement, all inclinometer pipes were sheared by the landslide (except SK-3 and SK-8) shortly after they are placed. These depths were considered as the depth of the slip surface. The cross section of the landslide were prepared according to the borehole data and inclinometer readings and the scarps of the progressive slips. The positions of the slope debris and tuff layers and also the scarps of the progressive failure slides are shown in Figure 2. The shear surface passes mostly through the colluvium material in the upper half of the sliding mass, whereas it passes near the contact between the colluvium and tuff (more within the tuff) in the lower half of the sliding mass. There was no groundwater level, however in stability analysis to be on the safe side some water level is considered.

It was not easy to take samples from the sliding mass near the shear surface, therefore only a limited number of soil samples were tested in the laboratory. Determination of the soil parameters at the sliding surface of a landslide at the limit equilibrium state by the back analyses of the movement is a widely used method. In this method the  $c$  and  $\phi$  parameter couples are determined which give a factor of safety value of one at the sliding surface. In the back analyses the cohesion and angle of friction parameter couples for the tuff and the slope debris layers are identified. In this case the number of the unknowns is four. They are decreased progressively using a methodology given below.

At the first stage, the back analyses of sliding surfaces of C3 and C4 were performed. By this way the parameters for the slope debris were determined as  $c'=5.6$  kPa and  $\phi'=15.7^\circ$ ,  $E'=35$  MPa are used in the analyses.

At the second stage, calculations for sliding surfaces of C1 and C2 were performed. The above parameters were used for slope debris, and the shear strength parameters for the tuff layers were determined. The parameters for the weathered tuff layer at the sliding level are assessed as  $c'=0$  kPa and  $\phi'=9.2^\circ$ . But these parameters were not suitable to use for the whole tuff layers. Table 1 summarizes the parameters used in the analyses.

Table 1. Material properties used in analyses

Material	Drained			Undrained	
	$c'$ (kPa)	$\phi'$ ( $^\circ$ )	$E'$ (MPa)	$c_u$ (kPa)	$E_u$ (MPa)
Slope debris	5.6	15.7	35	60-75	20
Weathered tuff (first 3 m)	0	9.2		100	60
Unweathered tuff	20	25	60	250	130

Undrained triaxial compression and consolidated drained direct shear tests were performed on the debris and tuff soil samples from the boreholes which are located between the slope debris and tuff layers. The results of these tests show that the internal friction angle for the slope debris and for the clay soil originated from tuff are  $15$  to  $20^\circ$  and  $10.2^\circ$  respectively. This findings support the results of the back analyses.

### 2.2 Slope Stabilization by Piles

Piles used in slope stabilization are subject to lateral force caused by the movement of surrounding soil, and they are called "passive piles" (Viggiani 1981; Poulos 1995). One of the major issues in the design of these piles is the magnitude of the force on the pile. Since this is related to the soil movement and soil movement is influenced by the presence of piles, the interaction between the passive piles and the soil is quite complicated. There exists a number of empirical, analytical, and numerical methods available in the literature about the design of piles used in slope stabilization (Brinch Hansen 1961, De Beer 1977, Fukuoka 1977, Ito and Matsui 1977, Sommer 1977, Winter et al. 1983, Popescu 1991, Reese et al. 1992). Some of these methods are pressure or displacement-based and some of them are numerical methods, such as finite element and finite difference (Kourkoulis et al., 2012).

In the pressure or displacement based methods, the pile is modeled as a beam supported by springs at its sides. A single laterally loaded pile is considered, and the ultimate soil-pile resistance is correlated with the undrained shear strength for clays, and with the overburden stress and friction angle for sands. In these methods group effects are taken into account by using reduction factors. Although spring constants are dependent on pile deflection, or the movement of the soil, they are typically assumed constant. In the current study this approach is used.

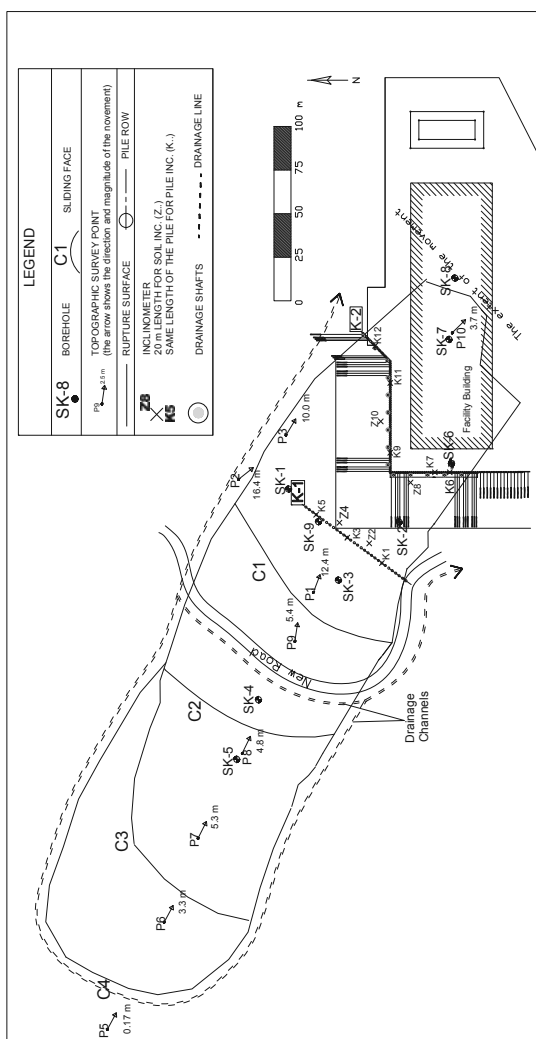

Figure 1. General layout plan

The general design procedure consists of two main steps: Step 1: Provision of the required total lateral force needed to increase the factor of safety of the slope to the desired value (based on analysis of the unreinforced slope). Step 2: Calculation of loading on piles and pile lateral capacity.

In the last few years, 3-dimensional finite-element and finite-difference methods are becoming increasingly popular. Using these methods complex geometries and complicated phenomenon such as soil arching, pile group effects, nonlinearity of soil and pile could be modeled. Use of 3D numerical methods is still not very attractive to practitioner engineers because of the long computational time and learning effort. Kourkoulis et al. (2012) developed a hybrid solution to the problem, combining the benefits of accurate 3D finite element simulation with the simplicity of widely accepted analytical techniques.

Figure 2. Cross section for the analyses

## 2.2 Stabilization Works for Foundation Excavation and Prevention of the Slope Movements

As a result of the preliminary works it is understood that the diameter of the stabilizing passive piles should be 1.2 m and more than single pile row would be needed. The depth of the sliding mass was 20 m at the centerline. It was not possible to stabilize this amount of soil mass by two rows of piles only. So stabilizing excavations were needed to decrease the amount of sliding mass (about half of the sliding depth was removed-see Figure 2), and then the following piled analyses were performed.

1. Slope Stability (GEOSLOPE 6.02, SLIDE 5.014) / Structural Analyses (SAP 2000, V8.4)

2. Finite Element Method (PLAXIS 2D, V8.6)

In this stabilization program, one row of stabilizing piles are placed at an upper level (Pile Row K1 in Figure 1). The lower row of piles (Pile Row K2 in Figure 1) will also have a function of retaining wall for the facility. To decrease the moment and the displacements of the piles in this second row, permanent ground anchorages were planned at the top beam of the piles.

The most critical issue in the analyses were the excavation works for the foundation of the facility which would be performed after the stabilizing works were completed. Because of the excavations just behind the second row of the piles, the pile displacements and the moments were increasing for both row of piles. This critical concept was best configured in 2D finite element analyses (figure 3).

## 2.3 Finite Element and Limit State Analyses

The place of the two rows of the stabilizing piles is shown in the plan view in Figure 1. In the analyses the construction stages were excavations for stabilization, the construction of the piles and the foundation excavations to the 1095 m elevation just in front of the K2 Pile Row. For the drained analyses of the K1 pile row it was found that the pile head displacement as 18 cm, the shear force as 468 kN/m and the bending moment as 1240 kN.m/m. The same values for the K2 pile row were 10.8 cm, 387 kN/m and 970 kN.m/m, respectively.

The horizontal peak ground acceleration at the construction site was accepted as 0.25g and accordingly the seismic stability of the stabilizing system was also checked. The slope stability analyses of the final stage of the works were repeated for a horizontal seismic ground acceleration of 0.125g.

The cohesive soil exerts a pressure on the piles when it tries to pass between the piles forming a failure mechanism. This pressure being related to the undrained cohesion of the soil and is a limit value to be checked (see Eq. 1). This equation is valid for  $s \geq 3d$  where  $s$  is the pile center-to-center spacing and  $d$  is the pile diameter. If  $s < 3d$  there will be a reduction up to a factor of 0.5.

$$p = c_u k D \quad (1)$$

Active and passive lateral earth pressures are represented by spring constants  $k$  above and below sliding surface. The  $k$  values for this case were 1.30 for the passive side of the lower level (K2) piles and 1.34 and 0.86 for the passive and active side of the upper level (K1) piles. These are lower than the limit values (Ergun, 2000).

## 3 CONCLUSION

A long landslide which progresses backwards had occurred because of the foundation excavations of an industrial plant which coincided with the toe of a historic landslide. The construction works were stopped, and the landslide was investigated through boreholes. The clayey debris (colluvium) containing limestone cobbles and boulders had slid over

plastic tuffs. Back analyses and the laboratory tests were performed for the determination of the shear strength parameters at the sliding surface. Two rows of stabilizing piles were designed through the sliding mass and the structural analyses and also FE analyses of these piles were performed independently.

Figure 3. Total displacements plot of FE analysis

10 to 15 m deep excavations were performed for the first stage of the stabilization works. The upper level piles (K1) were 12 m in length and 1.2 m in diameter. Center to center spacing of piles were 2.5 m. The total number of stabilizing piles is 30 covering a longitudinal length of 72 m reaching the South edge of the landslide. The 2nd row of stabilizing piles (K2) was also used as the retaining walls of the facility. The 1.2 m diameter bored reinforced concrete piles are placed with 1.25 m spacing in this row. The pile lengths are 17 m. The total length of the pile row is 137 m in plan view passing over the South edge of the landslide.

Figure 4. Cumulative displacements (mm) at Z4 (soil) and K6 (pile) inclinometers

The permanent ground anchors were constructed at the head beam of the piles with 1.25 m spacing, 30 to 35 m in length and inclined at 30 and 45 degree to the horizontal.

No drainage system was planned in the sliding mass. Instead surface drainage was implemented as reinforced concrete drainage channels at the edges of the landslide and at the upper levels of the new road. Behind the retaining walls of the construction site 0.60 m diameter vertical drainage shaft between the piles were planned and the collected groundwater was transferred to the water drainage system of the facility.

The deformations of the system are controlled by the 12 inclinometers (8 in the soil, 4 in the piles) at each stage of the construction works. There are no displacements in three years (Figure 4).

**ABSTRACT:** Landslide phenomenon at An Linh commune, Tuy An district, Phu Yen province is more and more severe year after year. The prediction of a highly landslide susceptibility zone will support the government and local residents to save their properties. In this paper the authors carried out the landslide susceptibility mapping at An Linh commune using the deterministic approach with knowledge-driven methods and the stochastic approach with data-driven methods. The deterministic approach is conducted using traditional survey, field investigation, geophysical survey... to evaluate not only geotechnical properties of rock and soil materials but also the mechanism of landslide phenomenon in the studied area. The stochastic approach with probability methods is chosen to evaluate the weights of influence factors such as the elevation, aspect, slope angle, distance to roads and distance to drainages, geology and topographical wetness index of the materials. Landslide susceptibility zonation is developed using the model of Bayesian conditional probability with different criteria for weighting factor calculation integrated with GIS analytical tools. Landslide susceptibility maps from different models are validated with the current landslide inventory to select the most reasonable model for the study area.

**RÉSUMÉ :** Les glissements de terrain sont devenus de plus en plus fréquents sur la commune de An linh, district de Tuy An, province de Phu Yen, au cours des dernières années. Les auteurs ont réalisé une carte de risques de glissement de terrain sur la commune An Linh selon une approche déterministe fondée sur une connaissance experte et à l'aide d'une approche stochastique basée sur les données. L'approche déterministe est conduite à partir des méthodes de reconnaissance, d'observation du terrain, de prospection géophysique... afin de quantifier non seulement les propriétés géotechniques du sol et de la roche mais aussi le mécanisme de glissement de terrain dans la région concernée. L'approche stochastique fondée sur les modèles statistiques est choisie pour évaluer le poids de facteurs d'influence comme l'altitude, l'aspect, la pente, la distance aux cours d'eau, la distance aux voies routières, et au drains, les paramètres géologiques, et l'indice de l'humidité des sols. Le zonage des risques de glissement de terrain a été développé en utilisant un modèle de probabilité conditionnelle de Bayes avec différents critères de calcul du poids des variables, en intégrant les outils analytiques de SIG. Les cartes de risques élaborées selon ces modèles ont été validées à l'aide de l'inventaire des glissements actuels afin de choisir le modèle le plus approprié pour ce site.

**KEYWORDS:** Landslide susceptibility; Bayesian conditional probability; Stochastic model.

## 1 INTRODUCTION

The study area locates at An Linh commune, Tuy An district, Phu Yen province in the south central coast of Vietnam (see Fig. 1).

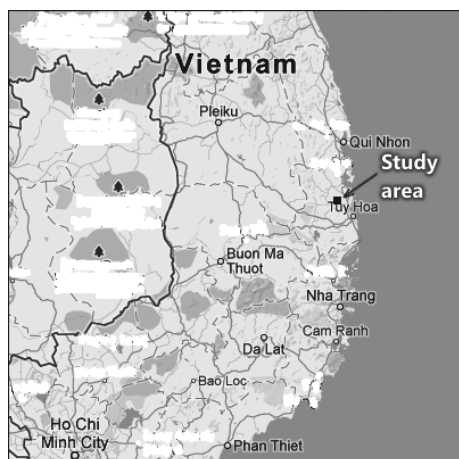

Figure 1. Location of the study area

During the past few years, landslides often occur in the study area after heavy and long rains. This phenomenon damages roads and construction works and results in serious cracks in the residential areas that in turn affect to human lives. Therefore the landslide prediction is an urgent task for scientists to support the government in planning and save human lives of local residents.

### 1.1 Geographic characteristics

An Linh area which has hill and mountain landscape locates on the eastern side of Van Hoa highland whose elevation of 12 ~ 500m. In that area, hills are rounded and have steep slopes, decorated by narrow valleys which follow along north-south direction. The ground surface which inclines to the north is a bare area with basaltic boulders or cobbles. This topographic landscape is favorite for erosion progress and stimulate landsliding and cracking process.

The study area belongs to the monsoon tropical region with oceanic climate. The annual precipitation is approximate 2000mm. Especially in the rainy season the precipitation can reach 70 ~ 80% the annual precipitation. Furthermore, the precipitation concentrates in a short time – only one or two months at the end of a year.

Water systems strongly develop with Cai river and Ho Lo river in the west and the east respectively. Both rivers form a hydrological network distributed evenly in the study area.

### 1.2 Geological characteristics

A general stratigraphy of the study area composes of following formations:

Table 1. Brief description of geological formations

Formation	Composition
Phong Hanh formation (ε - Sph)	Quartzite of blocky structure, quartz-sericite schist
Mang Yang formation (T <sub>2</sub> my)	Boulders, cobbles, sandstone, siltstone and claystone, blocky structure, thick bedding
Kon Tum formation (N <sub>2</sub> kt)	Green, dark grey, greenish grey basalt, bubble or porosity structure, fracturing; diatomite, clay with diatomite, basalt with interbedded clay
Dai Nga formation (N <sub>2</sub> - Q <sub>1</sub> đn)	Greenish grey, dark grey basalt, blocky structure, fracturing
Quaternary formation	Boulders, cobbles, gravel, sand, silt, clay

### 1.3 Landslide characteristics

Landslide occurs mainly at low areas with elevations less than 200m and gentle slopes (slope angles vary from 5° to 20°) in heavily weathered rocks which compose of clay, swelling clay with diatomite... Landscape after sliding forms terraces with many fractures on the ground surface. Landslide exposures usually locate at positions associated with hydrological factors. There are water flows at the toe of slopes in massive landslides. The shear strength of soils within landslide areas is rather low (cohesions vary from 12 to 17kPa, friction angles from 10° to 13°).

### 1.4 Landslide causes

The fieldwork study shows some of causes of landslides in the study area:

- Heavy landslides usually occur at geological structures which compose of clay, clay with diatomite underlying thin heavily weathered basaltic layers. Soils and rocks at landslide areas are different in permeability, swelling, strength (weak soils overlay hard rocks).
- The erosion process occurs at the toe of slopes and piping develops due to the surface run off and underground water flow.
- Heavy and long rains cause rocks and soils swelling or liquefaction that in turn cause the volume change suddenly.
- Human activities also take part in the landslide trigger: the forest clearance, reservoir and rice field preparation... Those activities result in losing strength at the toe of slopes.

## 2 LANDSLIDE SUSCEPTIBILITY MAPPING

### 2.1 Theoretical Background

Nowadays there are two common groups of methods for landslide prediction:

- a) Knowledge-driven methods: those methods are based on experiences of experts and rely on empirical relationships.
- b) Data-driven methods: those methods analyse collected data and establish models based on the inherent relationship of data. This approach, especially, Bayesian conditional probability method will be applied for the landslide susceptibility mapping in this research. In Bayesian conditional

probability method, the likelihood of event D given the presence of factor B can be expressed as the prior probability:

$$P\{D|B\} = \frac{P\{D \cap B\}}{P\{B\}} = P\{D\} \frac{P\{B|D\}}{P\{B\}} \quad (1)$$

On the contrary, the unlikelihood of event D given the presence of factor B is the probability:

$$P\{\bar{D}|B\} = \frac{P\{\bar{D} \cap B\}}{P\{B\}} = P\{\bar{D}\} \frac{P\{B|\bar{D}\}}{P\{B\}} \quad (2)$$

- where
- $P\{D|B\}$  the likelihood of event D given the presence of factor B
  - $P\{\bar{D}|B\}$  the unlikelihood of event D given the presence of factor B
  - $P\{B|D\}$  the likelihood of factor B given the presence of event D
  - $P\{B|\bar{D}\}$  the likelihood of factor B given the absence of event D
  - $P\{D \cap B\}$  the probability of the presence of both event D and factor B
  - $P\{B\}$  the probability of the presence of factor B

If there are more datasets (more B factors) involved in the mapping prediction and those datasets are conditionally independent to each other with respect to a set of landslide occurrences, the Bayesian conditional probability of event D is expressed by the following formula:

$$P\{D|(B_1 \cap B_2 \cap \dots \cap B_n)\} = \frac{e^{(\log it\{D\} + \sum W^k)}}{1 + e^{(\log it\{D\} + \sum W^k)}} \quad (3)$$

where

$$\log it\{D\} = \ln \frac{P\{D\}}{1 - P\{D\}} \quad (4)$$

$$W^+ = \log \frac{P\{B|D\}}{P\{B|\bar{D}\}} \quad (5)$$

$$W^- = \log \frac{P\{\bar{B}|D\}}{P\{\bar{B}|\bar{D}\}} \quad (6)$$

$W^k$ : positive weight ( $W^+$ ) or negative weight ( $W^-$ ) of factor B depending on the presence or absence of factor B

The total weight of all B factors at each pixel on the prediction map is the sum of  $W^k$ , in which  $W^k$  will be the positive weight  $W^+$  if the factor B is present or negative weight  $W^-$  if B is absent.

The contrast of weight is:

$$C_w = W^+ - W^- \quad (7)$$

### 2.2 Landslide susceptibility mapping

After the landslide survey at the end of year 2010, 142 landslide occurrences are recorded in which 103 positions are used for the landslide susceptibility prediction by Bayesian conditional probability and 39 occurrences are used for the validation. The location of 103 landslide occurrences is presented in Fig 2. Black plus symbols on this figure are landslide occurrences.

There are seven factors chosen for the calculation of the landslide probability: elevation (DEM), slope direction (ASPECT), slope angle (SLOPE), geology (GEO), distance to road (DTR), distance to drainage (DTD), topographical wetness

index (TWI). Each factor is classified into several classes; the positive and negative weights of each class for each factor are calculated using an open-source software ILWIS (Integrated Land and Water Information System). To each factor, a class trigger for positive or negative weight is chosen at the class whose contrast reaches the highest value (see highlight classes in Table 2).

Figure 2. Landslide inventory map for modelling (103 points)

Table 2. Weight values of classes from parameters

Parameter	Value	W <sup>+</sup>	W <sup>-</sup>
DEM	100m ~ 200m	0.620	-0.488
ASPECT	West	0.470	-0.121
SLOPE	0° ~ 10°	0.073	-0.078
GEO	Claystone, sandstone with diatomite	1.009	-1.960
DTR	< 100m	0.758	-0.274
DTD	300m ~ 400m	0.881	-0.180
TWI	4 ~ 6	0.137	-0.077

The flow chart of the procedure for landslide susceptibility mapping by Bayesian conditional probability is shown in Fig. 3.

Weights of seven factor maps are calculated and expressed as weight maps and displayed in Fig. 4 to Fig. 10.

The Bayesian conditional probability map is derived from seven factor maps using the formula (3). However the slicing of this probability map into landslide susceptibility zones is not applicable because the ranges of landslide probability on different probability maps from different methods are totally different. Therefore the probability pattern is sliced into susceptibility zones using the ranking of predicted probability value instead of predicted value itself (Chung and Fabbri, 2003). A pixel of highest probability will be assigned the highest rank and pixel of lowest probability will be the lowest rank. After ranking all pixels within the study area, the landslide zoning could be carried out using predefined threshold values of different zones: high, moderate and low susceptibility.

In the study area, those threshold values are 15%, 25% and 60% for the high, moderate and low susceptibility area respectively. The landslide susceptibility map is presented in Fig. 11.

### 2.3 Validation

The landslide susceptibility map is validated by using 39 heavy landslide occurrences (white plus symbols on Fig. 12). Among them there are 31 points classified as high landslide susceptibility (80% accuracy).

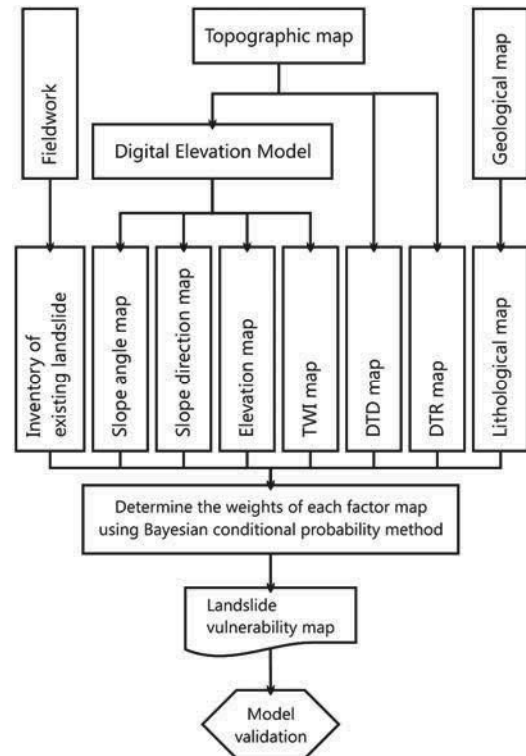

Figure 3. Procedure of landslide susceptibility mapping

Figure 4. Weight of elevation factor

Figure 5. Weight of aspect factor

Figure 6. Weight of slope angle factor

Figure 7. Weight of DTR factor

Figure 8. Weight of DTD factor

Figure 9. Weight of geological factor

Figure 10. Weight of TWI factor

Figure 11. Landslide susceptibility map

### 3 CONCLUSION

a) The landslide susceptibility map shows that most of landslide occurrences concentrate at the areas of low elevation (100~200m), gentle slopes (slope angles vary from 5° to 20°), high TWI values (high water accumulation).

b) Landslides are also triggered due to the road construction. The roadway cuts into the slope faces and reduces the stability of slopes. Landslides occurs near the road construction sites (approximate 100m far from roads).

c) Landslides also distribute along the east-west direction which coincides with the direction of narrow valleys of steep slopes in the study area.

d) The results of Bayesian conditional probability model and the fieldwork survey show that landslides occur usually in soil layers with high proportion of clay and diatomite clayey soils which are heavily weathered.

e) The Bayesian conditional probability model gives the reliable result of landslide susceptibility for the study area. The validation was conducted for 39 heavy landslide positions which show that there are 31 positions (80% accuracy) located in the high landslide susceptibility zone.

f) The reliability of this model could be improved year after year when new landslide occurrences are updated annually in the landslide inventory.

# Influence of Ground Motion Variability on Seismic Displacement Uncertainty

## Influence de la variabilité des mouvements de terrain sur l'incertitude des déplacements en régime sismique

**ABSTRACT:** A series of probabilistic seismic displacement analyses were performed to understand how material property variability coupled with systematic changes in the type and complexity of ground motion variability affect the displacement prediction uncertainty of the Newmark rigid-block method.

**RÉSUMÉ:** Une série d'analyses probabilistes des déplacements en régime sismique ont été effectués pour comprendre comment les variations des propriétés des matériaux couplées avec le type et la complexité des variabilités des mouvements de terrain affectent les incertitudes dans les prédictions de déplacement avec la Méthode des blocs rigides de Newmark.

**KEYWORDS:** Newmark, displacement, seismic, probabilistic, ground motion, variability, uncertainty, Monte Carlo

### 1 INTRODUCTION

Seismic slope deformation methods are used to make predictions of earthquake-induced permanent displacements in natural slopes and man-made dams and embankments. The predictive capability of well-established methods such as rigid-block (Newmark 1965) and decoupled (Makdisi and Seed 1978) procedures, however, are often associated with a high-degree of uncertainty which is a consequence of both parametric and modeling sources of variability. Parametric variability describes a method's sensitivity to the range of input parameters (e.g., shear strength, groundwater and earthquake ground motions) and is a function of the number of input parameters as well as the amount of variability in each parameter. Modeling variability is related to how well the method captures the actual physical mechanism of seismic-induced deformation when all input parameters are fully known. Although the majority of deformation-based method available today have a common conceptual origin in the sliding-block model proposed by Newmark (1965), differences in their analytical formulation, procedural structure, underlying assumptions and mathematical or regression functional form can result in different predictive capabilities and sensitivities to parametric variability (Strenk and Wartman 2011).

In seismic slope deformation analyses, parametric variability comes from parameters characterizing the seismic demand (earthquake ground motions) and those characterizing the slope's seismic resistance (represented by the seismic yield coefficient,  $k_y$ , which is a function of the slope geometry, shear strength and groundwater conditions). In a probabilistic framework, the interplay between these two sources of parametric variability can make evaluating their relative contributions to total displacement uncertainty a difficult task. The main focus of this study is to examine how ground motion variability influences the prediction uncertainty of the Newmark (1965) rigid-block method. To that end, a series of probabilistic seismic slope deformation analyses were performed on an idealized slope for a scenario earthquake event. Displacement uncertainty was quantified for several scenarios designed with increased levels of ground motion variability. Variability in the seismic resistance of the slope was also included. In this approach, realistic levels of variability in both seismic

resistance and demand are systematically changed to evaluate their collective effect on displacement prediction uncertainty.

### 2 PROBABILISTIC DISPLACEMENT ANALYSIS

Performing a rigid-block analysis consists of the following steps: (1) a limit-equilibrium pseudostatic slope stability analysis to compute  $k_y$ ; and (2) characterization of the earthquake-induced shaking at the site. The seismic yield coefficient represents the minimum acceleration required to initiate down-slope displacement of a slide mass. In the rigid-block method, earthquake shaking is characterized by acceleration time-histories that represent a rock outcropping condition which is consistent with the concept of slide mass rigidity assumed by Newmark (1965). Each of these analyses was implemented in a probabilistic framework using Monte-Carlo simulation. All simulations were performed for 1000 iterations using Latin-Hypercube sampling of the input distributions.

The idealized slope model has a height of 20 m with a slope face inclined at an angle of 18 degrees. The failure surface shown in Figure 1 is intended to represent a first-time, shallow translational landslide. Shear strength of the landslide material (unit weight,  $\gamma = 20 \text{ kN/m}^3$ ) was assumed to be controlled by the peak friction angle ( $\phi'_{peak}$ ) only.

Figure 1. Cross-section of the idealized slope model with a shallow failure surface (maximum thickness of 2 m).

The scenario earthquake used for this analysis is the 1994 Northridge event (moment magnitude,  $M_w = 6.7$ ), in California, USA. The slope was assumed to be located 28 km to the northwest of the epicenter. Based on the assumed site location, acceleration time histories were selected from recording stations that recorded the Northridge event. Four stations were selected: (1) Lake Hughes 12A (LHA); (2) Castaic-Old Ridge Road (ORR); (3) Vasquez Rock Park (VAS); and (4) Newhall-West

Pico Canyon Road (WPI). These time-histories were rotated to their fault-normal/parallel components and only the fault-normal components were used in the analysis.

### 3 GROUND MOTION VARIABILITY

Shaking experienced at the hypothetical site was characterized using published ground motion prediction equations (GMPE) using a pseudo-probabilistic approach to model variability in the ground motions. In this approach, the Abrahamson and Silva (2008) GMPE was used to obtain a median acceleration response spectrum and the intra-event component of standard deviation ( $\sigma$ ) (i.e., single-event variability) for the median prediction. Variability was modeled by varying the number of standard deviations ( $n_\sigma$ ) around the median spectrum ( $n_\sigma = 0$ ) as a normally-distributed random variable ranging from  $n_\sigma = -3$  to  $+3$ . The use of a normal distribution achieves symmetry in the range of  $n_\sigma$  generated while preserving the underlying log-normal distribution of the spectral ordinates. Different target response spectra were obtained by multiplying  $n_\sigma$  by the intra-event standard deviation and adding or subtracting this from the median spectrum. The median,  $\pm 1\sigma$  and  $\pm 3\sigma$  spectra are shown in Figure 2; the *PGA* ranges from 0.07 g to 1.15 g with a median value of 0.28 g. A rock outcropping condition was simulated by assuming a shear wave velocity over 30 m ( $v_{s30}$ ) of 1100 m/s and depth of rock of 0 m (ground surface).

Figure 2. Illustration of the range of acceleration response spectra for the hypothetical site

To understand how ground motion variability affects the displacement uncertainty, the pseudo-probabilistic approach described above was implemented in the seismic displacement analysis in a systematic way by performing multiple probabilistic analyses for four different scenarios. These scenarios were designed to progressively increase in their inherent complexity by introducing different types of ground motion variability to the seismic displacement analysis. The four scenarios evaluated are described below.

**No variability** – This is a baseline condition with no variability where the ground motion is held at a constant intensity. Each parent motion (LHA, ORR, VAS, WPI) was spectrally-matched to the median target response spectra generating four separate motions each with a *PGA* of 0.28 g. All spectral-matching was performed using a wavelet-based algorithm developed by Mukherjee and Gupta (2002).

**Variable intensity** – For this scenario, variability in the ground motion intensity is introduced. Using the median spectrally-matched motions from the previous scenario, in this approach, variation in intensity is modeled by simple uniform-scaling to the target  $\pm 3\sigma$  *PGA* values generated from the pseudo-probabilistic approach. For each parent motion, a suite of 1000 *PGA*-scaled acceleration time-histories were generated.

**Variable intensity and frequency** – For this case, additional variability in form of richer ground motion frequency content is combined with the variation of intensity. This form of variability was introduced by considering the variation of spectral acceleration ( $S_a$ ) with period ( $T$ ) provided by the full target response spectra. Variability in the frequency content is

modeled in an approximate manner through variation of the spectral shape and bandwidth of the response spectra between the  $\pm 3\sigma$  bounds (Figure 2). This additional variability was achieved by spectrally-matching a single parent ground motion to randomly-selected response spectrum between  $\pm 3\sigma$  bounds generated from the pseudo-probabilistic approach. For each parent motion, 1000 spectra-compatible acceleration time-histories were generated.

**Variable, intensity, frequency and waveform** – In this approach, additional variability is introduced by using all four parent ground motions in the spectral-matching process. Since the wavelet-based spectrally-matching algorithm generally maintains the non-stationary characteristics of the parent motions, this scenario provides variability in the core waveforms that are propagated through the displacement analysis. To accomplish this, randomly selected parent motions are paired with randomly selected response spectra (between the  $\pm 3\sigma$  bounds generated from the pseudo-probabilistic approach) and spectrally-matched. A total of 1000 spectra-compatible acceleration time-histories were generated that incorporate all four parent ground motions.

### 4 SEISMIC DISPLACEMENT NON-LINEARITY

While the intended purpose of this study is to examine ground motion variability, Strenk and Wartman (2011) demonstrated that predictive uncertainty of common seismic displacement methods is also a function of a slope's relative degree of stability. In the context of Newmark's sliding block analogy, the stability of a slope with respect to sliding is defined as the ratio of a slope's ability to resist sliding ( $k_y$ ) over the peak value of the earthquake-induced acceleration (*PGA*) and is referred to as the acceleration ratio ( $k_y/PGA$ ). For a variety of simplified, equation-based methods and even more complex decoupled methods, a highly-nonlinear relationship exists between the acceleration ratio and displacement ( $\delta$ ); this is illustrated in Figure 3.

Figure 3. Illustration of the relationship linking the position of the acceleration ratio distribution to displacement prediction uncertainty.

Non-linearity is a consequence of Newmark's modeling decision to approximate the physical mechanism of earthquake-induced displacement after the inherently non-linear dynamic behavior of a sliding-block system. This inherent non-linearity manifests itself through the calculation procedure of "double-integrating" the acceleration time-history in excess of  $k_y$  (Newmark 1965) to compute the permanent displacement. In a probabilistic framework, non-linearity was observed to have a strong influence on how parametric variability (in seismic resistance and demand) is propagated through the analysis and can lead to varying degrees of displacement uncertainty (Strenk

and Wartman 2011). This relationship is characterized by a threshold behavior whereby nominal changes in acceleration ratio are greatly amplified into large changes in predicted displacement and hence uncertainty (Figure 3).

In order to capture this, multiple simulations were performed with the purpose of generating three different distributions of  $k_y$ , targeted to have low, moderate and high median values. To do this, probability distributions of  $\phi'_{peak}$  were systematically varied through the pseudostatic analysis to control the slope's seismic resistance; these distributions are referred to as "low", "moderate" and "high" strength and are illustrated in Figure 4a.

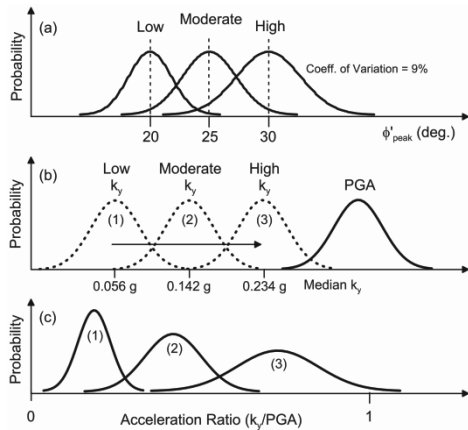

Figure 4. Illustration of the relationship between the  $k_y$  and  $PGA$  distributions and the resulting  $k_y/PGA$  distributions. Corresponding distributions of  $\phi'_{peak}$  are shown for the three strength conditions.

By holding the distribution of  $PGA$  constant and varying the  $k_y$  distributions (Figure 4b), sampling of acceleration ratios was targeted to concentrate along different portions of the  $k_y/PGA$  scale (Figure 4c). For each ground motion variability scenario, three separate simulations for each strength condition were performed. This approach allowed displacement uncertainty to be quantified along different regions of displacement-acceleration ratio relationship and provided insight into how both method non-linearity and ground motion variability affect the level of prediction uncertainty.

## 5 DISPLACEMENT ANALYSIS RESULTS

Statistical measures of central tendency and spread were calculated for the displacement data obtained from the Monte-Carlo simulations of the different scenarios of ground motion variability. Overall, the displacement data was observed to be positively skewed as a result of several sources including inherent distributional assumptions (e.g. log-normal GMPE), truncation at prescribed limits (e.g.  $k_y$  below zero cannot exist, no  $k_y/PGA$  greater than 1) and method non-linearities (Figure 3). Non-parametric statistics based on percentiles that are less sensitive to data asymmetry and were used to describe the data.

For this study, uncertainty in the displacement predictions was assessed using the interquartile range ( $IQR$ ). This parameter represents the range of the middle 50% of the displacement data and is calculated as:

$$IQR = P_{75} - P_{25}$$

where,  $P_{75}$  and  $P_{25}$  are the 75<sup>th</sup> and 25<sup>th</sup> percentiles of the data. Interquartile range data is summarized in Table 1 for the different ground motion variability scenarios and strength conditions.

Table 1. Summary of displacement interquartile range for the different types of ground motion variability and strength conditions

Ground Motion Variability	Displacement $IQR$ (cm)			
	LHA	ORR	VAS	WPI
<b>No Variability</b>				
Low Strength	8.2	7.5	9.1	9.4
Moderate Strength	0.4	0.5	0.9	0.8
High Strength	0.1	0.1	0.2	0.2
<b>Varied intensity</b>				
Low Strength	14.6	12.9	15.9	16.4
Moderate Strength	2.3	2.0	3.4	3.0
High Strength	0.7	0.7	1.3	1.0
<b>Varied intensity-frequency</b>				
Low Strength	15.3	13.9	17.1	17.5
Moderate Strength	2.6	2.3	3.9	3.5
High Strength	0.8	0.9	1.5	1.3
<b>Varied intensity-frequency-waveform (all 4 motions)</b>				
Low Strength			16.7	
Moderate Strength			3.0	
High Strength			1.0	

## 6 DISCUSSION

The seismic displacement results presented in Table 1 demonstrate that the combined variability from both ground motions and the soil properties have a marked influence on displacement prediction uncertainty. For the scenarios evaluated, uncertainty is also observed to increase as variability in the intensity, frequency content and waveform are incrementally introduced into the probabilistic seismic displacement analysis.

### 6.1 No Variability

For this scenario, displacement uncertainty is due *entirely* to the variability in the seismic resistance, specifically the  $k_y$  distributions. With no variability in the ground motions, the displacement-acceleration ratio relationship ( $\delta-k_y/PGA$ ) plots as a smooth, monotonically-increasing line; the  $\delta-k_y/PGA$  relationship for the LHA parent motion is shown in Figure 5. At low acceleration ratios, this relationship is highly non-linear which causes parametric variability of  $k_y$  to be magnified into large displacement uncertainty ( $IQR$  of 8 to 9 cm at the low strength) that progressively reduces as the relative stability of the slope increases (moderate to high strength conditions). This is consistent with the median  $k_y/PGA$  that increases from about 0.20, 0.51 and 0.83 for the low, moderate and high strength  $k_y$  distributions. For this scenario, the  $\delta-k_y/PGA$  relationship for the LHA motion is similar to that for the other parent motions which is due to the fact that all four motions were spectrally matched to the same median response spectrum and thus predict a similar response.

### 6.2 Varied Intensity

For this scenario, variability in  $k_y$  and intensity of the ground motions contribute to the overall displacement uncertainty. As these are scaled motions, the frequency content is constant in the displacement analysis of each parent motion. The  $\delta-k_y/PGA$  relationship for the LHA motion is compared to the case of no ground motion variability in Figure 5. Significant scatter is observed in the  $\delta-k_y/PGA$  relationship and the displacement uncertainty for each parent motion is higher than that for the case of no ground motion variability. By including variability in the shaking intensity, the displacement  $IQR$  is observed to increase by a factor of nearly 2 for the low strength condition. The  $IQR$  increases by factors of 4 and 5 for the moderate to high strength conditions.

Figure 5. Comparison of the  $\delta$ - $k_y/PGA$  relationships for the LHA parent motion for the different ground motion variability scenarios

From this it may be inferred that the displacement uncertainty for marginally stable slopes is more sensitive to variability in the site conditions (i.e., input parameters that feed into  $k_y$ ) while slopes with greater relative stability are more sensitive to ground motion variability. This suggests that for weaker slopes, greater resources and effort should be focused on constraining the variability of the subsurface conditions, whereas for more stable slopes the focus should be on characterizing the earthquake ground motions.

### 6.3 Varied Intensity and Frequency

When additional variability from frequency content is introduced into the analysis, marginal increases in the displacement uncertainty are observed. This is indicated by the slight increase in scatter in the  $\delta$ - $k_y/PGA$  data shown in Figure 5. For the four parent motions, displacement uncertainty increases by a factor of about 1.2, this is substantially less change than that observed when variability in intensity was introduced into the analysis. This is consistent with research that has demonstrated the efficiency of intensity ground motion parameters (e.g.,  $PGA$ , peak ground velocity,  $PGV$  and Arias Intensity,  $I_a$ ) over frequency content parameters for correlating with displacement predictions (Saygili and Rathje 2008).

While the range of response spectra simulated in the analysis (Figure 2) do show variations in their spectra shape, the peak spectral acceleration between the  $\pm 3\sigma$  bounds remains constant at a predominant period ( $T_p$ ) of about 0.2 s. This characteristic as well as the frequency-smoothing affect that spectral-matching has on the output motions could explain the marginal increase in displacement uncertainty. It is likely that displacement uncertainty would increase had the  $T_p$  of the simulated response spectra been allowed to take on a range of values. If, for example, the sub-model for site-conditions (specifically  $v_{s,30}$ ) in the Abrahamson and Silva (2008) GMPE had been modeled as a random variable this would have generated more diverse spectral shapes and hence additional variability in the ground motions. If this technique is implemented in a probabilistic analysis it should be compatible with the underlying assumptions of the method being used. For example, the Newmark (1965) rigid-block model assumes that the slope and slide mass are a non-deformable, rigid body. As such it would be inappropriate to use motions spectrally-matched to a response spectrum for site conditions representative of soft soil as this implies that the slope and slide mass can respond dynamically to the motions. In this case, decoupled-type analyses such as Makdisi and Seed (1978) would be appropriate.

### 6.4 Variable Intensity, Frequency and Waveform

When the intensity, frequency and waveform are varied, the combined affect yields displacement uncertainty that is marginally different from the previous case. Similar to frequency, introducing more diverse waveforms has little effect on the prediction uncertainty. However, it is interesting to note that  $IQR$  for this scenario is sometimes greater or less than the  $IQR$  for the individual parent motions. This is related to the wavelet-based spectral-matching process where the parent motion is decomposed, scaled up/down using wavelets and re-assembled such that modified time-history is compatible with the spectrum and non-stationary characteristics of the parent motion are preserved. Thus, even though the response spectra varies between  $\pm 3\sigma$  bounds using only one parent motion yields a suite of spectra-compatible motions that have very similar non-stationary characteristics. This explains the systematic differences between the four parent motions for three previous ground motion variability scenarios. For example, the non-stationary characteristics of the VAS and WPI motions are such that when input into the “double-integration” computation of the rigid-block method, regardless of being scaled or spectrally matched, systematically yield higher median displacements and more prediction uncertainty than motions LHA and ORR. When all four motions are propagated through the displacement analysis, the effects of individual motions are tempered and a more average displacement response is computed. This average response, however, is not necessarily more precise than using a single parent motion.

## 7 CONCLUSIONS

Systematically increasing ground motion variability (and complexity) in the probabilistic displacement analysis showed a trend of increased displacement uncertainty. For the idealized slope, this trend was consistent across a range of relative stabilities (low, moderate and high). Ground motion variability had its most pronounced affect on displacement uncertainty at low acceleration ratios as a consequence of the non-linear  $\delta$ - $k_y/PGA$  relationship. Of the four scenarios considered, variability in ground motion intensity alone has the greatest impact on the displacement prediction uncertainty. When additional variation in frequency content and waveform is introduced, only minimal changes in uncertainty are observed. These results suggest that displacement uncertainty may be adequately characterized through simple scaling of ground motion intensity and that the effort required to create variability in both intensity and frequency through spectral-matching may be of limited utility. Also, the use of multiple parent motions in a displacement analysis can overcome potential biases introduced by individual motions, but may not always lead to more constrained prediction uncertainty.

# A new approach to assess the potential for flow slide in sensitive clays

## Une nouvelle approche pour évaluer le potentiel d'écoulement des argiles sensibles

Thakur V., Degago S.A., Oset F., Dolva B.K., Aabøe R.  
Geotechnical section, Norwegian Public Roads Administration

**ABSTRACT:** Sensitive clays could constitute a major threat to nearby infrastructure due to potential flow slides. A key question is if all sensitive clays have the same potential to retrogress to the same extent and the significance of remoulded shear strength ( $c_{ur}$ ) in flow slides. This paper proposes a new approach to assess the potential for flow slides and in doing so presents a new laboratory test procedure referred to as the quickness test. The test focuses on remoulded behaviour of sensitive clays in terms of a numerical value referred to as quickness ( $Q$ ). Sensitive clay samples were collected from three different landslide locations. The quickness test was used to demonstrate why sensitive clays with  $c_{ur} > 1$  kPa are not susceptible to flow slides. Based on this study, it is possible to state that a  $Q < 15\%$  or  $c_{ur} > 1$  kPa seems to be the threshold limit above which the extent of the retrogression of a landslide is limited to the initial slide. This criteria has been supported using data available from several Norwegian landslides in sensitive clays.

**RÉSUMÉ :** Les argiles sensibles pourraient constituer une grave menace pour les infrastructures en raison de coulées potentielles. Une question clé est de savoir si toutes les argiles sensibles ont un potentiel de rétrogression équivalent et de d'estimer l'amplitude de la résistance de cisaillement remaniée ( $c_{ur}$ ) des les coulées. Cet article propose une nouvelle approche pour évaluer le potentiel de coulées et présente ainsi une nouvelle procédure de laboratoire appelée le test de rapidité. Le test se concentre sur le comportement de l'argile sensible remaniée en termes de valeur numérique dénommée rapidité ( $Q$ ). Des échantillons d'argiles sensibles ont été recueillis à partir de trois sites différents où il y a eu des glissements de terrain. Le test de rapidité a été utilisé pour démontrer pourquoi les argiles sensibles avec  $c_{ur} > 1$  kPa ne sont pas sujettes à des coulées. Sur la base de cette étude, il est possible d'affirmer que  $Q < 15\%$  ou  $c_{ur} > 1$  kPa semble être le seuil au-delà duquel l'ampleur de la rétrogression d'un glissement de terrain est limitée à la rupture initiale. Ce critère se base sur des données disponibles à partir de plusieurs glissements de terrain dans les argiles sensibles norvégiens.

### 1 INTRODUCTION

Soft sensitive clays are normally associated with loss of stability as well as substantial ground deformation, which can lead to structural damage and jeopardize the overall stability of an area. It is worth mentioning the statement by Bishop in 1973 that "Rotational slips alone may cause damage to services and property, but seldom involve loss of life. It is the subsequent development into a flowslide which has been responsible in each case where disaster has occurred". In the sensitive clay deposits of Scandinavia and eastern Canada, landslides are particularly destructive, due to the possibility of small landslides initiating a flow slide, which may involve massive soil movements in the order of millions of cubic meters.

For flow slides to occur after an initial slide, it is important that at least the following two criteria are fulfilled (Tavenas et al. 1983):

- The slide debris should be sufficiently remoulded.
- The slide debris should be able to flow out of the slide area if remoulded.

There may be additional factors, such as the topography and the stability of the area behind the initial slide zone. However, if the two criteria mentioned above are not fulfilled, then vast landslides, such as those listed in Table 1, are unlikely to occur. An overview of Norwegian landslides as shown on Table 1 clearly indicates that soft sensitive clays must be handled carefully. However, the term 'sensitive clay' encompasses a wide range of clays depicting significant variations in engineering behaviour such as the remoulded shear strength

( $c_{ur}$ ). Therefore, a key question is whether all sensitive clays have the same potential to create flow slide and the significance of  $c_{ur}$  for occurrence of flow slide? Answer to this question has a direct relevance in the selection of an appropriate safety level for constructions, measures and in hazard mapping.

A relationship between the  $c_{ur}$  and the soil sensitivity ( $S_t$ ) as well as between  $c_{ur}$  and the liquidity index ( $I_L$ ) has been used to evaluate the potential for flow slides in sensitive clays. Mitchell and Markell (1974) suggest a direct relationship between  $c_{ur}$ ,  $S_t$  and the retrogression distance ( $L$ ). They suggest that landslides with an  $L > 100$  m are observed for  $c_{ur} < 1$  kPa. Retrogression was zero for  $c_{ur} > 1$  kPa. Leroueil et al. (1983) and Locat and Demers (1988) presents correlations between  $c_{ur}$  and  $I_L$ . The correlations are  $c_{ur} = (I_L - 0.21)^2$  and  $c_{ur} = 1.46 I_L^{-2.44}$  respectively. These showed that sensitive clays with  $I_L > 1.2$  are susceptible to flow slides. This finding is also supported by the landslide data presented in Table 1. It must be noted that, according to the correlations  $I_L > 1.2$  is only possible when  $c_{ur}$  is less than 1 kPa. In other words, the findings by Mitchell and Markell (1974), Leroueil et al. (1983), Tavenas et al. (1983) and Locat and Demers (1988) are in line with each other. Based on the landslide data, Lebus et al (1983) also suggested that  $c_{ur} < 1$  kPa may define the threshold limit for occurrence of flow slides.

$I_L$  and  $c_{ur}$  based criteria have been widely adopted to study the flow slide potential of sensitive clays. However, the measurement of  $I_L$  demands determination of three parameters a priori, i.e. liquid limit ( $w_l$ ), plastic limit ( $w_p$ ) and natural water content ( $w$ ). Notably the conventional thread-rolling method of

determining  $w_p$  has a significant drawback as it can easily be biased by subjective judgement. Also,  $c_{ur}$  is usually measured using the fall-cone test, a point based measurement system, which may not necessarily be representative of a large soil volume.

Keeping this in view this paper proposes a new test procedure, the quickness test, to evaluate the flow slide potential of sensitive clays. In contrast to the conventional  $c_{ur}$  and  $I_L$  based approaches, the quickness test is a soil volume based approach and has an added advantage of qualitative description that provides a better visualisation with respect to understanding of flow slides.

Table 1 Selected large landslides in Norwegian sensitive clays.

No.	Year	Landslide	$L_R$ [m]	$c_{ur}$ [kPa]	$S_t$ [-]	$I_L$ [-]	$I_P$ [%]
1	2012	Byneset	300	0.12	120	3.8	4.8

## 2 THE QUICKNESS APPROACH

In this section, a simple test known as the quickness test is presented. The quickness test aims to provide the basis for a physical understanding of flow behaviour of fully remoulded sensitive clays using a new type of geotechnical engineering test. Additional description on the test methodology can be referred to Thakur and Degago (2012).

Figure 1. Quickness test procedure (Thakur and Degago, 2012).

### 2.1 Test procedure

The quickness test is a simple procedure that is performed by filling an open ended cylinder with remoulded sensitive clay, then slowly lifting the cylinder, and finally measuring the deformation (height and lateral spreading) as the material is subjected to flow due to its own weight. The test concept is similar to the slump test for concrete that is used to measure the consistency of freshly mixed concrete. Two different cylinder sizes were used. The dimensions were the diameter ( $D_o$ ) = 65 mm and height ( $H_o$ ) = 45 mm for the small cylinder, and  $D_o$  = 100 mm and  $H_o$  = 120 mm for the large cylinder. The large cylinder has the same size as the cylinder used for the standard

proctor tests. Figure 1, taken from Thakur and Degago (2012), shows the concept of the proposed quickness test. The thoroughly remoulded material is placed into the cylinder, levelled off, and allowed to flow outward as the cylinder is slowly lifted upward with minimum disturbance to the sample. The difference in height between the cylinder and the slumped material ( $H_o - H_f$ ) is measured. The outward flow spread diameter ( $D_f$ ) is also noted. The quickness ( $Q$ ) in % is defined as  $[1 - H_f / H_o] \times 100$ .

### 2.2 The tested material

Quickness tests were performed on several sensitive clay samples taken from three different locations in the central Norway. One of the landslides, Lersbekken, have been studied and presented in Thakur and Degago (2012). In this work a similar approach is presented for two new landslide locations Byneset and Olsøy. These sites have been studied extensively in connection to landslide hazards. Laboratory index properties of the sampled material are presented in Table 2. Liquid limit ( $w_L$ ),  $c_{ui}$  and  $c_{ur}$  of the tested material were obtained using the fall-cone method as described by the National Standard NS 8015 in Norway.

Table 2 Properties of the tested materials from three different landslide locations

Properties	Lersbekken	Byneset	Olsøy
Sampling depth ( $H$ ) [m]	6 – 10	4 – 12	4 – 15
Clay fractions (< 2 $\mu$ m) [%]	30	30 – 55	50 – 65
Water content ( $w$ ) [%]	22 – 34	27 – 48	28 – 38
Plasticity index ( $I_P$ ) [%]	5 – 7	3 – 15	3 – 10
Liquidity index ( $I_L$ ) [-]	0.7 – 2.0	0.9 – 5.4	0.6 – 3
Undisturbed undrained			
shear strength ( $c_{ui}$ ) [kPa]	12 – 58	5.2 – 72	60 – 100
Remoulded undrained			
shear strength ( $c_{ur}$ ) [kPa]	0 – 2	0 – 3	0 – 2.1
Sensitivity ( $S_t$ ) [-]	16 – 29	4 – 400	30 – 100
Over consolidation ratio ( $OCR$ ) [-]	1.8 – 2.0	1.1 – 3.3	2 – 4

## 3 TEST RESULTS AND OBSERVATIONS

Quickness tests were performed on more than 60 different samples extracted from Lersbekken, Byneset and Olsøy landslide locations. A series of pictures taken during the quickness test on two Byneset clay samples, with  $c_{ur} = 0.1$  kPa and  $c_{ur} = 1.0$  kPa, are shown in Fig. 2. The figure shows slump and spread observed at selected stages of the tests given as the percent ratio of the height lifted to the cylinder height ( $H_o$ ).

Previous observations during a quickness test conducted on Lersbekken clay showed that sensitive clays with  $c_{ur} \approx 0.5$  kPa were not as fluid as they were originally assumed and sensitive clays with  $0.5 \text{ kPa} < c_{ur} < 1.0 \text{ kPa}$  were semisolid in nature (Thakur and Degago, 2012). In line with this observations, the Byneset and Olsøy clay samples with  $c_{ur} < 0.2$  kPa, seemed to be more like a soup as reported by Mitchell and Soga (2004). The registered collapse of the remoulded material was negligible when the remoulded sensitive clay had  $c_{ur} > 1.0$  kPa.

Figure 2. Slump and spread observed from the start to the end of the Quickness tests for remoulded Byneset clays (a)  $c_{ur} = 0.1$  kPa and (b)  $c_{ur} = 1.0$  kPa.

A typical flow and spread behaviour of two remoulded clays from the Olsøy site are presented in Figure 3. The tests on Olsøy clay shows that the remoulded material with  $c_{ur} < 0.2$  kPa seemed to be more like a soup, Figure 3(a). As the  $c_{ur}$  increases from 0.2 kPa towards 1 kPa, the remoulded material increasingly showed less viscous behavior and for a  $c_{ur} > 1.0$  kPa little or no flow is observed, Figure 3(b). This simple test indicates why soft sensitive clays with a  $c_{ur} > 1$  kPa are less likely subjected to a large retrogression or run-out.

(a)  $c_{ur} = 0.2$  kPa

(b)  $c_{ur} = 1.2$  kPa

Figure 3. Flow and spread behaviour of the two remoulded Olsøy clays having (a)  $c_{ur} = 0.2$  kPa and (b)  $c_{ur} = 1.2$  kPa.

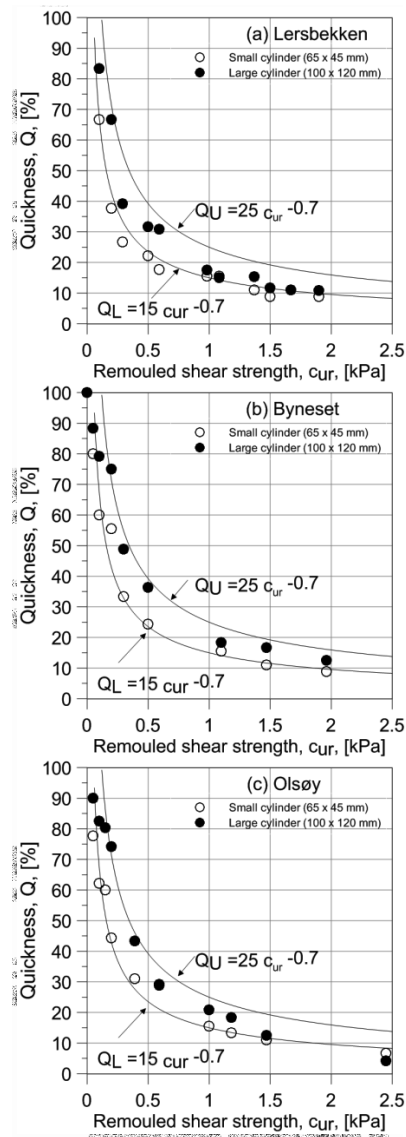

Figure 4.  $Q$  versus  $c_{ur}$  values registered on soil samples taken from a) Lersbekken b) Byneset and c) Olsøy landslide locations.

Figure 5. Compilation of  $Q$  versus  $c_{ur}$  values registered on soil samples taken from the three landslide locations.

Apparently, the flow behaviour of the Lersbekken, Byneset and Olsøy clay is identical. Figure 4 presents  $Q$  versus  $c_{ur}$  for various sets of tests on the Lersbekken, Byneset and Olsøy clays performed with two different cylinder sizes, 100 mm x 120 mm, 65 mm x 45 mm. For the major area of interest, i.e. clay samples with  $c_{ur} > 1.0$  kPa, material flow was not registered irrespective of the size of the test cylinders. Accordingly, this

study recommends using a cylinder size 100 mm x 120 mm and proposes some correlations based on this cylinder size because this cylinder size is readily available in connection with the standard proctor test. The Figures presents the lower and the upper bound  $Q$  values observed for various  $c_{ur}$  of the tested material. A combined plot is shown in Figure 5 where all the data from the three landslide locations are plotted together.

Thakur and Degago (2012) suggests considering the lower bound quickness in evaluating flow slide potentials since it provides a conservative estimate. It can be noticed from the quickness test results (Figure 4 and 5) that all Lersbekken, Byneset and Olsoy materials have nearly identical responses and the lower bound  $Q = 15\%$  corresponds to  $c_{ur} = 1$  kPa for all the three sensitive clays.

#### 4 SUITABILITY OF QUICKNESS TEST

Suitability of quickness value ( $Q$ ) as compared to remoulded shear strength ( $c_{ur}$ ) in relation to assessment of flow behaviour of materials is briefly discussed.

Fluidity of sensitive clays is difficult to interpret by small numerical values of  $c_{ur}$  because a seemingly small change could imply significant alteration in flow behaviour of clay. For example, a significant change in the flow behaviour of the sensitive clay from the Lersbekken site is observed for a small variation of  $c_{ur}$ , i.e. from 0.5 to 0.2 kPa. In this case, the significant behavioural change is reflected by the quickness test visually as well as numerically  $Q$  varies from 32% to 67% (Thakur and Degago, 2012). The quickness test amplifies the small range of  $c_{ur}$ , i.e. from 0 to 2.0 kPa, to a larger scale, 0 to 100%. Quickness test therefore gives a better visualisation of the flow behaviour of sensitive clays where small  $c_{ur}$  values have large implications in regards to understanding the potential for retrogressive landslides.

Figure 6. Estimated  $Q$  values for Norwegian landslides given in Table 1 and quickness based criteria for occurrence of flow slides.

In general, both  $c_{ur}$  and  $Q$  principally explains the same soil characteristic through different test approaches. The fall-cone test is a point specific method calibrated against the undrained shear strength of soil under undisturbed and remoulded state; whereas, the quickness test gives a value that is representative of the volume of the material tested. In contrast to the fall-cone test, the quickness test has an added advantage of qualitative

description that can provide a better visualization with respect to understanding flow slide (Thakur and Degago, 2012).

#### 5 ASSESSMENT OF FLOW SLIDE POTENTIALS

Significance of quickness test is illustrated in relation to assessment of potential for flow slides using the Norwegian landslides given in Table 1. In doing so the  $Q$  values for each landslides is estimated based on the corresponding  $c_{ur}$  values and using a lower bound correlation shown in Figure 5 ( $Q = 15 c_{ur}^{-0.7}$ ). The estimated  $Q$  values of the Norwegian landslides are shown in Figure 6 where the numbers corresponds to the landslide numbers as listed in Table 1.

Based on the quickness test results and the data from the Norwegian landslides, two distinct regions are shown in the Figure 6. These regions depict the potential for occurrence of flow slides based on  $Q$  values. Accordingly, large flow slides are less likely to occur when  $Q < 15\%$  (or  $c_{ur} > 1$  kPa) and in this case the slide will be limited to an initial slide only. However, for  $Q > 15\%$  (or  $c_{ur} < 1$  kPa), a flow slide is possible. Based on the retrogression length ( $L_R$ ) of the Norwegian landslides studied in this work,  $15\% < Q < 25\%$  (or  $0.5$  kPa  $< c_{ur} < 1$  kPa) mostly corresponds to a flow slide with  $L_R < 250$  m while  $Q > 25\%$  (or  $c_{ur} < 0.5$  kPa) corresponds to a flow slide with  $L_R > 250$  m. Effort is being made to establish a correlation between  $L_R$  and  $Q$  using several landslide data, however at this stage no specific recommendation is made.

#### 6 CONCLUSIONS

This paper presents a new laboratory procedure that focuses on remoulded behaviour of sensitive clays in terms of a numerical value referred to as quickness ( $Q$ ). The quickness test was used to demonstrate why sensitive clays with  $c_{ur} > 1.0$  kPa are not susceptible to flow. This particular study shows that a  $Q < 15\%$  or  $c_{ur} > 1.0$  kPa seems to be the threshold limit where the extent of the retrogression of a landslide is limited to the initial slide.

# Landslide risk assessment in the Göta river valley: effect of climate changes

L'évaluation des risques de glissement de terrain dans la vallée de la rivière Göta :  
effet des changements climatiques

Tremblay M., Svahn V., Lundström K.  
Swedish Geotechnical Institute, Linköping and Gothenburg, Sweden

**ABSTRACT:** The predicted effects of the ongoing climate change such as increased precipitation and longer dry periods are expected to result in an increased frequency of landslides in Sweden. In order to meet this challenge, the Swedish Government commissioned the Swedish Geotechnical Institute (SGI) to investigate and assess the landslide risk in the Göta river valley, which is one of the Swedish valleys with the highest landslide frequency and where consequences of a landslide could be severe due to the number of large industrial sites as well as residential areas and infrastructure. A mapping of the landslide risk considering both present conditions and the effects of a future climate change has been performed. The investigation shows that climate change will increase the risk of landslides in the valley. However, it also shows that high level of risk is already estimated in many areas which can be affected even in today's climate.

**RÉSUMÉ :** Les effets prévus du changement climatique en cours, comme l'augmentation des précipitations et des périodes sèches plus longues devraient se traduire par une augmentation de la fréquence des glissements de terrain en Suède. Afin de relever ce défi, le gouvernement suédois a chargé l'Institut suédois de géotechnique (SGI) d'étudier et d'évaluer le risque de glissement de terrain dans la vallée de la rivière Göta, qui est une zone à haute fréquence de glissement de terrain et une zone particulièrement vulnérable en raison du nombre de grands sites industriels ainsi que des zones résidentielles et des infrastructures. Une étude des risques de glissement de terrain considérant à la fois les conditions actuelles et les effets d'un changement climatique à venir a été effectuée. L'étude montre que le changement climatique augmente les risques de glissements de terrain dans la vallée, mais elle montre aussi que le niveau de risque est déjà élevé dans de nombreuses parties de la vallée, même dans le climat actuel.

**KEYWORDS:** landslides, risk assessment, climatic changes, mapping.

## 1 INTRODUCTION

The Göta river valley is situated in the southwest of Sweden and runs from Lake Vänern in the north to Gothenburg in the south, Figure 1. It is one of the areas in Sweden which is most frequently affected by landslides. Each year, several landslides of various size and character occur in this region. The landslides are generally small and shallow, however, a number of large landslides have occurred during the past century, some of them with human casualties and extensive property damages (e.g. Alén et al. 2000; Hultén et al. 2007). One reason for the high frequency of landslides in the Göta river valley is its geological history. The deep clay layers were formed during and after the latest glaciation period and in some parts reach a thickness up to 100 meters. The Göta river has overtime cut deep into the clay, forming the prerequisites for landslides. As the clays were mainly deposited in a marine environment, quick clay is therefore widespread in the area. The total length of the river is about 100 km.

The valley has a long history of human activities resulting in settlements, industries, shipping and harbours. Roads and railroads of national importance follow the river bank for kilometres, and environmentally hazardous activities and contaminated sites are common. More than 100,000 people live in the valley and the river is also the fresh water source for about 700,000 people. Due to the relatively high exploitation of the area, the consequences of a landslide in the Göta river valley can therefore be very severe.

The Göta river has suffered from many landslides over the years that have been documented. Parts of the most populated areas in the valley have earlier been investigated for mapping

the risk of landslides, but in order to predict the effect of climate changes, the Swedish Government has commissioned the Swedish Geotechnical Institute to investigate and map landslide risks in the whole valley.

Figure 1. Location of the Göta river

## 2 METHODOLOGY OF RISK MAPPING

The concept of risk used in these investigations refers to a combination of the *probability* that an event might happen in a given area and the *consequence* of this event occurring.

Risk is defined as a combination of these two parameters:  
 $Risk = Probability \times Consequence$

A landslide risk analysis thus includes three separate parts:

- the estimation of the probability for a landslide to occur,
- the determination of the consequences of such a landslide,
- the combination of these two factors resulting in a risk map.

Landslide probability is based on the calculation of the safety factor using conventional stability analysis. By studying the uncertainties in a number of parameters used in the calculation of the safety factor in a given area, the probability of a failure occurring in this area is estimated. The probability is therefore directly dependent on the safety factor and the variation in different parameters such as slope geometry, shear strength and density of the soil, etc. The probability of landslide occurrence is divided into five probability classes from "negligible probability of landslide" (probability class S1) to "substantial probability of landslide" (probability class S5).

The impact of a landslide in an area, i.e. damage to life, property and environment, is also defined in five consequence classes, from "minor damages" (consequence class K1) to "catastrophic damages" (consequence class K5). The assessment of the consequences of a landslide takes into account the damage that a possible landslide would cause. Extent of the damage is assumed to be in proportion to how the land is used for dwelling, industries, infrastructure and other facilities and activities. Of course, the size of the landslide is important for the assessment of the consequences, both on land and in the river, and it is affected by the presence of quick clay in the area as well as the topography of the slope. In earlier investigations, the consequences were described following a scale with incremental effects, but in the present project the financial aspects have been added on the impact assessment in order to more systematically compare the consequences of landslides in different areas, affecting different functions in the society.

The combination of landslide probability classes and landslide consequence classes results in an expression of the risk of landslide. Landslide risk class is expressed as a pair of numbers that reflects the consequences of a landslide (K) and its probability to happen (S). A total of 25 risk classes may be obtained from the risk matrix, see Figure 2, and they are clustered into three risk levels (low, medium, high) in order to simplify the risk mapping. The different levels of risk of landslides involve different requirements for geotechnical actions including the need of detailed stability investigations and eventually protective measures.

Probability class	S5	5/1	5/2	5/3	5/4	5/5	Low risk level Medium risk level High risk level
	S4	4/1	4/2	4/3	4/4	4/5	
	S3	3/1	3/2	3/3	3/4	3/5	
	S2	2/1	2/2	2/3	2/4	2/5	
	S1	1/1	1/2	1/3	1/4	1/5	
		K1	K2	K3	K4	K5	Consequence class

Figure 2. Risk matrix used in the present investigation.

The landslide risk map is obtained by overlaying the probability map and the consequence map and combining them into risk levels. The results of the risk analysis is finally presented in colored maps representing the three risk levels (low, medium and high) as shown in Figure 3. Areas with no landslide risk, e.g. areas with visible bedrock, are omitted from the risk map.

**Landslide consequences**

**Risk**

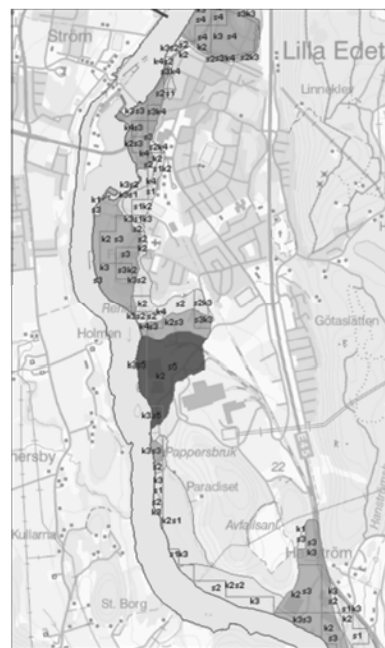

Figure 3. Principle of landslide risk mapping: probability map and consequence map are combined into a risk map.

### 3 EFFECTS OF CLIMATE CHANGE

Climate change is generally expected to result in increased frequency of natural disasters. In order to limit the damages and meet the new threat that a changing climate will mean for society, it is necessary to work both proactively to identify risks and to protect exposed areas by improving the quality of planning with regard to the new situation. SGI has for several years and on several occasions drawn attention to the geotechnical impacts of climate change. The analysis was summarized in an action plan for climate adaptation work and reported in various publications including the report "Geotechnical conditions for an increased flow of lake Vänern to the Göta River", SGI Varia 565 (Hultén et al, 2006).

Expected climate change in the Göta river valley over the coming 100 years includes gradually increase of yearly mean temperature and precipitation, see Figure 4 and 5, resulting in a higher mean water level in the river. The climate change will also result in an increase in most intensive rainfall events, an increased number of high and low discharges from the Lake Vänern due to increased inflow during autumn/winter and decreased inflow during spring/summer, and finally increased 100-year flows in Göta river tributaries (Bergström et al., 2011).

Figure 4. Calculated increase in temperature in the Göta river valley, based on 16 climate scenarios. The historical observations are shown as bars. The dark shaded area shows the 25-75 percentiles and the light shaded area the maximum and minimum values. The black line is the median value (after Bergström et al, 2011).

Figure 5. Calculated increase in precipitation in the Göta river valley, based on 16 climate scenarios. The historical observations are shown as bars. The dark shaded area shows the 25-75 percentiles and the light shaded area the maximum and minimum values. The black line is the median value (after Bergström et al, 2011).

A closer study of the results from the different climate scenarios which were performed in the present investigation

shows a significant increase in precipitation during the autumn/winter period, which means that the amount of water coming to the Göta river through discharge from the lake Vänern will increase, increasing the risk of erosion and the risk of landslides along the river.

The forecast produced by the different climate scenarios also shows reduced quantities of water during the drier spring/summer periods in the Vänern basin. This means that a lower water level is expected in the Göta river during these periods and thus an increased risk of landslides due to the decreased stabilizing effect of the water in the river. However, the water level in the Göta river is controlled by the presence of electric power plants along the river and is regulated by court statements and different agreements between the electricity producers and the authorities. Therefore, only minor changes of the highest or lowest water levels are expected to occur due to climate change. However, the mean water flow will increase over longer period, causing erosion along the river.

Studies of the changes in groundwater levels have shown that the expected variations are about 0,5 m in the area which means a minor effect on the total stability (see Blied and Persson, 2011).

An extensive study of the impact on the erosion process has also been conducted in this project. The results show that a number of river sections will be affected by the increase of flow in the valley resulting in an increase of erosion (see Rydell et al., 2011).

### 4 WORK DONE IN CURRENT INVESTIGATION

#### 4.1 Stability conditions

To improve the basis for stability calculations, a detailed topographical model of the area has been set up. The model includes topography from a laser scanning on land and a multibeam scanning of the topography of the river bottom.

Existing studies, surveys, maps, charts and other relevant material were collected from various stakeholders and analyzed. Inventory was also made regarding the older material from a stability study in 1962, and other SGI investigations.

To get an overview of ongoing work and a reasonable amount of stability studies, the river valley has been divided into 10 different areas. For all of these areas, a number of sections were chosen and studied using traditional methods to estimate the stability conditions in the current situation. Thereafter, the impact of climate change on the stability was assessed and quantified. A total of 240 sections along the river have been studied including over 2500 field investigation tests and laboratory testing on about 4000 soil samples.

Erosion of the Göta River is a very important factor associated with increased risk of landslides. Cooperation with universities, government agencies and other appropriate bodies was established early in the project in order to plan the study and investigation work necessary for the implementation of the mandate.

Mapping of quick clay areas has also been a major topic studied in this project since it is a primordial parameter needed for a better prediction of the size of expected landslides. Improved investigation methods have been tested and implemented in the project.

#### 4.2 Consequences of landslides

In order to perform a complete risk analysis, elements that may be affected by a possible landslide have been analyzed and taken into account. Among the major elements included in the study are human life, residential properties and infrastructures as well as contaminated soils. Extensive work has been performed for inventory, compilation and report of the selected

elements for impact assessment (see Andersson-Sköld et al, 2011).

#### 4.3 Data processing and databases

Information, data and results from different studies must be organized in an orderly manner to allow for quick access to all materials. For this purpose, a GIS database was built up to simplify data processing and to enable work with the large amount of information acquired during the project.

### 5 R&D IN CURRENT INVESTIGATION

The investigation included a comprehensive risk analysis to be performed in a rather large area with many factors to be taken into account. The methodology chosen for the investigation using a risk matrix was developed and used in previous landslide analysis.

The commission stipulates that the investigation is expected to result in a complete risk analysis along the Göta river together with a general increase of knowledge regarding landslide analysis and risk mapping. A number of working studies were therefore initiated to study and improve different methods used in this kind of analysis. The Research and Development efforts have mainly been concentrated on mapping of input parameters, understanding of the erosion process, the estimation of probability of landslide and new routines for assessment and presentation of impact of landslides in different areas.

The assignment, which in addition to studying the current situation should also take into account increased flow and runoff conditions in the river valley, asked for a study of the climate changes at a regional level.

The research and development linked to the commission was mainly needs-driven and provided direct assistance in the investigation. Research on mapping and handling of quick clay is an example of efforts which provided valuable knowledge for the investigation. A method based on field measurements has been improved and implemented in the project for classification and mapping of sensitive and quick clays.

Efforts have also been made to try to understand and predict the impact of climate changes on prevailing groundwater conditions. These changes are expected to affect both the mean value of the groundwater level and its variations in time.

Even though it has been the object of a number of earlier analysis and studies, the ongoing erosion in the Göta river valley is still incompletely known. Better knowledge has been acquired and improved models have been developed for both the bottom erosion and erosion of the slopes at the waterline. Analysis and measurements of erosion and sediment transport coordinated with the determination of bathymetric and topographic conditions have been performed in this project. The R&D-work has also included studies of boat related erosion and the use of advanced numerical models.

### 6 RESULTS AND REPORTING

The results of the project are presented in two different forms:

- a series of 34 reports in which the results from the different R&D groups are presented including study of groundwater, erosion, methodology of probability analysis, methodology for estimation of consequences, mapping of quick clay, etc.
- a final report in three parts including general discussions and recommendations, a complete presentation of the methods used in the investigation and finally risk maps covering the whole valley, see Swedish Geotechnical Institute (2012) or SGI's website: [www.swedgeo.se](http://www.swedgeo.se).

As expected, the investigation shows that climate changes will increase the risk of landslides in the Göta river valley. However, it also shows that high level of risk is already estimated in many areas which can be affected even in today's climate. Both the risk for landslide in the present climate conditions and the effect of the climate change in form of new estimation of risk in the future are presented in the final report.

The investigation also leads to a general presentation of protective and preventive measures which could be taken in different parts of the valley. Examples of practical measures that have to be considered are excavations, backfills, soil reinforcement and erosion protection. Besides a rough estimation of the costs of protective measures, the report also includes recommendations regarding different monitoring activities which should be regularly performed along the river.

**ABSTRACT:** Monitoring and early warning is one of the most effective ways toward reduction of disasters induced by landslides due to heavy rainfall. The authors has developed a simple and low-cost early warning system which measures tilting angles on the surface and/or in the ground of a slope, as well as volumetric water contents in the ground. Unlike conventional sensing devices, measurement with tilt sensors is simple and easy, but the translation of the obtained data of tilting angle is still under consideration. The authors conducted an artificial rainfall test on a natural slope of weathered and loose andesite deposit in order to observe its prefailure behaviours. The tilt angles and volumetric water contents were measured during the deformation and failure process. The tilt sensors showed tilting rates between 0.1 and 0.5 degree / hour before failure. In addition, there was a unique relation between the deformation and the water content, which is independent of the time history of the artificial rainfall. Simple shear tests were also conducted to observe the prefailure deformation of an unsaturated soil. These observations will give us ideas on the warning criteria for slope failure based on monitoring of tilting angle and water contents.

**RÉSUMÉ :** Donner l'alerte au plus tôt est sûrement la solution efficace pour réduire l'ampleur des désastres induits par les glissements de terrain dus à des chutes massives de pluie. Un système d'alerte simple et à bas-coût qui mesure les angles d'inclinaison de la surface du sol et/ou dans la terre, ainsi que le volume d'eau absorbé est proposé. Contrairement aux appareils conventionnels, la mesure avec les sondes de l'inclinaison est simple et facile, mais la traduction des données obtenues est encore à l'étude. Un test de chute de pluie artificielle sur une pente naturelle d'andésite durcie et dégagée pour observer les comportements des pré-fractures a été réalisé. L'orientation de l'inclinaison ainsi que le volume d'eau ont été mesurés pendant la déformation de la surface. Les sondes ont révélé des pentes comprises entre 0,1 et 0,5 degré/heure avant glissement. De plus, une relation unique indépendante de la durée de la chute de pluie artificielle est établie entre la déformation du sol et le contenu d'eau. Des tests de cisaillement ont aussi été effectués pour observer la déformation des pré-fractures d'un sol non saturé. Ces observations nous donnent des informations sur les critères d'alerte pour prévenir un glissement de terrain.

**KEYWORDS:** landslide, slope failure, monitoring, early warning.

## 1 INTRODUCTION

There is a long history in prevention and mitigation of rainfall and/or scouring-induced landslides. Mechanical countermeasures to prevent slope failure, like retaining walls and ground anchors, have been widely used. However, they are expensive and it is not realistic to apply such mechanical measures for all of these slopes with potential risk, because most of landslide occurs in small scale, but a large number of slopes. Therefore, careful monitoring of slope behaviors and consequent early warning is reasonable as alternatives.

The authors have proposed and developed an early warning system for slope failures, as one of feasible countermeasures (Figure 1) (Uchimura, et. al. 2010 & 2011a). The system consists of minimum number of low-cost sensors on a slope, and the data is transmitted through wireless network. Thus, the system is low-cost and simple so that the residents in risk areas can handle it to protect themselves from slope disasters.

There are several publications which report incremental deformation of slopes before failure due to heavy rainfall (Ochiai, et. al. 2004, Orense, et. al. 2003 & 2004). These behaviors can be used as criteria of early warning for slopes disasters. Extensometers and borehole inclinometers are conventional and widely used devices to detect such displacements of slopes. But, these devices require high skills and equipments for installation and operation, resulting in a respectable cost.

Therefore, the proposed early warning system uses tilt sensors to detect abnormal deformation of slopes as shown in

Figure 1. The surface tilt sensor is installed with a rod inserted into the slope surface for a depth of 0.5 or more. It has a MEMS tilt meter (nominal resolution = 0.04 mm/m) to measure the tilting angle in the surface layer of the slope. The obtained tilt angle is equivalent to shear deformation of the surface layer, which can be translated to the surface displacement if the tip of rod reaches the intact base layer.

Figure 1. Tilt sensor units and wireless monitoring system

The miniature ground inclinometer consists of stainless steel pipe segments with a length of 50cm or 1m and outer diameter of 25 mm. The segments are connected to each other by a

flexible mechanism, so that the device moves together with the ground displacement. A sensor unit covered by a small aluminum cylindrical case is installed in each segment. The sensor unit contains the MEMS tilt meter and a geomagnetic sensor (digital compass, nominal resolution = 0.5 deg) to detect the direction of unit. Each unit also contains a microcontroller chip, which control the sensors, and transfer the control commands and the obtained data to the next units by serial interfaces. A significant advantage of this device is that it can be installed quickly into the slope ground being blown with a hammer, as its diameter is as small as 25 mm. Besides, it can be installed into a deeper layer of slopes (3-5 m) by connecting the segments as many as needed.

Unlike conventional sensing devices, such as borehole inclinometer and extensometer which measures displacements of slope, measurement with tilt sensors is simple and easy. However, the translation of the obtained data of tilting angle is still under consideration. It is because there are few case histories of early warning with tilt sensors compared to those with conventional sensors. Therefore, it is essential to observe the behaviors of tilt angles in prefailure stages of slopes.

## 2 SLOPE FAILURE TESTS BY ARTIFICIAL RAINFALL

An artificial rainfall test was conducted on a natural slope of weathered and loose ( $N_d < 10$  for 10 cm of penetration by portable dynamic cone penetration tests) andesite deposit in order to observe its prefailure behaviour. The site is located on an unstable slope in Taziping, Sichuan Province, China. Figure 2 shows the cross-section and photo of the site together with the instruments. The slope angle is around 18 degrees, and its lower end was excavated for a depth of 1.4 m with an angle of 40 degrees. The deposit contains some big rocks with diameter of 300 mm or more. The particle size distribution of component finer than 100 mm is show in Figure 2. It is a sandy material containing some gravel and fine particles.

Figure 2 also shows surface tilt sensors (T50-1, T50-2, T200, and T300), and miniature ground inclinometer (K50 and K150). The number in the notation of each sensor represents the distance from the bottom end of slope in cm. Each rod of the surface tilt sensors was inserted into the ground by 75 cm. Each miniature ground inclinometer consists of 2 segments with a length of 500 mm.

Figure 2. Cross-section, photo, and particle size distribution (finer part than 100 mm) of the site for the artificial rainfall test.

Figure 3. Records of the artificial rainfall.

Figure 4. Tilting angles on the slope.

Artificial heavy rainfall was given as shown in Figure 3. The rainfall intensity fluctuated due to restriction of water supply, but around 500 mm of total of rain was applied in the first day, and 700 mm was given in the second day.

Major deformation was observed in the second day, and the slope failed progressively from the bottom with scarp angle of 40 to 50 degrees. The final shape of scarp is shown with thick broken line in Figure 2.

Figure 4 shows the changes in tilting angles detected by the tilt sensors due to the rainfall in the second day. Tilt angles of the upper segment are shown for the miniature ground inclinometers. The nearer to the bottom of slope, the more tilting angles are observed. The tilting rate for each sensor is between 0.1 and 0.5 degree / hour before failure. It is also remarkable that K150-upper, 150 cm apart from the bottom of slope, started to tilt slowly in the early stage, when the failure was observed only at the bottom scarp. This suggests that the sensor detected slight effects of the failure event at some distance of the sensor position. This behaviour is not visible to human eyes because its tilting rate was only 0.02 degree / hour.

Figure 5 shows the behaviours of the tilting angle of the upper unit of the miniature inclinometer, K50, at 50 cm from the bottom of slope. This represents the average shear deformation of the soil layer between depth of 0 and 50 cm. Besides, Figure 5 also shows the volumetric water content at a depth of 50cm at a position of 50 cm from the bottom of slope. The volumetric water content repeated to increase and decrease corresponding to the intermissive rainfall and drainage stages.

Figure 6 plots the tilting angle versus the volumetric water contents of Figure 5. This represents relationships between the shear deformation and water content. The deformation increased when the water content was high corresponding to rainfall, although some additional deformation was also recorded due to removal of soil which dropped and deposited in front of the bottom of slope.

Figure 5 Time histories of tilting angles and volumetric water contents at 50 cm from the bottom of slope.

Figure 6 Tilting angles versus volumetric water contents at 50 cm from the bottom of slope.

A unique relation between the deformation and the water content can be drawn as an envelope of the plot, as indicated in Figure 6, which is independent of the time history of the artificial rainfall. Similar behaviours was be also observed in laboratory model tests on slip surface of unsaturated soil under constant shear stress and cyclic water infiltration/drainage processes (Uchimura et. al. 2011b).

### 3 SIMPLE SHEAR TESTS ON SLIP SURFACE

A series of simple shear tests were conducted on unsaturated sandy soil specimens to observe their prefailure behaviors more precisely. Figure 7 shows the arrangement of the testing device. Edosaki Sand ( $D_{max} = 2$  mm,  $D_{50} = 0.23$  mm, fine content = 6 %,  $G_s = 2.665$ ,  $e_{max} = 1.685$ ,  $e_{min} = 0.578$ ) was compacted into a disc shape with a diameter of 60 mm and a height of 20 mm, and a relative density of  $D_r = 70$  % with initial volumetric water content of 7 %. The specimen is surrounded by a stacked layers made of Teflon, which has low friction coefficient, to reduce the effect of friction. The specimen was loaded with 60 kPa of vertical confining pressure. And then, 15, 24, 30 kPa of constant shear stress was applied, which corresponds to 0.25, 0.4 and 0.5 of stress ratio, respectively. These three stress ratio simulate the stress state on the slip surface for gentle, medium, and steep slopes. Then, water was injected into the specimen from the top and bottom surface through ceramic discs with a constant injection rate of 310 ml/hr, which corresponds to a rainfall intensity 110 mm/hr fall on the top area of the specimen.

Figure 8 shows the obtained volumetric water contents and shear strain during the water infiltration process. It seems that there are three patterns of deformation and failure processes. In the case with stress ratio of 0.25 (gentle slope), the shear deformation increases with water infiltration, but it converged to a limited value not showing failure. On the other hand, in the case of steep slope with stress ratio of 0.5, the strain started to increase with a similar rate to that in the case of gentle slope, but it suddenly yielded at incremental volumetric water content of around 7 % and shear strain of around 1.7 %, followed by a quick deformation with high strain rate.

Figure 7 Equipments for direct shear tests.

Figure 8 Shear strain versus volumetric water content under 3 values of constant stress ratio.

The behavior in the case of medium slope with stress ratio of 0.4 was more complicated. The strain started to increase with a similar rate to those in the other cases, but it slowed down when the change of volumetric water content was between around 7 % and 18 %. And then, it yielded, followed by a quick deformation with high strain rate.

The reason for the slowing down of strain rate observed in the case of medium slope could be explained with the behaviors of suction. The authors developed a miniature suction sensor to measure the suction in the specimen (Figure 9). A tiny metal pipe ( $\phi 1.5 \text{ mm} \times 4 \text{ mm}$ ) with small hole is wrapped with a micro-porous membrane. One end of the pipe is connected to a water pressure transducer via a plastic tube, while the other end is closed. The membrane allows water to pass through, but prevent air to pass by capillary effect. Thus, the pipe with the membrane works just like a miniature ceramic cup. Properties of a similar membrane are studied by Nishimura et. al. (2011). Due to its small size, the miniature suction sensor can be installed with minimum disturbance to deformation and water seepage in the specimen as seen in Figure 9.

Figure 10 shows relationships between the suction and the change of volumetric water content measured in another specimen during water infiltration process. The suction decreases with fast rate until the change of volumetric water content reaches around 4.5 %. Then, the decreasing rate of suction slowed down.

Figure 9 Miniature suction sensor with microporous membrane.

Figure 10 Relations among volumetric water content, suction, and shear strain.

The strain rate of the specimen also slowed down at the same change of volumetric water content. Thus, this behavior can be

explained with the suction-water characteristics curve (SWCC) of the soil. Finally, the specimen yielded at higher change of volumetric water content, corresponding to lower suction.

This observation suggests that a tentative slowing down of slope deformation does not always mean stabilization of slope.

#### 4 CONCLUSIONS

A slope failure test with an artificial rainfall was conducted on a natural slope. The tilt sensors installed into the slope showed tilting rates between 0.1 and 0.5 degree / hour. These values of tilting rate could be used as criteria of early warning for slope disasters.

The deformation proceeded when the water content was high corresponding to rainfall, while it is less progressive when the water content is low. Similar behaviours were also observed in model test in laboratory, where an unsaturated soil layer was sheared under constant shear stress with cyclic water infiltration and drainage. It seems that there is a unique relation between the deformation and the water content, which is independent of the time history of the artificial rainfall. These results suggest a possibility of combined monitoring of tilting angle and water contents for more precise comprehension of the status of slopes.

The results of direct shear tests on unsaturated soil under constant shear stress and constant water injection rate suggest that there are three patterns of deformation and failure processes corresponding to the slope angle. In a case of medium slope, the strain rate may slow down due to the SWCC of the soil even though water is injected with a constant rate. However, it does not always mean that the slope is getting stable.

# Study on field detection and monitoring of slope instability by measuring tilting motion on the slope surface

## Détection et surveillance in situ des phénomènes d'instabilités de pente par mesure locale des mouvements de surface

Wang L., Nishie S., Seko I.  
Chuo Kaihatsu Corporation, Tokyo, Japan

Uchimura T.  
University of Tokyo, Japan

**ABSTRACT:** Monitoring and early warning is one of the most effective methods toward reduction of disasters induced by landslides and slope instabilities, but the traditional methods such as multiple borehole inclinometers or extensometer are expensive and unsuitable to zoning monitoring. To overcome the above weaknesses, a simple and low-cost early warning system was developed for slope failure and landslide (Uchimura et al. 2009). The developed tilt sensor is easy to install and it can monitor slope deformation by means of a tilting MEMS module angle which embedded in the sensor, and transfers real time data via wireless network. The warning system with its developed equipments has been deployed in several actual slopes for validation of field performance in Japan and China. In this paper, the authors will show that the developed system and sensor can successfully detect the situation of slope and landslide, and issue useful information that allows residents to avoid slope failure or landslide disasters. Based on the results of field case studies, the developed low-cost sensor unit and real-time warning system are considered particularly effective against rainfall-induced slope failure or landslides and its general use is recommended.

**RÉSUMÉ :** Une surveillance constante associée à un dispositif rapide d'avertissement est une solution efficace pour lutter contre les désastres et les pertes humaines liés aux glissements de terrain ou aux ruptures de pentes. Cependant, les équipements traditionnels tels que les inclinomètres ou extensomètres installés par forage sont généralement d'un coût prohibitif et sont peu adaptés à une surveillance plus généralisée du territoire. Un nouveau système plus flexible et de coût plus réduit a été proposé par Uchimura et al. (2009). Il incorpore des micro-inclinomètres de type MEMS faciles d'installation qui permettent d'estimer les mouvements de surface. Les données peuvent être transmises en temps réel via réseau sans fil. Ce système a été déployé sur plusieurs sites en Chine et au Japon. A partir des données recoltées sur ces sites, il est démontré que ce système est efficace et fiable dans l'estimation et la détection précoce des glissements de terrain, et qu'il permet d'obtenir des renseignements cruciaux pour prévenir leur poursuite ou pour réduire les dégâts occasionnés.

**KEYWORDS:** landslide, slope failure, monitoring, early warning.

## 1 INTRODUCTION.

Typical measures to prevent slope failure are retaining walls and ground anchors which improve safety factor against failure. These measures have been widely used everywhere in the world and its effectiveness has been confirmed. However, the traditional methods take a lot of cost, as a result that a limited application can be used only for large scale slopes. In fact, most of landslide occurs at small scale slopes, but with a large number. It is not realistic to apply mechanical reinforcement measures for these slopes with potential risk.

Rainfall-induced slope failures are one kind of the most destructive natural hazards. Many slope failures have been observed to occur during or immediately after rainfall. For a wide range slope safety monitoring, a problem in the first was that the equipments were high-cost; this is a problem that

disaster prevention measures was difficult for implementation into developing countries. The cost issues should be overcome for a purpose of widespread use; another is that a simple and effective real-time monitoring becomes necessary.

The authors have proposed an early warning system for sediment disasters, as one of more feasible countermeasures for small-scale slope failures. The system measures minimum number of items by using the developed smart sensor units; the measured data is transferred through wireless network. Thus, the system is low-cost and simple enough so that the residents in risk areas can handle it to protect themselves from slope disasters (Uchimura et al. 2009).

## 2 A LOW-COST AND SIMPLE WARNING SYSTEM.

A simple and low-cost early warning sensor unit was developed that only two parameters of the volumetric water content of soil and the inclination of slope or landslide were focused, and its applicability and effectiveness were tested on model slopes under artificial heavy rainfall (Uchimura et al. 2009). The sensor unit works with batteries, and transfers real time data via wireless network, and installation is simple and easily to control so that non-expert residents in risk area can handle it by themselves, even in developing countries. Figure 1 shows the basic concept of the wireless monitoring unit using for early warning system.

### 2.1 RF (Radio Frequency) wireless data transmit method

Figure 2 shows the outline of wireless monitoring and early warning system for slope failure. The system is designed to be wireless, that is, each unit works autonomously with

Figure 1. Wireless tilt sensor unit with water content sensor.

microcomputer with independent power supply by batteries or

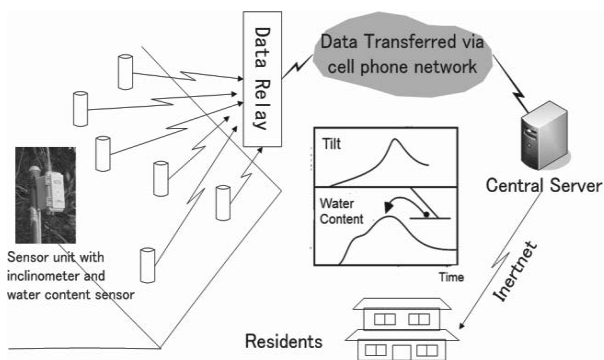

Figure 2. Outline of wireless monitoring units and early warning system for slope failure.

solar cells. Radio modems operated in the 429 MHz ISM band for Japan, 434 MHz ISM band for E.U. countries and China.

The sensor units measure the condition of the slope periodically every 10 minutes for example. The data is transferred to a gateway unit, which is also placed near the slope, by using low power radio communication modules. The data transmitting distance is 300-600 meters under typical conditions in the field. The gateway unit collects the data from all the sensor units, and sends them to a data server on internet through a mobile phone network. Thus, the data can be browsed anywhere and anytime on web site. The data is processed by the server, and any abnormal phenomena of the slope can be detected and used for a precaution of failure, and then issue an evacuation warning.

### 2.2 MEMS inclinometer technology embedded to sensor unit

The proposed system measures the inclination on the slope surface and the volumetric water content in the slope. A MEMS tilt module (nominal resolution = 0.04 mm/m = 0.0025 degree) is embedded in each sensor unit. The tilt module is a 3D-MEMS-based dual axis inclinometer that provides sensor unit grade performance for leveling applications. The measuring axes of the sensing elements are parallel to the mounting plane and orthogonal to each other. Low temperature dependency, high resolution, power-saving and low noise, together with robust sensing element design, if we keep on leveling installation, this MEMS type inclinometer is ideal choice for slope failure sensors.

### 2.3 Saving power designed based on 16-bit ultra-low-power MCU

In order to reach the purpose of a low-cost and simple warning system, the choice of CPU controller become very important. 16-bit Ultra-Low-Power MCU with ultralow power consumption being very suitable to no commercial power supply region was selected.

A long-term sensor unit power consumption test (not include Micro SD) was started on July 7, 2008, the interval time of data sampling and transmit was 10 minutes. 4 cells alkaline batteries were installed in the test sensor unit. Figure 3 shows the relation of battery voltage and elapsed time, the test unit has been worked for 3.5 years.

## 3 FIELD VALIDATION FOR SIMPLE SLOPE MONITORING AND LANDSLIDE IN JAPAN AND CHINA.

### 3.1 A case of detection on Three Gorge Dam landslide failure in China

Prototype of the developed monitoring system has been established on a side slope of Three Gorge Dam region, the

Figure 3. Sensor unit long-term power consumption test.

world largest dam in China, since 2008. The site named Sai Wan-Ba is located on the right side of the dam lake, near Wenzhou Ward, 80 km eastward from Chongqing City (Figure 4). Several landslide blocks were found by geological investigations.

The time histories of the tilting angles in X-axis and Y-axis, the volumetric water content at a depth of 30 cm on the ground surface, and the record of precipitation are shown in Figure 5 and Figure 6 respectively.

A consecutive movement of a sliding block shown in Figure 5 was observed for a long period. A quick movement of tilt sensor was detected at a heavy rainfall event on June 6-7, 2009; a large scale of landslide disaster nearby observation point 2

Figure 4. Location of Sai Wan Ba landslide site.

Figure 5. Time history of tilting angle & precipitation by sensor unit 2.

Figure 6. Time history of volumetric water content & precipitation by sensor unit 2.

was happened on 8 June shown in Figure 7, and this landslide disaster caused the slope of observation point 2 inclined gradually at the same time. As a result, there was almost two day for taking refuge before the landslide happened.

Figure 7. New landslide on June 7, 2009.

1.1 Monitoring of a slope failure site for secondary disaster prevention in Japan

Another field detection result of a slope failure site along a national road in Kyushu of Japan is shown in Figure 8. This slope consists of strongly weathered granite, and it was failed due to a heavy rainfall in July of 2009. The slope was excavated to have a gradient of 45 degrees for disaster relief work, and was monitored with three sensor units. Heavy rainfall caused a second failure, and a local part of slope including the sensor unit fallen down. Figure 9 shows the records of tilt sensor of the unit, in directions toward and laterals to the slope, respectively. Specially, the tilting in Y-axis (lateral direction) showed

Figure 8. Sketch of failed slope along highway

Figure 9. Tilt angle change just before the second failure.

extraordinary behaviors 50 minutes before the second failure.

Its tilting rate was around 3 degrees per day (0.12 degrees per hour). As this second failure took place adjacent to the location of the sensor unit 2, the behaviors of the slope before and after the failure was detected by the monitoring system. The site manager got aware of the extraordinary behaviors of the data from sensor unit 2, and he stopped the disaster relief work and the road service to avoid large loss successfully.

1.2 Field evaluation for developed tilt sensors to traditional extensometers based on in-site measuring

Another in-site measurement results were showed in Figure 10 to Figure 11a-e, a heavy rainfall on July 2011 caused a slope failure along local national road in Kyushu of Japan.

For the road earthwork construction, an emergency monitoring system using multiple borehole inclinometers, extensometers, tilt sensors and rain gauge has been set up at

Figure 10. A field site of failed slope along national road in Japan

Figure 11. Time histories vs. measuring values.

slope failure site. For validating developed tilt sensor with field extensometers data, the three tilt sensors were installed nearby

fixed pole of extensometers moving point shown in Figure 10. In this field site, other 4 boring surveys have been carried out and multiple borehole inclinometers were installed, two of the tilt sensors (K-2, 3) were just set up nearby the survey boring holes. According to the result of boring survey, a landslide slip surface, which depth was 17m, was found shown in Figure 12.

Figure 10a-b show the time histories of tilt sensor inclination alone extensometer wire direction (tilt sensor x axis) and the extensometer movement(S-1, S-2), Figure 10c shows the result of cumulative rainfall value by rain gauge. Figure 10d shows the result of volume water content by FCH2O water content

Figure 12. The result of multiple borehole inclinometers.

sensor.

The normal case, the fix pole of tilt sensor was inserted into earth of slope surface at the depth of 1.0 meter, so that the inclination of tilt sensor means average movement of the slope surface. The inclinations of tilt sensors especially tilt sensor K-3, and movement of extensometers were increased with rainfall and showed a strong correlation each other based on the results of Figure 10a-e.

Figure 13 shows the relation of slope movement (mm) by extensometer(S-1) vs. inclination (degree) by tilt sensor (K-3). Based on the result, the almost linear relationship between extensometer and tilt sensor was obtained except for the storms period of August, October and November, 2011.

Figure 13. The relation of slope movement vs. tilt angle.

Another important result is that between heavy rainfall start and landslide initiation, the value of extensometer seems no any change but the tilt sensor inclination has reacted quickly, for example, the heavy rainfall on 18 November 2011, that hourly rainfall reached 20mm and continues rainfall reached 96mm, run continuously for 16 hours, during this period, the inclination of tilt sensor was increased but the value of extensometer

showed no any change (Figure 13). The tilt sensor measures a local change of slope surface, and the extensometer measures a whole movement of slope failure or landslide. The failure of slope starts from local and enlarges to whole area usually, so that this result should be considered as an important slope pre-failure phenomenon, which can let warning system to issue useful information to residents to avoid slope failure or landslide disaster in advance.

## 2 CONCLUSION

Based on above case histories and field validation result, a low-cost and simple monitoring method of measuring tilting motion on these slope surface is effective and proposed for precaution of rainfall-induced slope failure and landslides; The tilt sensor unit with MEMS inclinometer module and wireless module is very save power and installed easily. At a side slope of Three Gorge Dam in China, consecutive movement of a sliding block was observed for a long period.

A quick movement was detected at a heavy rainfall event, in which a tilting rate of about 3 degrees per day was continued for 2 days. This event includes a slope failure and significant displacement in a wide area including the position of the sensor unit.

At a slope failure site along a national road in Japan, the slope surface showed abnormal tilting behaviors 30 to 50 minutes before failure. The tilting rate was around 3 degrees per day, although it continued for only 50 minutes before failure. Such behaviors could be used as a signal for early warning.

Furthermore, between heavy rainfall and landslide initiation, the tilt sensor inclination has reacted quickly than extensometer value; it can be considered that the tilt sensor unit is effective tool for early warning system.

## 3 ACKNOWLEDGEMENTS

The present study has been supported by the research funding supplied by JSPS of Japanese government as well as the Science Academy of China. These research assistants are deeply acknowledged by the authors.

**ABSTRACT:** The physical vulnerability of roads to debris flow is expressed through fragility functions that relate flow volume to damage probabilities. Fragility relations are essential components of quantitative risk assessments (QRA) and allow for the estimation of risk within a consequence-based framework. This paper describes fragility curves produced in order to provide the conditional probability for a road to be in, or to exceed, a certain damage state for a given debris flow volume. Preliminary assessments were undertaken by means of a detailed questionnaire. Fragility curves have been defined for three damage states for high speed (reported herein) and for low speed roads (to be reported later) in order to cover the typical characteristics of roads vulnerable to debris flow. The probability of any given damage state being met or exceeded by a debris flow of a given volume ( $10\text{m}^3$  to  $100,000\text{m}^3$ ) was derived from the mean of the responses received. The development of the fragility curves is described and data issues discussed.

**RÉSUMÉ :** La vulnérabilité physique des routes aux coulées de boue s'exprime à travers des fonctions de fragilité qui mettent en rapport le débit volumique et les probabilités de dommages. Les relations de fragilité sont des composantes essentielles des évaluations quantitatives de risques (QRA) et permettent d'estimer le risque au sein d'un cadre basé sur les conséquences. Cet article décrit les courbes de fragilité produites afin d'indiquer la probabilité conditionnelle qu'une route se trouve, ou dépasse, un certain état d'endommagement pour un débit volumique donné de boue. Des évaluations préliminaires ont été réalisées au moyen d'un questionnaire détaillé. Des courbes de fragilité ont été définies pour les trois états d'endommagement pour les routes à grande vitesse (présentées dans ce document) et pour les routes à petite vitesse (qui feront l'objet d'un rapport ultérieur) afin de couvrir les caractéristiques typiques des routes vulnérables aux coulées de boue. La probabilité d'atteinte ou de dépassement d'un état d'endommagement donné en présence d'une coulée de boue d'un volume donné ( $10\text{m}^3$  à  $100\,000\text{m}^3$ ) a été dérivée de la moyenne des réponses reçues. L'élaboration des courbes de fragilité est décrite et les problématiques liées aux données sont abordées.

**KEYWORDS:** Landslides, debris flows, hazard, risk, probability, fragility, QRA.

## 1 INTRODUCTION

Fragility curves are a graphical means of describing the physical vulnerability of elements at risk to a given hazard. They give the conditional probability of a particular element at risk to be in, or to exceed, a certain damage state as a result of a hazard of a particular type or intensity (Mavrouli & Corominas 2010). Fragility relationships are essential components of quantitative risk assessments (QRA) as they allow for the estimation of risk within a consequence-based framework.

For the purposes of this work the element at risk is a road and the hazard is debris flow. Damage probabilities have been assigned for specific debris flow volumes; these should not be confused with the probability of event occurrence. Fragility curves have been produced which indicate the probability of a debris flow of a given volume exceeding each of three damage states. To the best of the Authors' knowledge this is the first time that fragility curves have been developed for the effects of debris flow on roads. Fragility relationships are widely adopted in seismic 'expected loss' and risk assessments, being a valuable tool to explicitly assess the vulnerability of structures to earthquake hazard (Pitolakis et al. 2006).

While several possible approaches were available, including analytical and empirical ones, for the development of fragility curves, it was decided that expert engineering judgement should be used due to a lack of a comprehensive empirical dataset as well as the complex nature of the problem.

This paper describes the questionnaire sent to experts globally to collect data for the fragility curve development. It

also describes the analysis and interpretation of the data collected, and its validation using real world examples.

## 2 METHODOLOGY

### 2.1 Road characterisation

Many different classifications of roads could be considered, covering numerous key factors such as construction type, stiffness, and traffic speed. However, in order to reduce the questionnaire to a reasonable size some simplification was needed. Primarily it was decided that, for the purposes of this exercise, all roads could be considered to be relatively stiff and brittle (the low strain stiffness of even an unbound pavement is such that it is likely to behave in a stiff, brittle manner). In order to further simplify the analysis roads have been divided into low and high speed roads, characterized as follows:

- High speed: speed limit between 80 and 110km/h and one or more running lane in each direction, most likely in conjunction with a hardstrip or hard shoulder.
- Local (or low speed) roads: speed limit typically  $<50\text{km/h}$  on a single-carriageway (one lane for each traffic direction) or single-track. This category is intended to encompass both paved (bituminous, unreinforced or reinforced concrete) and unpaved constructions.

The gap between the speed limits of the two classes of road, reflects the transition between local roads and high speed roads, which is by no means geographically consistent. This reflects reality – in some countries and regions certain road geometries are more closely aligned with the definition of local roads and

in others they are more closely aligned with the definition of high speed roads. The results reported here are for high speed roads.

### 2.2 Damage states

Representative damage states associated with the consequences of a debris flow of a given volume intersecting a road were defined. The damage states considered in the questionnaire are defined in Table 1 and range from the type of damage that is unlikely to significantly affect the passage of vehicles, at least on high speed roads, to that which causes longer term damage and restrictions to the speed and/or passage of traffic.

Respondents to the survey were requested to use their expert judgement to assess the probability of each damage state being exceeded (Table 2) for a given event size. Respondents were asked to use the qualitative descriptors ‘Highly Improbable’ and ‘Extremely Likely’ with caution, and only where an extensive, high quality dataset supports the classification.

Table 1. Damage state definition.

Damage State	High Speed Roads
P1 (Limited damage)	Encroachment limited to verge/hardstrip
P2 (Serious damage)	Blockage of hardstrip and one running lane
P3 (Destroyed)	Complete blockage of carriageway and/or repairable damage to surfacing

Table 2. Description of probabilities.

Qualitative Descriptor	Description	Value for Analysis
Highly improbable	Damage state almost certainly not exceeded, but cannot be ruled out	0.000001
Improbable (remote)	Damage state only exceeded in exceptional circumstances	0.00001
Very unlikely	Damage state will only be exceeded in very unusual circumstances	0.0001
Unlikely	Damage state may be exceeded, but would not be expected to occur under normal circumstances	0.001
Likely	Damage state expected to be exceeded under normal circumstances	0.01
Very likely	Damage state expected to be exceeded	0.1
Extremely likely	Damage state is almost certainly exceeded	1.0

## 3 RESULTS

The questionnaire was sent to 176 experts; 47 responses (27%) were received from 17 countries: UK (34%), Greece (23%), other European countries (26%), Asia (4%), Australasia (4%), North America (4%) and the Middle East (2%). The respondents’ backgrounds were Academia (32%), the Commercial Sector (51%) and Government Bodies (17%).

## 4 ANALYSIS

### 4.1 Preliminary fragility curves

It is a relatively straightforward matter to construct preliminary fragility curves from the average of the probability responses at each volume, at each damage state and for both high speed roads and local roads as illustrated in Figure 1. These curves have the basic attributes of typical fragility curves. In broad terms these curves and the data that underpin pass the sense test. The curves generally show that landslides of a given volume are associated with higher probabilities of exceeding a certain damage state when they affect local roads than when they affect high speed roads, as would be expected. In addition, the curves for high speed roads generally show little effect at small landslide volumes, below a few hundred cubic metres.

It is noticeable that the mean probabilities do not reach unity for any of the curves. This implies that the damage states as defined can never be met or exceeded with complete certainty. However, this is an inevitable function of using the average of the responses, as the maximum possible response coincides with the desired termination point of each curve (a volume at which exceeding the given damage state is inevitable and the probability is unity). Further stages of analysis were undertaken to interrogate and better understand the data.

Figure 1. Preliminary fragility curves for high speed roads.

### 4.2 Curve fitting

Standard Excel<sup>TM</sup> curves were fitted (third order polynomial for Limited Damage and fourth for Severe Damage and Destroyed states). This gave better separation of the individual curves than is shown in Figure 1, and there was greater contrast between the results for high speed and local roads (Pitilakis & Fotopoulou 2011). This technique allows a degree of extrapolation of the data to higher volumes/probabilities. However, over application of such extrapolation tends to distort the curves at lower volumes.

### 4.3 Manual extrapolation

The data presented in Figure 1 may be manually extrapolated by a further logarithmic cycle by visually judging the appropriate value of probability at 1,000,000m<sup>3</sup> in order to maintain the broad appearance and trend of the curves. It is noticeable that, even when the volume is increased to 1,000,000 m<sup>3</sup> in this way none of the fragility curves reach unity; only that for Limited Damage for local roads reaches a value of around 0.95.

### 4.4 Weighting the data

Clearly the experience of the respondents is a critical metric in terms of understanding, evaluating, analysing and interpreting these data. The respondents were asked to assess their experience on a scale of zero (no experience) to 10 (extensive experience). The scores of this self-assessment weight towards the higher end of the range, as might be expected from a sample of respondents who were selected for their known expertise in this area. It thus seems potentially appropriate to place a greater confidence in the responses received from those who reported that their level of experience was higher than the average and a number of approaches is possible.

Firstly, a weighting approach may be taken. However, care is needed to ensure that the sample is weighted rather than the individual responses; otherwise bias will be introduced into the results. (Weighting the individual responses will, depending upon the precise approach taken, either increase or decrease the individual probabilities contained within the questionnaires for those with higher expertise and the converse for those with lower levels of expertise. There is no logical justification for such a change and this should therefore be avoided.) Weighting the sample may be done as follows

$$p = \frac{\sum_{i=1}^n p_i E_i}{\sum_{i=1}^n E_i} \quad (1)$$

where  $p$  = weighted mean probability of a particular damage state being exceeded;  $p_i$  = the individual responses of the probability of a particular damage state being exceeded;  $E_i$  = the individual responses in terms of self-assessed experience; and  $n$  = the number of responses.

However, there does remain a question as to what a weighted average means and statistical advice (Sexton, pers. comm.) indicates that the results should be treated with a degree of caution.

This yields fragility curves with lower probabilities of given damage states being exceeded by a given event volume than those derived from the full data set (Figure 2). This may indicate that either those with less experience overestimate, or those with greater expertise underestimate, potential damages.

The second approach involves rejecting the data from those respondents reporting less experience, leaving only that from those who assessed themselves as more experienced in this area. Statistical advice (Sexton, Pers. Comm.) indicates that approximately only scores from the upper 25% of the available range should be examined. This implies that the analysis should be undertaken for those judging their experience level as eight or above (33% of respondents). However, plotting the data led to a rather confused picture and to the conclusion that the 16 responses corresponding to the 33% of respondents reporting their experience level to be eight or above were insufficient to present a coherent picture. As for the weighting approach the resulting fragility curves yield lower probabilities of given damage states being exceeded by a given volume of event than those derived from the full data set.

Figure 2. Weighted fragility curves: top, local roads; bottom, high speed roads.

## 5 INTERPRETATION

The curves illustrated in Figure 1 do not stretch between zero and unity. Even when manually extrapolated to a landslide volume of  $1,000,000\text{m}^3$  the curves do not reach unity as would be expected if they had been derived from by modelling in which such an outcome would have been constrained.

Using the current approach it is inevitable that the mean probability of each damage state being reached or exceeded is less than unity unless all of the respondents return such a value. This then begs the question of how to account for such an inevitable, and seemingly contradictory, facet of the results. It is straightforward to 'force' the curves to reach to unity by a ratio approach (the forced probability at any value of landslide volume,  $p_{if} = p_i \cdot [1/p_n]$  where  $p_i$  is the mean probability and  $p_n$  is the mean probability at the maximum landslide volume).

In order to determine whether such an approach can be justified one must examine the more detailed responses of the respondents to the questionnaire and in particular the responses

of those where a probability of unity was assigned to the combinations of landslide volume and damage state. These data illustrate, as might be anticipated, that the number of responses assigning a probability of unity increases markedly with landslide volume while decreasing with increased damage state severity. Most importantly, for high landslide volumes, the majority of respondents give unity for the likelihood of a given damage state being reached or exceeded, lending justification to 'forcing' the curves to reach unity.

As discussed, the preliminary fragility curves of Figure 1 can be forced to unity, and manually extrapolated to the next order of magnitude in terms of landslide volume (i.e.  $1,000,000\text{m}^3$ ). The next logical step is to combine these two actions as illustrated in Figure 3. The curves illustrated therein conform to the 's'-shape generally perceived as being the correct form for fragility curves. Notwithstanding this, one would normally expect that the curves for different damage states would reach unity at different landslide volumes; that they do not is a function of the type of analysis undertaken and it seems reasonable, as none of the curves reach unity, to force them all to such a level at the highest volume considered.

Geographical variations and variations potentially caused by respondents' backgrounds (Academic, the Commercial Sector, and Governments) were investigated. It was concluded that the datasets were generally too small to draw definitive conclusions albeit that the data appeared to suggest that:

- Responses for the UK exhibited slightly higher probabilities for larger landslide volumes compared to those for the 'Rest of the World'.
- The responses for Academia exhibited slightly higher probabilities for larger landslide volumes compared to those for the Commercial Sector.

Figure 3. Fragility curves for high speed roads 'forced' to unity and manually extrapolated to the next order of magnitude of debris flow volume. Lines for Limited Damage at 200, 500, 1,000, 5,000 and  $10,000\text{m}^3$  are also shown.

## 6 VALIDATION

The comments received from respondents generally supported the use of curves of the form illustrated in Figure 3 and events from Scotland in the UK and the Republic of Korea are considered here. Figure 4 illustrates hypothetically-shaped curves in which the numbers given relate to a  $5,000\text{m}^3$  event on a high speed road (Figure 3). The probabilities ( $p$ ) of the damage being equal to or greater than a given level are:

- Damage greater than or equal to 'Limited',  $p = 0.6$ .
- Damage greater than or equal to 'Serious',  $p = 0.4$ .
- Damage greater than or equal to 'Destroyed',  $p = 0.3$ .

The discrete, or conditional, damage state probabilities (i.e. the probabilities of the occurrence of a given damage state) are estimated from the probabilities given above:

- Probability of no damage =  $1.0 - 0.6 = 0.4$ .
- Probability of 'Limited' damage =  $0.6 - 0.4 = 0.2$ .
- Probability of 'Serious' damage =  $0.4 - 0.3 = 0.1$ .
- Probability of 'Destroyed' damage state =  $0.3$ .

Note that the conditional probability of the ‘Destroyed’ damage state is always equal to the probability of that state being exceeded. Vulnerability assessment using fragility curves is, of course, probabilistic in nature and the models used in their construction – in this case based upon expert judgment – have inherent uncertainties. Accordingly, the validation examples are not expected to precisely predict the observed damages.

Figure 4. Hypothetical fragility curves: the numbers relate to a 5,000m<sup>3</sup> event on a high speed road (see Figure 3) and show conditional probabilities and those of a given event exceeding a damage state.

### 6.1 A85 Glen Ogle, Scotland

In August 2004 two debris flow events occurred at Glen Ogle blocking the A85 strategic road, culverts and other drainage features, and necessitated a full repair to the road pavement, safety barriers and parapets. Some 20 vehicles were trapped by the events and 57 people were airlifted to safety; one vehicle was swept away in the latter stages of the event (Winter et al. 2005, 2006, 2009). The smaller southerly and larger northerly events were estimated to have deposited around 3,200m<sup>3</sup> and 8,500m<sup>3</sup> in their respective debris lobes having been triggered by smaller translational slides of around 285m<sup>3</sup> and 280m<sup>3</sup> (Milne et al. 2009). These figures are believed to exclude material deposited on the road and it seems reasonable therefore to round these figures up to around 5,000m<sup>3</sup> and 10,000m<sup>3</sup>. This illustrates the uncertainty when dealing with debris flow volumes between the amount mobilised and that deposited at road level.

Figure 4 shows how these event volumes plot on the fragility curves. For the smaller (5,000m<sup>3</sup>) event the conditional probabilities for no damage, ‘Limited’, ‘Serious’ and ‘Destroyed’ damage states are 0.4, 0.2 (0.6), 0.1 (0.4) and 0.3 (0.3) (the probabilities of the damage states being met or exceeded are given in parentheses); for the larger (10,000m<sup>3</sup>) event the conditional probabilities are around 0.3, 0.15 (0.7), 0.15 (0.55) and 0.4 (0.4). Certainly the damage caused by the larger event would have been described as ‘Destroyed’ using the scheme considered here and the probability of this state being 0.4 seems to be broadly in line with observations in its immediate aftermath, affecting a road length of around 200m. Similarly the damage caused by the smaller event, although significantly less in terms of physical damage to the infrastructure, would also be classified as ‘Destroyed’ and this seems to broadly reflective the probability of 0.3 (Figure 4).

### 6.2 Chuncheon National Highway, Republic of Korea

Debris flows of around 500m<sup>3</sup> to 1,000m<sup>3</sup> were evident at the Chuncheon National Highway Tunnel Portals (Lee & Winter, 2010). For an event of this volume (1,000m<sup>3</sup>) the conditional probabilities of the damage states no damage, ‘Limited’, ‘Serious’, and ‘Destroyed’ are 0.7, 0.1 (0.3), 0.18 (0.2), and 0.02 (0.02) (Figure 4).

Only very minor damage was incurred and this reflects the small volumes and the combined conditional probabilities of 0.8 for no damage and of the ‘Limited’ damage. The road was not

open at the time of the event and there is every possibility of both further and larger events that have the potential to meet or exceed higher damage states.

## 7 CONCLUSIONS

A survey of experts was conducted to develop of preliminary fragility curves for the effects of debris flows on roads.

Included in the questionnaire was the opportunity for the respondents to make ‘free text’ responses to defined questions. Their responses have been used, in part, to determine the form of analysis. Consequently the proposed fragility curves have been extrapolated to include events one order of magnitude greater than the largest considered in the questionnaire. In addition, this form of determining fragility curves renders it almost impossible for the probabilities to range from zero to unity; according the proposed fragility curves have been stretched to ensure such a spread.

The derived fragility curves have been compared to known events in Scotland (UK) and the Republic of Korea. In general the curves tend to give results that might be deemed ‘sensible’ with probabilities of around 0.3 to 0.8 being suggested for the known damage states. Exceptions to this occur when detailed site characteristics introduce complexities that are not, and could not be, accounted for in the analysis.

Notwithstanding this, the method of data acquisition and the perceived interpretations of the questionnaire for this first approach raise some interesting issues that will be explored in a later paper. Continued efforts are needed, potentially including the use of modelled and empirical data.

## 8 ACKNOWLEDGEMENTS

The work described in this paper was (partially) supported by the European Commission through the project “SafeLand – Living with landslide risk in Europe: Assessment, effects of global change, and risk management strategies” of EU’s 7th Framework Programme. Their support is gratefully acknowledged. The TRL authors gratefully acknowledge additional funding from Transport Scotland.

# Inspection and Capacity Assessment of Anchored Slopes

## Inspection et évaluation des capacités des pentes renforcées par ancrage

Yeh H.n-S., Wang C.-S., Wei C.-Y.

**ABSTRACT:** In Taiwan, anchors were first used in the Techi Dam for slope protection in 1970s. Since then, anchors were often used for stabilizing slopes in the construction of roads or communities. Lots of anchor experience of engineering practices have been accumulated in the past 40 years, however, it still remains some problems to be solved. In particular, after the failure of anchored slope at station 3.1K of Highway No. 3 in 2010, the function of existing anchors and the safety of anchored slopes have raised lots of concern. This paper introduces examining items, methods and processes of functional inspection of existing anchors. Also, results of 16 functional inspection of existing anchors in western Taiwan are presented. It is expected that the concepts and suggestions described in this article would be helpful for an engineer in gaining the ability of the analysis of slopes so that the more effective design can be developed for such a problem in the future.

**RÉSUMÉ :** A Taiwan, les renforcements par ancrages ont d'abord été utilisé dans le barrage Techi pour la protection des talus dans les années 1970. Depuis lors, les ancrages étaient souvent utilisés pour la stabilisation des pentes dans la construction de routes. Beaucoup d'expérience dans les pratiques d'ingénierie d'ancrages a été accumulées au cours des 40 dernières années. Cependant, il reste encore quelques problèmes à résoudre. En particulier, après la rupture d'une pente ancrée à la station 3.1k de la route n°3 en 2010, l'efficacité des ancrages existants et la sécurité des talus ancrées ont soulevé beaucoup d'inquiétude. Cet article présente l'examen des ancrages, des méthodes et des processus de contrôle du fonctionnement des ancrages existants. En outre, les résultats d'inspection de 16 talus renforcés par ancrages existants dans l'ouest de Taiwan sont présentés. Il est prévu que les concepts et les suggestions décrits dans cet article soit utilisable par un ingénieur via l'acquisition d'outils d'analyse des pentes de sorte qu'une conception plus efficace puisse être développé à l'avenir.

### 1 INTRODUCTION

Taiwan's area is approximately 3,600,000 hectare, and of it moderately flat area comprises about 26% while sloped and forested land make up the remaining 74%. Therefore Taiwan is mostly mountainous with lesser plains topography, though in the recent decade with the economic growth and the pursuit of comfort and ease of transportation, the trend of developing public infrastructure such as roadways and public facilities is moving toward hillsides and slopes.

Ground anchoring usage over steep slope has its certain advantages. Ground anchoring technique originated since the 1970s in Taiwan. Since 1988, Northern Taiwan Second Highway construction had begun, as its alignment laid predominantly among mountainous ranges and slopes, this type of method had proved itself to be an effective technique under such natural constraints and coupled with rapid economic growth, many new projects had begun to adopt this method in many sloped terrain community developments. Until today, ground anchorage technique has proven to be a reliable method and have been widely used, as well as the design and field installation has vastly improved since its earlier days. However, there are still many ground anchoring failure instances in recent years, one of which is the quite high profiled case of the 1997 Xizhi Lincoln Mansions disaster and 2010 National Highway No. 3 at 3.1k accident. Both failure cases are considered ground anchoring accidents and attributed to parallel landslide as the cause.

According to Briaud et al.(1998), Bruce and Wolfhope (2007), Liao et al. (2011), Ho et al.(2011), Jeng et al.(2011) and various domestic and foreign ground anchoring case studies, failure instances involved most commonly pre-stressed losses.

The main cause of that include 1) free section of tendon(unbounded tendon) rusted and cracked, 2) ground anchoring wedges rusted or had sub-standard quality, 3) Installation did not conform to the specification, as the steel tendon had not gone far enough into the earth, 4) change of terrain layer, and 5) ground cave in at bottom of the bearing plate.

After the National Highway No. 3 incident involving ground anchoring failure, see Figure 1, a complete study had done on ground anchor inspection and assessment. Even so, the findings of the study were routine and not consistent among the investigators. This article will introduce and explain the currently most adopted ground anchoring inspection, procedure, and assessment. In addition, this article will propose a new way of ground anchoring assessment, in hoping to establish a standardized quantitative analysis procedure for professional reference.

Figure 1. National Highway No. 3 at 3.1k accident

## 2 INSPECTION ITEMS AND PROCEDURE

Ground anchoring inspection and assessment is aimed to analyze and understand the performance of existing anchors and the impact to the site and its surrounding.

### 2.1 Inspection items

Currently there are some initial inspection items including: exterior inspection, anchor head inspection, endoscopy inspection and Lift-off test, the four major items will be explained in detail later.

### 2.2 Inspection procedure

Inspection procedure is as indicated in Figure 2. First gather basic data from all sloped terrains for ground anchor index, then remove all outgrowth on the slope, and check the entire ground anchors for outside appearance, pressure bearing integrity and water seepage status. According to the gathered data and inspection results, select the most typical anchor in characteristics of all anchors, remove the concrete casing to examine the anchor head and steel tendon closely, and record findings. After examining the anchor, use the findings to select partial ground anchors for endoscopy inspection to examine steel tendon corrosion and proceed with Lift-off Test, in order to understand the existing ground anchor Residual load( $T_r$ ). Lastly, based on sloped terrain basic data and findings of various test results, evaluate in totality the ground anchors current capacity. If ground anchor capacities no longer meet the requirement of original specifications or there are other anomalies present which render the anchors inappropriate for continuing usage, then a proposal is required to improve or remediate the situation, including refurbishment, remedy, reinforcement or reconstruction as required.

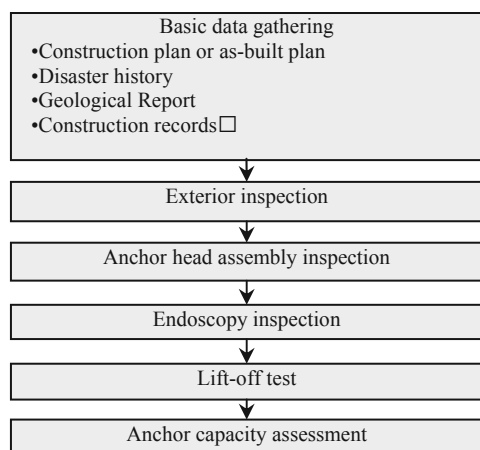

Figure 2. Ground anchor capacity assessment flowchart

## 3 CAPACITY INSPECTION METHOD

Various inspection category results can be used to provide as the basis for evaluating the capacity of anchors, summary of each categories is as follows:

### 3.1 Exterior inspection

Prior to knocking off the ground anchor concrete protected seats, obtain as-built drawings to mark off each and every anchors with numeric identifications. Visually inspect, investigate and record all anchor protected seats and load bearing structure system conditions. Visual inspection should emphasize on 1) anchor head protected seat hammer knocking test and the quality of sound whether solid or hollow, 2) visually inspect exterior of anchor protected seat for any damages, 3) between anchor head and load bearing structure,

look for any sign of separation, rotation, or even detachment, 4) Whether subsoil below shows sign of cave-in for the load bearing structure and 5) anchor head proximity has sign of efflorescence or ground water seepage, and all visual inspection should be carefully documented.

### 3.2 Anchor head assembly inspection

Anchor head assembly includes locking mechanism(wedges and screw head), load bearing plate and angle plate, as such parts tend to have anomalies. When inspecting anchor head assembly, carefully select a representative anchor head, after the removal of concrete protected seat, visually inspect the corrosive state of the anchor heads. After removal of anchor head protected seat the following category of items need to be recorded: load bearing plate dimension, angle plate dimension, load bearing plate angle, anchor head dimension, steel tendon style and remaining length data.

At this stage visual inspection should emphasize on 1) anchor head wedges and steel tendon corrosion, 2) anchor head assembly and water seepage condition and 3) steel tendon interior shortening, and all inspection should be recorded in detail.

### 3.3 Endoscopy inspection

Endoscopy can be used to inspect the backside of anchor head and free section of steel tendon, to determine whether the steel tendon is corroded, broken or free section has water inside. Entire inspection process should be video recorded to allow further inspection and study back in the lab. The equipment used is as shown in Figure 3.

Besides inspecting steel tendon status, this stage should measure the steel tendon length of free section. The measuring technique is to use a stainless steel rod to insert into the anchor free section portion until the rod can not be inserted further, as Figure 4 indicated. Then record the length of the rod which was inserted, as such length can be taken as the exposed section length.

Endoscopy inspection should emphasize on 1) steel tendon corrosion level, 2) steel threads loosened condition, 3) free-section concrete condition, 4) any concrete casting pipes and 5) interior moisture level or any water seepage, all inspection processes should be done carefully and in detail.

### 3.4 Lift-off test

After locking in load bearing of ground anchors, it's possible that due to creep at the bond end, wedges not properly function which would reduce or increase the loading capacities. To measure the change of loading capacities after lock-in, typical lift-off test is conducted, as shown in Figure 5. Lift-off test is aimed at finding the remaining load capacity of anchor( $T_r$ ), and the reason being when tensile load is greater than the anchor remaining capacity, anchor will demonstrate obvious displacement increase, from which can be taken to evaluate the remaining capacity of ground anchors, as shown in a standard test curve in Figure 6. Ground anchor residual load( $T_r$ ) divided by ground anchor original designed load capacity ( $T_w$ ) is the remaining load capacity ratio.

Figure 3. Equipment installation and operation

#### 4 GROUND ANCHOR CAPACITY ASSESSMENT PROCEDURE AND CASE STUDY

For the purpose of quantitative assessment on the ground anchor capacities, and with regard to the ground anchors performance on the sloping terrain application is the goal of this procedure. Based on the inspection and assessment items, this article shall introduce a new set of ground anchor capacity assessment procedure, in hoping to establish a standardized way to quantitatively evaluate and assess ground anchoring. Such procedure shall comprised of exterior inspection, anchor head

inspection, endoscopy inspection and lift-off test. The findings based on Table 1 distribution is point based. The total score will then be carried to Table 2 to evaluate ( $\beta$ ) and classification. Sloped terrain performance and ground anchoring total capacity shall be classified based on Table 2 standards. Ground anchoring total performance assessment classified as A or B grade, respectively, will be given corresponding effective rehabilitation to ensure the full and reliable capacity of the ground anchors.

		
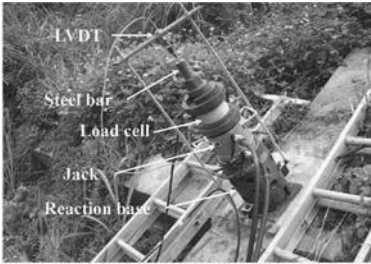

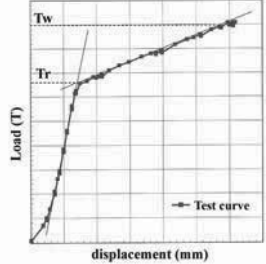

Figure 4. Free section exposed portion length investigation	Figure 5. Lift-off test installation	Figure 6. Lift-off test curve diagram

Table 1. Score of anchor capacity assessment

item	scoring	Content of inspection	Weight	subtotal
Exterior inspection	10	Buckled or detached.	0	
		Greater than 2mm separation from bearing plate or water corrosion is severe.	0.25	
		Anchor head protected seat and bearing plate separation is less than 2mm.	0.50	
		Anchor head protected seat surrounded by water seepage, efflorescence or anchor seat outside is slightly damaged or water corrosive level is moderate.	0.75	
		No observable anomalies or water quality is normal.	1.0	
Anchor head assembly inspection	15	Assembly came apart(clamp became loosened, steel tendon shrinkage or broken)	0	
		Anchor head surface appeared rusted and cracked, spread over 50% of the surface, steel tendon section is deformed due to corrosion.	0.25	
		Anchor head surface appeared rusted and cracked, but spread less than 50% of the surface.	0.50	
		Slightly corroded or water seepage. Anchor head appeared rusted, but the depth of the rust is quite thin, not measurable or lesser than 0.1mm.	0.75	
		No corrosion or water seepage is present.	1.0	
Endoscopy inspection	30	Steel tendon broken or steel threads became loosened and completely rusted.	0	
		Steel tendon appeared dark brownish, the surface already appeared corral-like or lumpy or rusted surface spread over 90%.	0.15	
		Steel tendon appeared dark brownish, the surface is rough, but not appearing corral-like or lumpy or rusted surface is between 50~90%.	0.45	
		Steel tendon appeared light brownish, but the surface is smooth and shining or rusted surface is between 10~50%.	0.75	
		No anomaly presence or rusted surface is below 10%.	1.0	
lift-off test	45	Detached, steel tendon broken or $Tr=0$ .	0	
		$Tr > 1.2Tw$ or $Tr \leq 0.2Tw$	0.33	
		$0.2Tw < Tr \leq 0.5Tw$	0.67	
		$0.5Tw < Tr \leq 0.8Tw$	0.75	
		$0.8Tw < Tr \leq 1.2Tw$	1.0	
Single ground anchor capacity assessment( $\beta$ )				
Total score of anchor capacity assessment( $\alpha$ )				

Remark: 1. If any of the items in categories 1,2,3,4 assessed a score of 0, such ground anchor shall be deemed as defective, and the total score of the anchor shall be zero.  
2. When a sloped terrain of which 1/3 of the ground anchors inspected has reach over 90% rusted surface under the examination of endoscopy, but the lift-off test revealed remaining capacity falls into the range  $0.8Tw < Tr \leq 1.2Tw$ , additional investigations in the field and test data is recommended to determine whether the slope may have a tendency to slide.

Table 2. Ground anchor assessment classifications

Individual capacity assessment		Total capacity assessment	
$\beta$	class	$\alpha$	class
0	X. Defective		
$\beta \leq 30$	A. Worst	$\alpha \leq 30$	A. Worst
$30 < \beta \leq 55$	B. Unacceptable	$30 < \alpha \leq 55$	B. Unacceptable
$55 < \beta \leq 80$	C. Acceptable	$55 < \alpha \leq 80$	C. Acceptable
$80 < \beta$	D. Normal	$80 < \alpha$	D. Normal

Ground anchor inspection items will be measured with apparatus, which is the best and most direct way to understand the existing conditions of the anchors and remaining bearing capacities. These values usually will be referred to while performing sloping reinforcing analysis. Of course the anchor capacity cannot and should not base solely on the lift-off test result. There are other factors such as ground condition below the anchors for possible cave-ins, steel tendon or anchor head surface appeared rusted and cracked. When a sloped terrain of which 1/3 of the ground anchors inspected has reach over 90% rusted surface under the examination of endoscopy, but the lift-off test revealed remaining capacity falls into the range  $0.8T_w < Tr \leq 1.2T_w$ . Such conditions should be cross referenced with other data like field observations and inspections and evaluate in totality whether the slope has a tendency to slide. This article brings forth various anchor evaluations by which will address the possible different scenarios that might be overlooked otherwise. In order to validate the practicality of Table 1, this article takes 16 slopes and conduct a simulating calculation for them. The results are as shown in Table 3 and 4. The results and classifications are consistent, thus prove the validity of this assessment procedure and its practicality.

Table 3. Case study of Single ground anchor capacity assessment

No. of anchors	S4-1	S4-2	S4-3	S4-4	S4-5
Exterior inspection	7.5	7.5	7.5	7.5	7.5
Anchor head assembly inspection	11.25	11.25	11.25	11.25	11.25
Endoscopy inspection	22.5	30	22.5	30	30
Lift-off test	33.75	45	33.75	45	45
$\beta$	75.0	93.8	75.0	93.8	93.8
$\alpha$	86.3				
Class of lift-off test	C	D	C	D	D
Class of $\beta$	C	D	C	D	D
Class of $\alpha$	D				

5 CONCLUSION

Based on collected statistical data, 90% ground anchor failure are resulted at the anchor head proximity and free section part of the steel tendon. This article had gathered data which initially showed free section was not completely filled with concrete for nearly 85% of the ground anchors being examined, therefore making it the most prevalent shortcoming. To avoid anchors becoming defective which leads to disaster, anti-corrosive remedy should be done promptly.

This article only took 16 areas of sloping terrain to gather data on ground anchors for inspection and assessment as explained previously. This evaluation procedure demonstrates that the four categories assessment: inspecting the exterior aspect of the anchor, the anchor head examination, endoscopy inspection and lift-off tests is a logical process in finding

shortcomings. In the future it is bound to have additional data available added to and revised upon, and would become a valuable systematic way for the engineering industry to adopt widely across.

# 2011 Seoul Debris Flow and Risk Analysis

## Coulée de boue à Séoul en 2011 et analyse des risques

Yune C.-Y., Kim G., Lee S.W., Paik J.

*Department of Civil Engineering, Gangneung-Wonju National University*

**ABSTRACT:** A series of debris flow events occurred around 8:00 to 8:50 a.m. on July 27, 2011 in the Umyeon Mountain area located in central Seoul, Korea. Umyeon Mountain is a relatively small one with a height of 250m and slopes with the average angle of around 15°. Due to the debris flows with runout distances ranging from 300m to 1,000m, 16 people were killed and more than 150 houses had been damaged in the area. In this work, we seek to understand the physical characteristics of the initiation and propagation behavior of debris flows from field investigation in the area and the analysis of rainfall data collected by AWS (Automatic Weather Stations) rain gauges. Field investigation shows that about 33 debris flows occurred in the Umyeon Mountain area and most of these debris flows were initiated from small slope failures induced by high-intensity rains. The application of landslide hazard map which has been recently developed by taking slope angle and direction, strength of soil, hazard record, rainfall condition and plantation into account demonstrates its good performance to highlight areas that are vulnerable of heavy-rainfall-induced slope failure and the resulting debris flow disasters.

**RÉSUMÉ :** Une série de coulées de boue s'est produite vers 8h00 ~ 8h50 le 27 Juillet 2011 dans la région du mont Umyeon situé dans le centre de Séoul, en Corée. La montagne Umyeon est relativement petite avec une hauteur de 250m et des pentes à angle moyen d'environ 15°. En raison de ces coulées de boue sur une distance allant de 300 à 1000m, 16 personnes ont été tuées et plus de 150 maisons ont été endommagées dans la région. Dans cette étude, nous chercherons à comprendre les caractéristiques physiques de l'initiation et du développement de la propagation des coulées de boue à partir d'une enquête sur place dans la zone concernée et de l'analyse des informations de précipitations recueillies par les pluviomètres de l'AWS (« Automatic Weather Stations », Station météorologique automatique). L'enquête sur place montre que près de 33 coulées de boue ont eu lieu dans la région du mont Umyeon et la plupart de ces coulées de boue ont pris naissance à partir de petites ruptures de pente provoquées par des pluies très intenses. L'application de la carte des risques de glissement de terrain qui a été récemment mise au point en prenant en compte l'angle et la direction des pentes, la résistance du sol, l'historique des désordres, les conditions des précipitations et des plantations démontre sa bonne performance pour mettre en évidence les zones qui sont vulnérables à des ruptures de pente provoquées par de fortes pluies et des catastrophes résultant de ces coulées de boue.

**KEYWORDS:** debris flows, field investigation, rainfall, hazard map

## 1 INTRODUCTION

Most of the debris flow hazard has been concentrated during the rainy season from June to August in Korea. In 2011, there were Typhoon Meari (22 June to 27 June), Typhoon Muifa (28 July to 9 August) and the seasonal rain front that stayed in the middle part of the Korean peninsula. They poured much more rainfall compared to the average value, and eventually led to debris flows around the country (Yune and Jun, 2011). A series of debris flow events occurred around 8:00 to 8:50 a.m. on July 27, 2011 in the Umyeon Mountain area located in southern part of Seoul, Korea.

Debris flows which generally contain more than 50% of granular materials larger than sand particles flow fast (Johnson and Rahn, 1970; Hutchinson, 1988). Because of their fast movement, it is very hard to take refuge, even though people recognize beforehand the outbreak of the debris flow. Between 8:00 to 8:50 a.m. on July 27, 2011, many debris flows occurred simultaneously at Umyeon Mountain in Seoul where there had been a previous debris flow event in 2010 caused by Typhoon Kompasu. Because the mountain is located at the center of a dense residential area in Seoul, the hazard had a great impact on the society compared to debris flows that occur in rural areas, and it led to careful scrutiny of the hazard area and the causes of debris flows.

In this research, a site survey on the debris flow at Umyeon Mountain was carried out to analyze the causes of the event, and rainfall records were also collected to investigate the triggering characteristics of the rain. In addition, risk analysis based on the hazard map of the landslide and debris flow was performed.

## 2 2011 SEOUL DEBRIS FLOW

### 2.1. Overview of Umyeon Mountain

Located in southern part of Seoul (Fig. 1) with the height of 312.6 m above the sea level, Umyeon Mountain includes lots of eco-friendly facilities, such as natural ecological park and mineral spring which can be easily accessed by local residents. It has a main ridge formed from the northeast to the southwest, including several valleys perpendicular to the main ridge. Most of the mountain consists of highly-weathered banded gneiss with subordinate granitic gneiss. Directions in ENE- and NW to NNW-striking faults are predominant with strike- or normal-slip sense. The groundwater level in the basin seems high because six mineral springs are located side by side at the altitude of 220 to 250 meters on the slope. Field observation of Son et al. (2012) also showed that groundwater level at locations where debris flows initiated reaches to the surface so that surface runoff occurs at the continuous rainfall condition of more than 250 mm, even if there is no significant antecedent rainfall. In

2010, regional intensive rainfall following Typhoon Kompasu caused a few landslides, and some of them developed as debris flows at the northern valleys in Umyeon Mountain (Fig. 2). However, the damage in 2010 was not great compared with the debris flow hazard in 2011.

Figure 1. Location of Umyeon Mountain

Figure 2. Locations of Slope Failures and Debris Flows around Umyeon Mountain in 2010

### 2.2. Field Survey

Field survey was performed to get data, such as longitude/latitude and topographical/geotechnical characteristics in places where debris flows were initiated, transported, and accumulated using a portable GPS, a laser ranger, and a clinometer. Based on the data from field survey, coordinates regarding initiation zones and debris flow routes were indicated on an aerial photograph around Umyeon Mountain as shown in Fig. 3. In this figure, the initiation slope failures are marked by blue dots, and debris flow routes are marked by yellow lines. Orange dots and green dots are also the initiation slope failure at the boundary and inside of air force base at the summit of the mountain, respectively. Most of the debris flows were initiated by slope failure and flowed down the valley. It was determined that they occurred simultaneously in the whole Umyeon Mountain area. The total number of slope failure that initiated debris flow was about 150. Based on the outlet in which the debris flows accumulated, the number of debris flows was about 33.

When we classified debris flows by direction, it was found that many of the slope failures occurred on the southern slope but many of the debris flows occurred on the northern slope. The debris flows moving towards the south were channelized debris flows which flowed down the valley and merged together. On the other hand, debris flows on the northern slope were hillslope debris flows which moved rapidly without being confined in an established channel. Therefore, the northern

slope has fewer initiation zones but more debris flows compared to the southern slope.

The field survey result showed that the average moving distance of debris flows in Umyeon Mountain was about 615m, ranging from 95 to 1,584m. Also, the average gradient of initiation slopes was about 27 degrees, ranging from 11 to 37 degrees. The initiation volume of the slope failure was measured from 73 to 4,000 m<sup>3</sup>.

Figure 3. Locations of Slope Failures and Debris Flows around Umyeon Mountain in 2011

### 2.3. Rainfall Conditions

Korea Meteorological Administration (KMA) reported that the torrential heavy rain which triggered landslides at Umyeon Mountain in 2011 was due to unstable atmospheric conditions mainly determined by cold and dry air from inland China along with the hot and humid air masses from the strong Southwestern wind alongside the Western North Pacific subtropical high (Fig. 4).

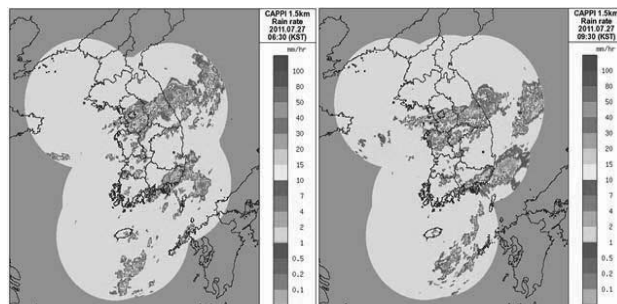

Figure 4. Spatial patterns of rainfall in Korea peninsula by KMA

There are two automatic weather stations (AWSs) operated by KMA near Umyeon Mountain as shown in Fig. 5. Namhyeon and Seocho stations are located at west and northeast part of Umyeon Mountain, respectively. Rainfall records from Namhyeon and Seocho stations were analyzed as daily and cumulative rainfall for 2 months as shown in Fig. 6. The cumulative rainfall for 2 months before debris flow event was 1,489.5mm and 1,105.0 mm at Namhyeon and Seocho station, respectively. Those values were comparable to the average annual rainfall in Seoul (1,450.5 mm). A significant amount of rainfall (681.5 mm at Seocho station) was concentrated during the period from 21 June to 18 July which was 10 to 36 days before the occurrence of the debris flows. Then there was no rainfall up to 4 days before the debris flow event and 88.5 mm of rainfall was recorded 1 to 3 days before debris flow. On the day of the debris flows, 359 mm and 281 mm of rainfall at Namhyeon and Seocho station were recorded. Unlike neighboring Gwanak Mountain, which is primarily

composed of granite, the geological structure of Umyeon Mountain is made up of gneiss. Therefore, the prolonged rainfall one month prior to the debris flow event might have caused saturation of the ground and made it more vulnerable to collapse. Average return period of rainfall for the duration of one hour and more was about 120 and 20 year for the Namhyeon and Seocho stations, respectively.

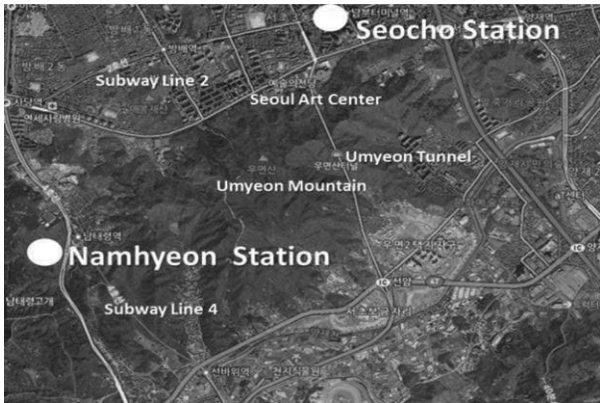

Figure 5. Locations of automatic weather stations around Umyeon Mountain

Figure 6. Locations of automatic weather stations around Umyeon Mountain

### 3 RISK ANALYSIS

#### 3.1 Landslide susceptibility assessment

There are two general approaches for landslide susceptibility assessment. The first approach is based on a physical mechanism and the second is based on a statistical method. In this work, statistical model developed in Gangneung-Wonju national university was used (Lee et. al., 2012). This model can directly yields the probability of landslide because the equation of the model was derived from logistic regression. The landslide susceptibility map is created by using GIS data which includes geomorphological characteristics, soil properties, rainfall, vegetation, and forest fire history. Figure 7 shows the landslide susceptibility map which was made with 329 mm of accumulated rainfall for 3 days, and the field survey result which included the initial slope failure and flow path of the debris flows was overlaid. As shown in figure 7, most of the slope failures were occurred in highly susceptible regions for landslide.

Figure 7. Landslide susceptibility map with field survey results

#### 3.2 Debris flow risk assessment

A methodology for the evaluation of debris flow risk in a watershed incorporated with GIS was proposed in this work. This model predicts the debris flow hazard risk on any given watershed. The model was developed using statistical analysis of debris flow hazard data in Korea from 2005 to 2011. These data was obtained from field surveys, disaster reports on national roads of Korea, aerial photos, and digital maps. Each set of data in the database includes geomorphologic factors influencing debris flow size, rainfall information, bedrock types, and run out distance of the debris. Figure 8 shows flow chart of the methodology.

Figure 8. Flow chart of the debris flow risk assessment

Debris flow hazard probability is calculated by equation (1).

$$\text{Debris flow hazard probability} = \text{Logit}(p) \quad (1)$$

where  $\text{Logit}(p) = -5.4 - 1.3E-5 \times (\text{area indicating landslide probability higher than } 50\% \times \text{depth of surface soil}) + 0.005 \times (\text{amount of continuous rainfall}) + 4.522 \times (\text{bedrock type}) + 2.1E-8 \times (\text{mean slope of flow path-area of watershed})$ . Table 1 shows the data and data acquisition method used in the model.

Based on the analysis of DEM (Digital Elevation Map) of Umyeon Mountain, 31 watersheds can be generated as shown in Figure 9. The probability of debris flow hazard for individual watershed in Umyeon Mountain is summarized in Table 2. As shown in Table 2, most of the watershed where debris flow took place showed high probability for the debris flow hazard except one watershed (Seonbawi) where debris flow hazard did not occur. Unlike the other watersheds, the bedrock of Seonbawi watershed was granite and the bedrock condition might be one of the important factor in the occurrence of debris flow. These results confirmed the applicability of the developed risk assessment model for the landslide and debris flow hazard.

Table 1. Data of the debris flow hazard occurrence

Dataset	Data acquisition
Potential landslide area ( )	Landslide susceptibility map

#### 4 CONCLUSIONS

A series of debris flow events occurred around 8:00 to 8:50 a.m. on July 27, 2011 in the Umyeon Mountain area located in Seoul, Korea. Field survey on the debris flow at Umyeon Mountain was carried out to understand the comprehensive situation of the hazard. The field survey result showed that debris flows occurred all around Umyeon Mountain and the average moving distance of debris flows was about 615m, ranging from 95 to 1,584m. Also, the average gradient of initiation slopes was about 27 degrees, ranging from 11 to 37 degrees. The initiation volume of the slope failure was measured from 73 to 4,000 m<sup>3</sup>.

In addition, risk analysis based on the hazard map of the landslide and debris flow was performed. Risk assessment of the landslide hazard showed the most of the slope failures were occurred in highly susceptible regions for landslide. And debris flow risk assessment also showed that the most of the watershed experienced debris flow hazard showed high probability of debris flow occurrence. And these results confirmed the applicability of the developed risk assessment model for the landslide and debris flow hazard.

#### 5 ACKNOWLEDGEMENT

This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education, Science and Technology (2012014940).

# General Report of TC209 Offshore Geotechnics

## Rapport général du TC209 Géotechnique marine

Jewell R.A.  
Fugro GeoConsulting

**ABSTRACT:** This general report introduces the discussion session organized by ISSMGE Technical Committee 209 (TC209) “Offshore Geotechnics”. The main topics include offshore wind projects, pipelines and seabed structures, seabed soils, coastal and nearshore work, and pile foundations.

**RÉSUMÉ :** Ce rapport général introduit la séance de discussion organisée par le Comité Technique 209 (TC209) “Géotechnique Offshore” de la SIMSG. Les principaux thèmes abordés sont les projets d’éoliennes offshore, les pipelines et structures sous-marines, les sols sous-marins, les travaux côtiers et nearshore et les fondations sur pieux

**KEYWORDS:** offshore, caisson, piles, pipes, cyclic load, stability diagram, lateral load, tests, numerical analysis, bearing capacity

### 1 INTRODUCTION.

The organizers of the 18th International Conference “Challenges and Innovations in Geotechnics” have implemented important changes to the conference format. One is the inclusion of Offshore Geotechnics at this main ISSMGE forum. Second is the focus given to the technical committees.

This general report covers the session organized by the ISSMGE Technical Committee 209 (TC209) “Offshore Geotechnics” chaired by Philippe Jeanjean. Participation by TC209 at this 18<sup>th</sup> conference includes the 2<sup>nd</sup> ISSMGE McClelland Lecture by Mark Randolph, this discussion session and a workshop on recent research and development on piles under cyclic loading.

The main difference in offshore geotechnics arises from the conditions and environment offshore. There is a stark contrast in access for site investigation, soil sampling, field testing, installation and observation. Activities offshore often require new tools. Soft soil conditions at seabed level are encountered in deepwater, frequently with high carbonate content, unusual mineralogy or biogenic activity. Combined and cyclic loading usually dominate design, whether caused by waves and currents acting on structures or by repeated expansion and contraction of pipelines on the seabed. Large displacement is a feature of the installation and operation of seabed pipelines. Many of the above features of offshore geotechnics are discussed in papers to this session.

This general report has been organized into five main subject areas: Offshore Wind; Pipelines and Seabed Structures; Seabed Soils; Coastal and Near Shore work; Pile Foundations.

Since papers on the cyclic loading of piles will be presented and discussed at the TC209 workshop, these are highlighted in this general report but will not be presented during the discussion session. The main focus for presentations will be Offshore Wind and large displacement as encountered with Offshore Pipelines.

Only a limited selection of papers will be presented at the discussion session. All the papers are in the proceedings and many will be presented at the poster session. Participants are strongly encouraged to attend the TC209 workshop where the cyclic behavior and design of piles will be presented and debated based around papers to this session.

### 2 OFFSHORE WIND.

#### 2.1 Site investigation

Project development, engineering design and project construction are three main phases for offshore wind farms. A major challenge is to minimize geotechnical risk for foundation engineering. In current practice, geotechnical risk is addressed mainly during the engineering design phase P2 in Table 1. Ben-Hazzine and Griffiths (2013) suggest that risk management may be improved through more extensive geophysical survey and preliminary site investigation during the project development phase P1. The authors highlight various sources of geotechnical risk such as inherent soil variability, measurement errors and “transformation errors” caused by simple empirical interpretation of data.

Table 1. Timing of Geotechnical Work for Offshore Windfarms (Ben-Hazzine and Griffiths, 2013)

Phase	Common			Proposed		
	P1	P2	P3	P1	P2	P3
Desk study	X			X		
Geophysical survey		X		X		
Preliminary investigation		X		X		
Full investigation		X			X	
Assurance & validation			X			X

Phases: P1 = Development, P2 = Design, P3 = Construction

Muir Wood and Knight (2013) use experience from 15 offshore wind farm projects in the UK to illustrate the manner in which geotechnical risk was managed and to define categories of poor, mediocre and good practice (or *vice versa*).

Poor practice includes appointment of the foundation design team after site investigation is completed, insufficient planning and poor interpretation of geophysical and geotechnical surveys. Mediocre practice often involves incorrect scope for geophysical and geotechnical surveys causing extra cost and increased risk. On projects with good practice the foundation design team was appointed at the start of the project and specified the site investigation work. The ground models were

developed and refined over multiple phases of geotechnical and geophysical investigation. The authors conclude that a formal approach to risk management with staged investigations and early appointment of the foundation design team is the best practice.

## 2.2 Wind turbine performance

A wind energy project involves several disciplines within civil engineering. The complex interaction between the turbine and the supporting structure governs the dynamic behaviour. Analysis is required of the structural modal parameters that influence fatigue of a wind turbine. Indeed, continuous monitoring of modal frequencies and damping ratios during the operational life of a wind turbine can provide early warning of the onset of structural damage.

Damgaard et al. (2013) assess instrumentation data from 30 offshore wind turbines in the North Sea. The measured modal frequency and damping ratio are found to vary with time. However, the observed magnitude and pattern of change with time might result from scour erosion or backfilling around the monopile structure. This highlights that the dynamic interaction between an operating turbine and the supporting structure may be affected by changes with time of the local seabed level, something that could be reduced by scour protection.

## 2.3 Foundation systems

The power capacity of a wind turbine, typically in the range 2MW to 5MW, but increasing toward 10MW in future, determines the required height above mean sea level and the maximum horizontal and vertical loads to be supported. Deeper water increases the moment arm for both wind and wave loading and often signifies larger design storms. There are many novel features to the required foundation engineering as discussed in papers to this session, Table 2.

Table 2. Papers on Foundation Systems for Offshore Wind.

	SINGLE LOAD		CYCLIC LOAD	
Shallow Foundation	Arroyo et al	A		
Monopile			Roesen et al	E.1g; A
Caisson	Kim et al	E.c; A	Versteede et al	A
Hybrid (pile/caisson)	Arshi et al	E.1g; A		

E = Experimental (E.1g lab floor; E.c centrifuge);  
A = Analysis

In brief résumé, shallow foundations and monopiles generally provide efficient support for wind turbines. However, these foundations are less effective when the moment load to be resisted increases due to larger turbines and/or deeper water. One approach is to improve the capacity by combining a monopile and shallow foundation, Figure 1. Alternatively, a caisson can support combined vertical, horizontal and moment loading at seabed level. Three or four caissons may be combined to support a structure where greater load carrying capacity is required, Figure 2.

The issues for foundation engineering discussed in the papers include: (1) the impact of the loading path and loading direction on safety factor and use of a single failure envelope; (2) improved performance by combining a shallow foundation and monopile; (3) the incremental displacement of cyclically loaded monopiles; and, (4) assessment of simultaneous pore water pressure generation and dissipation for caissons under storm loading.

(Arshi et al, 2013)

Figure 1. Hybrid Monopile and Shallow Foundation.

(Versteede et al, 2013)

Figure 2. Monopod and Multipod Foundations.

### 2.3.1 Bearing capacity analysis

The assessment of bearing capacity for offshore wind turbine foundations differs from onshore practice in several respects. The issues include: (a) separate correction factors in analysis for shape, depth, load inclination and eccentricity that are cumbersome and prone to calibration error; (b) use of separate partial factors on loads and resistances as in DNV-OS-J101 when the difference between favourable and detrimental effects can be subtle; and (c) simultaneous application of two major horizontal loads from wind and wave acting in separate directions. Arroyo et al highlight these issues and question the suitability of the conventional design approach for offshore wind foundations (Arroyo et al 2013).

A more satisfactory framework for capacity checks would be through failure-envelopes as detailed in the paper. Arroyo et al examine a synthetic design example to illustrate their case using the geometry of a Thornton Bank GBS and a set of derived loading parameters, Figure 3. The complex interaction between horizontal and moment loading, and the impact of different directions for wind and wave loading are illustrated by the authors using Figure 4 and the results in Table 3.

It is conventional to increase both detrimental loads at the same time, so that the load increment causing the limit to be reached is in the same direction as the reference combined load. The authors consider the cases where only wind or wave loading is increased. Such analysis might be used to assess the impact of any error in the assessment of those loads. Because of the greater influence on moment of wind loading, the analysis shows that an underestimate 21% (in this case) in the wind load would be sufficient to cause failure compared with an underestimate 50% for the wave load, Table 3.

Arroyo et al (2013) conclude that failure envelopes offer a powerful framework for analysis of shallow foundation capacity; the approach is particularly well suited for offshore wind structures that require refined design in the face of considerable uncertainty.

Figure 3. Thornton Bank GBS (after Peire et al 2009).

(Arroyo et al 2013)

Figure 4. Incremental loading paths to failure.

Table 3. Results of analysis on incremental load to failure.

Hypothesis	Hr (MN)	Hr / Hi	$\Delta H$ (%)
Sea	14.1	1.4	50
Both	11.6	1.15	15
Wind	10.5	1.04	21

### 2.3.2 Hybrid foundations

When considered as a monopile design, the addition of a shallow footing at seabed level may be thought of as adding “fixity” to the monopile “head” thereby generating improved resistance and stiffness to lateral loading, Figure 1. A simplified design analysis would assess the limiting moment capacity of the shallow foundation acting alone and include the equal and opposite moment resistance to the analysis of the monopile. The shallow foundation not only increases load carrying capacity but also reduces the bending moment supported by the monopile, by about 25% in the example cited by Arshi et al (2013).

Experimental modelling of these hybrid systems at 1g and in the centrifuge are described together with numerical and analytical work. The significance of the geometric ratio of footing to pile diameter, and pile length to pile diameter is demonstrated and a form for design charts proposed, Figure 5. Some tests on caisson/monopile combinations are noted and indicate additional benefit due to the lateral load resistance of

the caisson. Centrifuge tests are currently underway to define better the benefit of caisson versus simple shallow foundation in such hybrid foundation systems.

(Arshi et al 2013)

Figure 5. Moment resistance chart for hybrid foundations.

### 2.3.3 Lateral displacement due to cyclic loading

The focus above is the limit resistance of offshore wind tower foundations subject to a single application of combined loading. In practice, the structures are subject to several episodes of extreme loading caused by major storms and a great number of cycles of low amplitude loading from normal wind and wave conditions. The latter source of repeated loading may cause fatigue or serviceability problems (Roesen et al. 2013).

The authors report a series of 1g laboratory tests on monopiles in sand subject to one-way cyclic loading over more than 50,000 cycles. One limitation in these 1g tests is a more rigid pile compared with a typical prototype, but the trend of results should be similar. The cyclic loading is described by two non-dimensional ratios: the maximum moment compared with the static moment capacity  $\zeta_b = M_{max}/M_{static}$  in the range  $1 > \zeta_b > 0$ ; and the ratio of the minimum to the maximum moment  $\zeta_c = M_{min}/M_{max}$  which has a value 1 for a static test, 0 for one-way loading (the case examined by Roesen et al) and -1 for two way cyclic loading.

The pile displacement is measured by the rotation  $\theta$  at the soil surface. The results of a static load test and the measured displacement in one-way cyclic load tests ( $\zeta_c = 0$ ) with load intensity  $\zeta_b = 0.2$  to 0.4 are shown on Figure 6.

(Roesen et al 2013)

Figure 6. Static and cyclic one-way loading tests on model monopiles.

The incremental rotation due to one-way cyclic loading may be quantified with respect to the rotation caused by the first, single loading  $\Delta\theta_N = \theta_N - \theta_1$ . Tests with different loading intensity may then be compared through the non-dimensional form  $\Delta\theta_N/\theta_1$  as shown on Figure 7.

The test data are compared with a simple power law  $(\Delta\theta_N/\theta_1) = aN^b$ , where  $a$  and  $b$  are empirical constants found from testing. The power law seems to provide a reasonable asymptotic limit for the data after about 1000 or more load repetitions, Figure 7. The value of the constant  $a$  is found to vary almost linearly with the applied load magnitude  $\zeta_b$ . The slope of accumulating displacement with repeated loading, the constant  $b$ , appears to be a function of the combination of

monopile and sand parameters, presumably including the installation process. The rate of accumulation appears not to depend markedly on the applied load magnitude. The analysis in §6.2 suggests that the data might also fit with a natural logarithm through to low numbers of cycles ( $\Delta\theta_N / \theta_1$ ) =  $c \cdot \ln(N)$ .

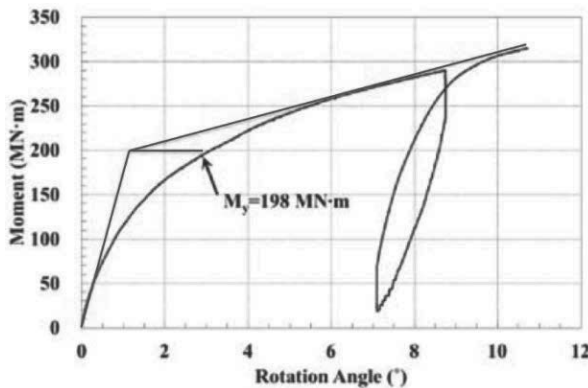

(Roesen et al 2013)  
Figure 7. Monopile rotation versus number of cycles.

### 2.3.4 Caisson foundations

A centrifuge test of a caisson in sand is reported by Kim et al. (2013). The caisson response to single combined load to failure is measured and numerical analysis applied. The test details are provided elsewhere and it is not clear whether the 1/70<sup>th</sup> scale caisson was installed by suction during the centrifuge test or before testing. Soil material from the proposed site is used to model a planned prototype caisson foundation. The measured response of the modelled prototype 15.5m diameter 10.5m long caisson is shown on Figure 8 in terms of applied moment versus rotation.

The authors report a parametric analysis using FLAC to show the significant influence of the assumed elastic modulus and cohesive strength parameters assumed for the soil.

(Kim et al 2013)  
Figure 8. Measured moment-rotation for prototype caisson.

The offshore design standard DNV-OS-J101 (DNV, 2011) requires structures to resist a 50 year design storm considering both peak loads and the entire history of cyclic loading. It is this latter requirement that is tackled by Versteede et al (2013) for the case of caisson foundations in sand.

Because a full analysis of cyclic loading of caissons in sand is not practically feasible with current numerical methods, the authors develop an analysis to provide insight into the competing processes of excess pore water pressure generation and dissipation during the design storm. The analysis breaks the storm into several packages of cyclic loading (magnitude, number of cycles and time). The excess pore water pressure generated at each point in the soil by the package of cyclic loading is computed analytically and input into the numerical analysis. The dissipation and redistribution of pore water pressure during the time period is computed numerically. The

process is repeated for the next package of cyclic loading, and so on.

The analysis for pore pressure generation uses two relations for the sand material. First the measured cyclic shear strength versus number of cycles to liquefaction,  $N_i$ , from cyclic laboratory tests; second an empirical formula linking pore water pressure generation to number of load cycles, Figure 9. Liquefaction occurs at  $u/u_{max} = 1$  when  $N/N_i = 1$ .

(Versteede et al 2013)  
Figure 9. Generation of excess pore water pressure.

The results of a 3D analysis for a caisson foundation are reported to illustrate the method, Figure 10. The 20m diameter by 10m length caisson is subjected to a 6 hour design storm of 2160 waves. These are split for analysis into 5 individual load packages. The direction of wind and wave loading is assumed to be aligned. The results illustrate the asymmetric nature of pore water pressure generation that has potential consequences for possible differential settlement and tilting of the caisson.

(Versteede et al 2013)  
Figure 10. Example of excess pore water pressure below a caisson.

Versteede et al (2013) conclude that the model is useful in predicting areas beneath the caisson prone to the development of excess pore pressure. However, the analysis does not predict liquefaction behaviour or compute settlement, nor does it allow for load redistribution in the caisson due to the changing effective resistance in the soil during the design storm. There is further development work to be done.

### 3 PIPELINES AND LARGE DISPLACEMENT.

A challenging feature for offshore pipelines is the large displacement that can occur during installation and service. Large displacement is particularly extreme for laying pipe on a soft seabed. Large displacement also results from multiple cycles of heat expansion and contraction of the operating pipeline. This requires engineering design to avoid localized

pipe distortion and over-stress irrespective of the sea bed soil type. A less discussed cause of large displacement is where a pipeline crosses a seismic fault; here it is movement of the ground with respect to the pipe that causes gross distortion. Fault crossings occur both onshore and offshore.

The geotechnical analysis for large displacement requires suitable tools and numerical models and both have developed significantly in recent years. A variety of large displacement numerical methods with 3D capability are commercially available for design purposes. Similarly, constitutive models for soft clay that account for competing strain rate and strain softening effects, and competing pore pressure generation and dissipation, are available for designers. Specific numerical elements to model the large displacement interaction between a pipe and the surrounding soil are also currently under development for practical application in design (SAFEBUCK JIP). However, the constitutive and numerical modeling for large displacement in dense sand is less well advanced.

Pipe buckling and pipe walking is usually assumed to occur between fixed seabed structures. There may be scope for permitting the seabed structures to move horizontally to help accommodate axial pipe displacement.

Several of these topics are described in four papers to the discussion session.

### 3.1 Dynamic embedment of offshore pipelines

Dutta et al (2013) examine pipe laying and dynamic embedment using Coupled Eulerian Lagrangian (CEL) methods available in ABAQUS software. Progressive degradation of undrained shear strength with plastic shear strain is included using the model of Einav and Randolph (2005). Similar analysis by Wang et al (2010) used remeshing and small strain (RITSS analysis).

The simplified problem is illustrated in Figure 11. A pipe is penetrated monotonically into a soft clay sea bed under self-weight (submerged weight of pipe). The pipe is then cycled laterally by a displacement  $u/D = \pm 0.05$ , in the  $x$  direction of Figure 11, under constant self-weight vertical load. This causes additional pipe penetration.

(Dutta et al 2013)

Figure 11. Pipe penetration of a seabed.

The analysis uses the same dimensions, soil parameters and loading sequence as the first stage of two pairs of centrifuge tests by Cheuk and White (2008) on a light and heavier pipe. The progressive pipe penetration and magnitude of horizontal resistance caused by cyclic lateral displacement is computed. The penetration of the pipe with cycles of lateral displacement is shown in Figure 12 for one pair of pipe tests.

Current practice is to estimate separately the embedment due to pipe laying and due to dynamic effects. The initial embedment on pipe laying involves temporary overload at the touch down point. Typically the pipe weight is increased by a "lay factor" and the initial pipe penetration under monotonic loading is computed for this higher load. The effect of small amplitude cyclic lateral motion is incorporated using a "dynamic embedment factor" that multiplies up the initial monotonic pipe lay embedment to determine a final estimated pipe embedment. The centrifuge tests and analysis here did not

incorporate initial overloading of the pipe, but the forty cycles of lateral loading resulted in a dynamic embedment factor of the order 4 to 5, within the range often assumed in practice.

(Dutta et al 2013)

Figure 12. Static and dynamic pipe penetration of a seabed.

As shown previously by Wang et al (2010), the analysis provides insight into the size of the zone of highly sheared and softened soil around the pipe and the shape of the berms formed by pipe penetration. The results in Figure 13 are for the heavier pipe and show dynamic pipe penetration and monotonic pipe penetration to the same depth (increased vertical load). The comparison is striking. Dynamic embedment causes more extensive plastic strain softening in the soil, coloured red, and wider and flatter berms than generated by monotonic pipe penetration. The latter could be important for the analysis of initial lateral breakout of the pipe. Dynamic embedment affects the magnitude of pipe penetration, the zone of soil remoulding and the shape of the berms formed.

(Dutta et al 2013)

Figure 13. Dynamic and monotonic pipe penetration of a soft seabed.

### 3.2 Pipeline fault crossing

Damage is caused to pipelines that cross a seismic fault that subsequently displaces. Rupture of oil or gas pipelines can cause fire and environmental risk. For critical pipelines, the magnitude and direction of localized fault displacement should be assessed and appropriate engineering implemented to avoid pipe rupture due to ground movement.

Moradi et al completed centrifuge tests on buried steel pipe subject to an upward thrust fault at  $30^\circ$  to the vertical in the direction of the pipe. A fault displacement 70mm was applied across an 8mm diameter buried pipe with 0.4mm wall thickness tested in a centrifuge at 40g. In one test the pipe is simply buried in the compacted sand. A low density and light weight loose backfill was used in the second test. The axial and bending strain in the pipe was measured in both tests. The light backfill allowed the pipe to buckle and displace over a greater length considerably reducing the damage to the pipe. The pipe embedded in the sand suffered more localized deformation and damage, as illustrated by the photos post testing, Figure 14.

(Moradi et al 2015)

Figure 14. Pipe response to shear fault displacement in a centrifuge.

### 3.3 Seabed structures that displace horizontally

The sea bed in deep water is generally soft and often requires large shallow foundations to support seabed facilities. If some movement could be tolerated the size could be reduced. Further, if the structure connects with a pipeline subject to walking or other axial force, there may be merit in allowing the structure to slide horizontally to help relieve concentrated load.

Bretelle and Wallerand (2013) examine the design for a shallow foundation that displaces horizontally in a cyclic fashion, as might be caused by repeated pipe expansion and contraction. The influence of soil softening, foundation settlement and potential change in stiffness with time is examined through relatively straightforward analysis. The authors conclude that shallow foundations designed to displace horizontally could be useful for subsea pipeline networks.

### 3.4 Large displacement in dense sand

While numerical analysis for large deformation is increasingly amenable for engineering design, a relatively simple constitutive model for dense sand that provides stable large deformation analysis is still subject to study. Li et al (2013) propose a Critical State Mohr Coulomb (CSMC) model: deformation up to peak strength is elastic and thereafter dense sand dilates (including non-associated flow) and reduces in strength to the critical state angle of friction. The concept of the state parameter defined by Been and Jeffries (1985) is used.

A key objective is analysis for punch through of a spudcan footing in dense sand overlying soft clay. Li et al (2013) have not reached that target. However, development of the model starkly highlights non-uniform deformation and preferential shear band formation in dense sand post peak that makes data acquisition (lab tests) and model calibration such a challenge.

In analysis for bearing capacity of a circular plate on uniform sand, the authors found that the elastic stiffness of the sand influences bearing capacity by as much as 50% over the realistic range, reminiscent of rigidity index in penetration problems. Stiffness was found to have greater impact than dilation angle. The analysis for bearing capacity is described in terms of a combined bearing capacity factor  $N_{q\gamma}$  that applies across the range from  $N_q$  alone to  $N_\gamma$ . The proposed formula for  $N_{q\gamma}$  includes soil stiffness and dilation angle along with peak friction angle, foundation size, soil unit weight and surcharge.

## 4 SEABED SOILS.

The three papers on soil properties cover diverse topics. Ho et al (2013) describe undrained cyclic triaxial compression tests on isotropically consolidated Singapore Marine Clay. The focus is the behavior of the clay when it is sheared monotonically to failure after cycling. The tests show that when the current mean effective stress in the sample reduces below half the original preconsolidation pressure,  $p/p_c \leq 0.5$ , due to cyclic loading, some increase in mean effective stress commences at higher stress ratio in each cycle. At mean effective stress  $p/p_c \geq 0.6$  (first few cycles) the mean effective stress of the clay always reduces. This behavior is similar to normally versus over consolidated clay. The final effective stress path for monotonic triaxial compression to failure after cycling similarly depends on the mean effective stress  $p/p_c$  at the end of

cycling. However, the shear strength is found to be largely independent of the previous number of load cycles and the strain amplitude.

Kim and Safdar (2013) report cyclic direct simple shear tests on compacted silty sand to define the limiting cyclic stress ratio versus number of cycles for two initial void ratios.

Tyldesley et al (2013) describe site investigation to define parameters for wind farm foundation design on a deep deposit of carbonate clayey silt till in Ontario Canada. This onshore site investigation demonstrates the use of insitu tests and shear wave velocity measurement, interpreted together with laboratory tests, to assemble knowledge on soil strength and stiffness properties.

## 5 COASTAL AND NEARSHORE WORK.

There are three papers on diverse topics. Madrid et al (2013) describe site investigation, cyclic laboratory tests and numerical analysis for the stability of a caisson breakwater in about 20m to 25m depth of water. The caissons are founded on a rubble mound infilling a large zone where the deep underlying soft clay soil was removed, Figure 15.

(Madrid et al 2013)

Figure 15. Caisson breakwater and stability analysis for wave impact.

There is much detail in the paper on soil testing and soil properties, loading cases for various phases of project construction and hydrodynamic testing to determine dynamic uplift. A good description is provided on the way cyclic loading and shear strength reduction were treated for design.

Relic footprints from earlier jack-up activity can occur next to the location for new shallow foundations. Ballard and Charue (2013) describe a study on a circular zone of remoulded soft clay ( $S_r = 2$ ) with a diameter equal to the size of the square mudmat and with soft clay thickness of half that size. The limiting envelope for combined moment and horizontal resistance is computed for a range of applied vertical load ( $V/V_{ult}$ ), and a range of distance between the mudmat and the remoulded zone/footprint that causes the moment and horizontal resistance to be reduced, as well as  $V_{ult}$ . 2D and 3D analyses show very substantial benefit from the 3D geometry in this case.

A detailed design and project record for installation of large diameter, buried HDPE pipes in a nearshore environment prone to seismic loading is described by Bellezza et al (2013). Details for the case history and the various code requirements considered in design are documented. Initial measurements are provided on the vertical deflection of the installed pipes.

## 6 PILE FOUNDATIONS.

A lack of code guidance on capacity, stiffness and displacement for cyclically loaded piles is being addressed by collaborative research including the original GOPAL study and the current SOLCYP project, supplemented by individual research work. Several papers to this session report on SOLCYP results from instrumented field tests, calibration chamber and centrifuge

tests. SOLCYP will be presented and discussed at the TC209 workshop and recorded for publication. Therefore only some key aspects are described below to avoid duplication.

There are four axial load magnitudes: the mean  $Q_{\text{mean}}$  and the half-amplitude of the cyclic load  $Q_{\text{cyclic}}$  define the maximum  $Q_{\text{max}} = Q_{\text{mean}} + Q_{\text{cyclic}}$  and the minimum  $Q_{\text{min}} = Q_{\text{mean}} - Q_{\text{cyclic}}$  pile loads. These loads are typically referenced to the ultimate pile capacity in tension  $Q_T$  or compression  $Q_{UC}$ . The ultimate capacity and the capacity under cyclic load is determined at a limiting displacement (0.1D or less) or due to an increasing rate of displacement; either continuing displacement after a static load increment or the cyclical displacement rate (mm/cycle).

### 6.1 Stability diagram: cyclic axial loading

The stability diagram is a non-dimensional map for cyclic pile behavior. The diagram in Figure 16 is for axial tension tests on model driven piles in dense sand in a calibration chamber (Silva et al, 2013). A similar diagram is found for the equivalent field test data (Rimoy et al, 2013). The chart defines the region of stable cyclic load combinations for a number of load cycles to be resisted. One way loading ( $Q_{\text{mean}} > Q_{\text{cyclic}}$ ) is more stable. The dashed line shows the limit of valid load combinations.

Puech et al (2013) provide the equivalent stability diagrams for cyclic compression loading of bored piles in dense sand from field and centrifuge tests. The field tests by Benzaria et al (2013a) are shown on Figure 17. The results from centrifuge model tests are very similar. Note that only one-way loading was tested and the data should not be extrapolated beyond.

While bored piles in stiff clay have lower ultimate resistance compared with driven piles, cyclic compression tests on bored piles in over-consolidated clay indicate a much larger range of stable load combinations compared with piles in dense sand (Benzaria et al, 2013b).

Information on deformation can be included on the stability diagram as shown by Rimoy et al (2013) for field tests under cyclic axial tension on driven piles in sand, Figure 18. The data on the accumulation of displacement with cycling shows mostly stable behavior that suddenly degrades near the limiting number of cycles, a rather "brittle" behavior under tensile load.

A consistent observation for driven piles in dense sand is that stable cycling increases the ultimate capacity when tested subsequently. This is attributed to densification with some relaxation in lateral effective stress around the pile, as measured in the exceptional data of Silva et al. (2013). Conversely, strong cyclic loading (as would lead to instability) acts to reduce the ultimate axial pile capacity that can be mobilized subsequently.

Data on large axial pile tests in silt on a 4.2m long test pile are also interpreted in a stability diagram by Chen et al (2013).

### 6.2 Cyclic lateral loading

Rosquoët et al (2013) report data on lateral displacement for model driven piles in sand tested under one-way loading at 40g in a centrifuge. As in §2.3.3, but for displacement rather than rotation, the lateral displacement  $y_N$  compared with the first load displacement  $y_1$  [ $\Delta y_N = y_N - y_1$ ] is linked with the number of cycles. A logarithmic form  $\Delta y_N / y_1 = c \cdot \ln(N)$  fits the data well where  $c$  varies with the amplitude of cyclic load and the maximum lateral load (equivalent to  $2Q_{\text{cyclic}} / Q_{\text{max}}$  in the axial terminology above, written as  $DF/F$  by Rosquoët et al). Based on their test data the authors suggest  $c = 0.1(DF/F)^{0.35}$  as a general fit, but sand and pile properties might also be important.

(Tsuha et al (2012) calibration chamber tests)

Figure 16: Stability diagram: tension tests on model driven piles in sand.

(Puech et al, 2013)

Figure 17: Stability diagram: field compression on bored piles in sand.

(Rimoy et al, 2013 field tension tests on driven piles in sand)

Figure 18: Stability diagram: accumulated displacement.

The natural logarithm form has the advantage of fitting the data through to low numbers of cycles (recall §2.3.3). Rosquoët et al (2013) also note that the maximum moment in the pile does not increase significantly with lateral cyclic loading. Finally, the work to extend  $p$ - $y$  analysis for laterally loaded piles failed to capture the measured behavior beyond the first few cycles.

### 6.3 Extension of *t-z* analysis to cyclic loading

Burlon et al (2013) extend static *t-z* analysis for piles in sand to the case of tensile and compressive cyclic load and compare the results with centrifuge test data. The analysis turns out not yet to be practical as four new parameters are introduced that require measurement in cyclic pile tests. Even then, the fit with the test data is good only for relatively few load cycles.

### 6.4 Plugging of open-ended displacement piles

Laboratory tests on sand to measure pile plugging, using PIV observations, are described by Lueking and Kempfert (2013). The fully plugged limit IFR=0 was not achieved in the tests. The results of 2D Plaxis analysis are reported to investigate the mechanism of plugging. Based on this study, the authors propose two largely empirical calculation methods for the analysis of end-bearing for open-ended, partially plugged piles.

### 6.5 Cyclic pressuremeter tests

Reiffsteck et al (2013) report new work on the application of Ménard and self-boring pressuremeter tests to measure the change in soil properties with cyclic loading and, potentially, liquefaction resistance. Data are reported for several sites where cyclic pile tests were completed (SOLCYP). The authors emphasise the importance of a high quality borehole and the need for at least 50 cycles of repeated load to characterize the shear modulus. Soil horizons susceptible to liquefaction could be identified by large volume expansion. The acquisition of pore water pressure data during the test would greatly improve the test control (data on drainage/rate effects) and interpretation.

### 6.6 Osterberg cell testing

The general reporter is not aware of recent cyclic pile tests using O-Cell technology (Osterberg, 1989). A two level O-Cell test arrangement, for example, permits end bearing to be eliminated from cyclic axial compression tests on piles.

## 7 CONCLUSIONS.

As demonstrated by papers to this session, the practical challenges of offshore geotechnics actively drive forward the development of soil mechanics and geotechnical engineering. This is partly due to more extreme loading and deformation than usually encountered onshore. The fruits of this research and development are of great value for the overall understanding and practice of geotechnical engineering. That is why offshore geotechnics should remain part of this key ISSMGE conference.

## 8 ACKNOWLEDGEMENTS

The author would thank TC209 Chairman Philippe Jeanjean for the invitation to prepare this General Report, and colleagues J.C. Ballard, P. Peralta and V. Whenham for valuable support.

# Shallow foundations for offshore wind towers

## Fondations superficielles pour des installations éoliennes maritimes

Arroyo M., Abadías D., Alcoverro J., Gens A.

*Dep. of Geotechnical Engineering and Geosciences, Technical University of Catalonia, Barcelona, Spain*

**ABSTRACT:** Direct foundations are present in about 25% of the installed offshore wind power towers. The peculiarities of this type of structure are well known: high dynamic sensitivity, complex couplings between environmental actions, machine operation and structural response, complex installation and maintenance, difficult site investigation. There is a clear need for optimized foundation design tools that would enable cost reduction and a more detailed assessment of the risk of every installation. One such tool is likely to be the systematic use of failure envelopes for capacity checks. The paper explores the benefits of such an approach with various realistic design examples.

**RÉSUMÉ :** Les fondations superficielles interviennent dans la réalisation de 25% des structures éoliennes maritimes. Les particularités de ce type de structures sont bien connues: haute sensibilité dynamique, couplages complexes entre les actions environnementales, le fonctionnement de la machine et la réponse structurelle, installation et maintenance difficiles, investigation géotechniques onéreuses. Un besoin évident d'optimisation des outils de conception est nécessaire pour permettre la réduction des coûts et une évaluation plus détaillée du risque de chaque installation. Le recours systématique à des enveloppes de rupture pour les justifications de la capacité portante des fondations peut bien être un tel outil. Ce papier explore les avantages d'une telle approche avec divers exemples de conception réalistes.

**KEYWORDS:** direct foundation, capacity, offshore, energy, wind farms

### 1 INTRODUCTION

Offshore wind is an increasingly large contributor to the energy production mix of several European countries, particularly those bordering the North and Baltic seas. An exponential increase in installations is currently anticipated in this region. It is reasonable to expect that other regions of the world will follow suit.

Offshore wind turbines (OWT) are generally larger than those installed on land, with 3 to 5 MW of nominal capacity being now the norm, but with turbines of up to 10 Mw coming soon to the market. Rotor diameters of more than 100 m and nacelle locations 80 m above mean sea level are common. The result is a relatively lightweight and slender structure, supporting a rotating machine finely tuned to maximize power production while minimizing structural loading.

While initial OWT installations took place near shore (< 10 km) at locations with relatively shallow water depths (< 20 m), current developments are clearly located offshore (10 -100 km from the nearer coast) with water depths of 20-50 m being typical. Several floating support concepts are now being developed; however, commercial installations are still always supported by some kind of fixed structure. For these, the foundation of choice would depend in any case on the particular site conditions, construction equipment availability and, to a certain extent, local traditions.

To this date pile foundations have been largely dominant, mostly as single large (4-6 m diameter) monopile installations, and lately also as smaller (1-2 m) piles for jackets and tripods. However, examining the industry databases (e.g. Burton et al 2011) it appears that at the end of 2011 about 25% of the installed power was supported by direct foundations or gravity base substructures (GBS). Most of these GBS installations took place in relatively shallow waters, but there are some examples already at larger distances from the coastline and in deeper waters. Perhaps the most significant is the Thornton Bank I

project, 27 km offshore Zeebrugge in Belgium, where 6 OWT of 5 Mw were installed in water depths of 20-30 m. The foundation design for this installation was described by Peire et al (2009) and its outline is reproduced here in Figure 1. These are large (44 m height; 23.5 m base diameter) concrete shells, floated into place and later ballasted with a mixture of sand and olivine with the base at 4 m below the original seafloor level. The geotechnical profile at the site comprises medium and high density sands and stiff tertiary clays.

### 2 DESIGN ISSUES FOR DIRECT OWT FOUNDATIONS

There are several specific standards dealing with OWT. Perhaps the highest ranked is IEC 61400-3 (2009) which, from the point of view of structural design, establishes design cases and site ambient load specification procedures, introduces a safety format and gives broad indications about structural design procedures. However, detailed specification of structural and foundation design procedures is deliberately referred to other documents, like the ISO 1990X offshore standard series or DNV-OS-J101 (2010).

As might be expected, the indications given by such standards are, on the one hand, firmly based in conventional design practice when being specific, and somewhat elusive with problems that lack a clear conventional solution. An example of the later is the consideration of fatigue or foundation failure under cyclic loading. An example of the former is the consideration of foundation bearing capacity which, for shallow foundations, follows a conventional superposition and correction procedure not very different from those outlined by Brinch-Hansen (1970) or Vesic (1975).

When designing foundations for OWT, there will be of course issues of geotechnical capacity under extreme loads. However the design drivers might be sometimes related to other considerations, such as dynamic characteristics of the whole

structure (Van der Temple and Molenaar, 2002) or displacement limits imposed by operating constraints (e.g. foundation tilting limits of 0.25° - 0.5° are sometimes quoted). However, even if we narrow our focus to bearing capacity considerations there are reasonable grounds to question the suitability of the conventional design approach.

Figure 1. Thornton Bank GBS (Peire et al., 2009).

Indeed there are several aspects of the traditional approach to bearing capacity that are poorly suited to deal with OWT. Firstly, using separate corrections for shape, depth, load inclination, load eccentricity is cumbersome and prone to calibration error if the effects that are being corrected for are not truly independent. This is perhaps the reason behind the large scatter between inclination factor formulations (Siefert & Bay-Gress; 2000); that uncertainty is particularly undesirable for structures, like OWT, that are mostly designed to sustain horizontal loads.

Secondly, the traditional approach to bearing capacity quickly leads to conundrums when the security format (as is the case for most modern codes, like DNV-OS-J101) is based on separate partial factors for loads and resistances. As discussed in detail by Lesny (2007) the same action might have a detrimental or favourable effect depending on which other actions are being simultaneously considered. Also it is fairly evident that a traditional bearing capacity check is far from eliminating the most likely path towards failure.

Finally, it is very difficult to generalize the traditional approach to cases when two major horizontal loads (wind, wave) are acting in separate planes. All these problems are best dealt with if the traditional approach to capacity checks is replaced by a failure-envelope based one.

### 3 FAILURE ENVELOPES

#### 3.1 Concept

Failure envelopes were introduced (Butterfield & Tiof, 1979) as an alternative to classical bearing capacity analyses. They were based on the concept of interaction diagram, which was applied to the system of loads acting on the foundation. Most developments to date –but not all–, refer to the case in which that system can be reduced to loads acting within a plane ( $V, H, M$ ) –where  $M$  represents the moment acting within the plane,  $M$  normalised by a characteristic foundation dimension,  $M/B$ .

Failure envelopes are implicit in the traditional approach to bearing capacity. However, it was clearly appreciated from the beginning that an explicit failure envelope was useful to link previously separate checks on different foundation failure modes (e.g. sliding and bearing capacity) into a coherent view. Failure envelopes offered advantages also from the experimental viewpoint, because they provide a clearer framework for experimentation, even suggesting new, more efficient, procedures (like “swipe” tests).

Failure envelopes are also attractive because they can fit well with generalized force-displacement foundation models (“macroelements”; Nova and Montrasio, 1991) that are used to compute foundation displacements and represent an economical solution to non-linear soil-structure interaction studies. Finally, failure envelopes are interesting because they enable a more coherent approach to foundation safety.

#### 3.2 Safety considerations

Already Georgiadis (1985) clearly identified as one major advantage of failure envelopes that they allow a very natural consideration of the influence of different loading paths. To do that, it is important to distinguish between the reference design load state and incremental loading paths (Figure 2).

Figure 2. Schematic load envelope illustrating a reference design load and one incremental load path

Any load system ( $V, H, M$ ) shall remain within the failure envelope. It is however convenient to establish a non-dimensional safety measure. To do so a simple approach is, for any incremental loading direction, to obtain the crossing point with the failure envelope ( $V_r, H_r, M_r$ ) and then define a generalized safety factor,  $SF$ , as

$$SF_{(\bar{V}, \bar{H}, \bar{M})}(V, H, M) = 1 + |\lambda_r| \quad (1)$$

$$(V_r = V + \lambda_r \bar{V}, H_r = H + \lambda_r \bar{H}, M_r = M + \lambda_r \bar{M}) \quad (2)$$

It is thus made explicit the fact that safety is not only dependent on the initial design situation but also on the incremental loading path. This definition includes, as a particular case, the traditional safety factors against bearing capacity (the incremental load direction and the reference

design load are collinear) or sliding (incremental loading direction collinear with the Horizontal component of the reference design load). Another particular case included is that of “plastic overturn”, a prescribed check for breakwater design in Spanish regulations (Puertos del Estado, 2005) in which the lever arm of the horizontal loading is maintained (i.e. the incremental load is aligned with the the Horizontal and Moment components of the reference load).

### 3.3 Example formulations

Figure 3 Failure envelope by Gottardi et al (1999)

There are many failure envelopes in the literature. For foundations failing without drainage at the soil-foundation interface Gourvenec & Randolph (2011) offer an excellent review. For the example below a sand profile is assumed and drained conditions are reasonable. In these circumstances a convenient expression for a failure envelope is that proposed by Gottardi et al. (1999) (Figure 3)

$$F(V, H, M) = \left(\frac{h}{h_0}\right)^2 + \left(\frac{m}{m_0}\right)^2 - 2a\left(\frac{hm}{h_0 m_0}\right) - (4v(1-v))^2 = 0 \quad (3)$$

Where  $(a, h_0, m_0)$  are shape factors, empirically determined as  $(-0.22, 0.12, 0.09)$  for quartzitic sand, and we use a non-dimensional notation in which  $v = V/V_0$ ,  $h = H/V_0$ ,  $m = M/(DV_0)$  and  $D$  is the foundation diameter. The normalizing factor  $V_0$  is the maximum load (i.e. centered vertical) that the foundation can sustain. Here that maximum load is computed assuming no embedment and introducing the bearing capacity factor  $N_\gamma$  from Bolton & Lau (1993) into

$$V_0 = \frac{1}{2} \gamma D N_\gamma \left(\frac{\pi D^2}{4}\right) \quad (4)$$

It is worth noting that (a) it is relatively straightforward to generalize expression (3) to more complex loading situations – e.g. Lesny 2010- although the experimental base for adjusting the parameters in those circumstances is somewhat scarce, (b) that the shape of (3) above has proven rather resilient and very similar expressions have been found to fit well other foundation test results in materials like carbonate sand or even clay (Martin & Houlsby, 2001), as long as the contact surface remains drained. Of course the choice of  $V_0$  would change according to the material and foundation shape.

## 4 EXAMPLE APPLICATION

To illustrate the argument we propose an example, synthetic but realistic. The case is developed using the characteristics of the gravity base substructure built at Thornton Bank (Peire et al. 2009) and the design loading specified for a Baltic windfarm development site, Kriegers Flak (Bulow et al, 2009). This reference gives some basic characteristics for the OWT superstructure (Table 1).

Table 1 Super-structure characteristics

Rated power	5 MW
Rotor diameter	126 m
Nacelle height above msl	90 m
Nacelle-rotor weight	4.1 MN
Tower weight	3 MN

The same reference also includes resultants from ambient loads for a range of depths and load hypothesis (e.g. extreme, fatigue). Using these data, Table 2 has been computed for a 30 m depth case and extreme load scenario. It appears that, in this particular case, 80% of the total horizontal thrust is due to sea action, but this load is the source of less than 20% of the overturning moment at foundation level. This might partly reflect the fact that at that particular site sea current is relatively strong, lowering the action line of sea forces.

These ambient loads should be combined with the OWT selfweight. Using the Thornton Bank design like a template for substructure shape, the relevant characteristics of that part of the OWT are those listed in Table 3. As usual with gravity base OWT, the dead weight of the substructure is significantly larger than that of the superstructure. Combining all environmental actions and structure selfweight the resultant load combination acting at the foundation level is  $(H, V, M) = (10.1; 44.5; 284.3)$  in MN and MNm. This will be the reference design load state in this example.

Table 2 Ambient loading parameters

Parameter / load	Unit	Value
Total thrust, H	MN	10.1
Total overturning moment, M	MNm	284.3
Wind thrust, H <sub>w</sub>	MN	2.03
Wind arm lever, b <sub>w</sub>	m	120
Sea thrust, H <sub>s</sub>	MN	8.07
Sea arm lever, b <sub>s</sub>	m	5

Table 3 Thornton Bank type substructure characteristics

Parameter / load	Unit	Value
Base diameter	m	23,5
Concrete weight	MN	30
Fill weight	MN	38
Buoyant volume	m <sup>3</sup>	2965

From that reference state we probe the failure surface alongside three different incremental loading paths. One will correspond to a simultaneous and proportional increase of all ambient actions (the “plastic overturn” case). The other two hypothesis would correspond to increases of just one of the

ambient horizontal actions, (sea, wind) while the other remains constant. These hypotheses would, for instance, naturally follow from any circumstance in which the estimates of wind and wave carry different uncertainties. Figure 4 illustrates graphically the meaning of these load directions in an idealised section of the failure envelope at constant  $V$ .

For this check we use the failure envelope of Gottardi et al described above. The soil profile below the foundation is characterised by a friction angle of  $33^\circ$  and submerged weight of  $10 \text{ kN/m}^3$ . These values might correspond well to the characteristic values of a medium-dense sand profile, frequently encountered in North Sea locations. It is assumed that the foundation base is perfectly rough.

Figure 4 Incremental load paths in the example

Table 4 Example: results

Hypothesis	$H_r$ (MN)	$H_r / H_i$	$\Delta H$ (%)
Sea	14.1	1.4	50
Both	11.6	1.15	15
Wind	10.5	1.04	21

Some relevant results from the computation are presented in table 4. For each incremental loading path a failure point is identified in the envelope, with values ( $H_r$ ,  $M_r$ ). In the table the value  $H_r$  corresponding to each loading path is reported in the first column. In the second column this value is normalized by the reference state horizontal load. This corresponds to the generalized safety factor defined above, which, only for the hypothesis in which both loads are simultaneously increasing, coincides with the “plastic overturn” safety factor of ROM 0.5-05. As a reference the value required for that safety factor in breakwaters is commonly above 1.3 (Puertos del Estado; 2005).

For the other two load hypothesis in which only one environmental action is increased no similar reference exists to judge on the computed safety factor. For these cases it is perhaps more meaningful the number in the third column of Table 4, where the difference between failure and reference thrust is expressed as a percent of the reference ambient load that is increasing. In the case computed, a 21% error in the reference estimate of wind thrust would result in foundation failure, whereas it would be necessary a 50% underestimate of the hydrodynamic thrust to fail the foundation.

The previous computations have always been made under the hypothesis of increased thrust and constant lever arm. This can be interpreted as action magnitude uncertainty. Alternative hypothesis dealing with lever arm uncertainty can be equally set up with relative ease. Note, finally, that most geotechnical uncertainty can be lumped in the  $V_0$  estimate to achieve a relatively straightforward approach to reliability evaluation.

## 5 CONCLUSION

Failure envelopes offer a powerful framework to analyze shallow foundation capacity problems. They seem particularly suitable for offshore wind towers, where refined design in the face of large load uncertainties is likely to be a frequent situation.

## 6 ACKNOWLEDGEMENTS

The research on direct foundations for offshore wind towers described in this paper was partly funded by the company ACCIONA ENERGY within the framework of the CENIT-AZIMUT project supported by the Spanish Ministry of Science.

# Modelling of monopile-footing foundation system for offshore structures in cohesionless soils

Modélisation d'un système de fondation superficielle isolé pour sur les structures maritimes dans les sols pulvérulents

Arshi H.S., Stone K.J.L.  
University of Brighton, UK

Vaziri M.  
Ramboll UK Limited, UK

Newson T.A., El-Marassi M.  
University of Western Ontario, Canada

Taylor R.N., Goodey R.J.  
City University London, UK

**ABSTRACT:** While monopiles have proven to be an economically sound foundation solution for wind turbines, especially in relatively shallow water, their installation in deeper water and in hard ground may require a more complex foundation design in order to satisfy the loading conditions. One approach is that foundation systems are developed which combine several foundation elements to create a 'hybrid' system. In this way it is possible to develop a foundation system which is more efficient for the combination of vertical and lateral loads associated with wind turbines while maintaining the efficiency and simplicity of the design. Previous studies have reported the results of single gravity tests of the hybrid system where the benefits of adding the footing to the pile are illustrated. This paper presents experimental results on the performance of skirted and unskirted monopile-footings. A simplified design approach based on conventional lateral pile analysis is presented.

**RÉSUMÉ :** Alors que les fondations de type monopile se sont révélées être une solution économiquement viable pour les fondations d'éoliennes, en particulier dans les eaux relativement peu profondes, leur installation dans des eaux plus profondes et dans un sol dur peut exiger une conception plus complexe afin de satisfaire les conditions de chargement. Une approche possible est que les systèmes de fondations développés combinent plusieurs éléments de fondation pour créer un système hybride. De cette manière, il est possible de développer un système de fondation plus efficace vis à vis des charges verticales et latérales associées aux éoliennes, tout en maintenant une conception efficace et simple. Des études antérieures sous gravité simple ont montré l'efficacité d'un système hybride en combinant une semelle et un pieu. Cet article présente des résultats expérimentaux sur la performance de systèmes avec et sans pieu pour des semelles. Une approche de conception simplifiée basée sur l'analyse classique d'un pieu sous charge latérale est présentée.

**KEYWORDS:** Hybrid monopile footing, offshore piles, laterally loaded piles, wind turbine foundations

## 1 INTRODUCTION

Due to the needs of on-going developments in the oil and energy sector, the design of offshore foundations is constantly evolving. In the hydrocarbon extraction sector, exploration and development is moving in to ever deeper water resulting in ever more challenging geotechnical conditions. Similarly the expansion of the offshore wind sector involves the development of deepwater sites, together with requirements for heavier high capacity turbines. Conventional offshore foundations are not always economical or practical for this new generation of turbines, and there remains a requirement to develop foundation solutions which can better satisfy future developments in the offshore wind sector.

The foundations of a typical offshore wind turbine are subjected to combined loading conditions consisting of the self-weight of the structure ( $V$ ), relatively high horizontal loads ( $H$ ) and large bending moments ( $M$ ). The preferred foundation system to date has been the monopile, which has the advantage that it can be employed in a variety of different soil conditions. However, a disadvantage in the use of monopiles in deep water sites is that the system can be overly compliant. For sites with intermediate water depths, it may be possible to stiffen the lateral response of the monopile at the mudline.

Figure 1. Schematic illustration of the prototype hybrid system.

One such approach to increase the lateral resistance of a monopile is the 'hybrid' monopile-footing system. As schematically represented in Figure 1, this foundation system

comprises of a circular footing attached to the monopile at the mudline. A 2-D analogy of this system is that of a retaining wall with a stabilising base (Powrie and Daly, 2007). The role of the footing is to provide a degree of rotational restraint at the pile head, leading to an improvement in the lateral resistance of the pile. It has also been shown that the use of a relatively thick pile cap leads to an increase in the lateral resistance through the development of passive soil wedges (Mokwa, 1999), in a similar way to the behaviour of skirted foundations (Bransby and Randolph, 1998).

Analysis of the hybrid system would involve both lateral pile analysis and bearing capacity analysis. The lateral response of piles is well reported in the literature and various methods of analysis have been proposed by numerous researchers, such as Matlock and Reese (1960), Broms (1954), Poulos (1971), Reese *et al.* (1974), Randolph (1981), Duncan *et al.* (1994) and Zhang *et al.* (2005). Where the plate diameter is relatively small, the system is similar to a single capped pile, for which methods have been developed for analysing the influence of the pile and pile cap under axial loading (Poulos and Randolph, 1983), and the effect of the pile cap on the lateral performance of single piles has also been investigated by others (Kim *et al.*, 1979), (Mokwa and Duncan, 2001: 2003), (Maharaj, 2003).

The bearing capacity problem has also been investigated under different loading conditions relevant to offshore foundations, see for example references Houslsby and Puzrin (1999), and Gourvenec and Randolph (2003).

## 2. EXPERIMENTAL INVESTIGATIONS

The potential performance of the hybrid system was investigated in single gravity studies (Stone *et al.* (2007)) and is illustrated in Figure 2. These studies suggested that the additional rotation restraint provided by the footing can result in a stiffer lateral response of the pile and greater ultimate lateral load. The degree of restraint at the pile head was dependent on the size of the footing, the initial contact between the soil and the footing and the stiffness of the soil beneath the footing. Observations of heaved and displaced soil in front of the edge of the footing also suggested that a degree of passive soil resistance is likely to be generated under the lateral movement and rotation of the footing.

Figure 2. Lateral load response of the hybrid system (after Stone *et al.* 2007).

Arshi (2011), and Arshi and Stone (2012) reported the results of a comprehensive series of single gravity tests carried out on the foundation system where the elements affecting the overall performance of the foundation system was investigated in depth. It was reported that the size for the footing has a direct effect on the overall lateral load bearing capacity of the foundation system. Furthermore it was reported that the ratio between the vertical and horizontal load has a significant effect on the lateral performance of the foundation system where larger vertical loads tend to improve the lateral load bearing capacity of the hybrid system. The connection between the

footing and the pile was also investigated where it was suggested that the hybrid foundation system tends to be more effective if vertical movements are allowed at the pile-footing connection. This movement allows the footing to act independently from the pile where the positive contact between the footing and the soil underneath is solely controlled by the vertical load acting on the footing.

Table 1. Notations for skirted hybrid foundations system

ID	Footing size (mm)	Skirt length (mm)	Dead load (N)	Footing to pile connection
P.W0	-	-	0	-
P.F80.W1.FR	80	-	100	Slipping
P.F80.S1.W1.FR	80	-	100	Slipping
P.F80.S2.W1.FR	80	-	100	Slipping
P.F80.S3.W1.FR	80	-	100	Slipping

More recent single gravity tests are presented in Figure 3 where skirts with different lengths have been added to the footing. The tests were conducted in sand and the results indicate that the presence of the skirts has a relatively significant contribution on the lateral load capacity of the system. The results show that adding the skirts to the footing and increasing the skirt length tends to increase the lateral load bearing capacity of the foundation system by about 50% in comparison to a non-skirted hybrid system. It is also apparent that footings with very short skirts do not tend to show any ‘apparent’ additional advantage to that without the skirt. This could be due to the fact that the stresses around the skirt induced by the soil are very small at 1g. Further studies in the centrifuge are in the taking place to investigate the effect of the skirts and the results will be reported soon.

Figure 3. Load vs. deflection plot for the hybrid system with skirts.

Stone *et al.* (2011) reported the results of a series of centrifuge tests in sand. The results of the combined vertical and lateral loading tests are best represented through plots of lateral load versus lateral displacement. Figure 4 shows a plot of the lateral load versus lateral displacement for the monopile-footing (HL 1) and single pile (PL 1) with a vertical load of 600N at 50 g. It is apparent from this plot that the initial lateral stiffness of the monopile-footing and pile are similar for the first 1–1.5mm of lateral displacement. However the monopile-footing continues to exhibit a stiffer response than the single pile as the lateral displacement increases. Further analyses of these data provided information on the redistribution of bending moment in the pile due to the plate.

Figure 4. Load deflection graph for centrifuge tests carried out on the hybrid system (after Stone *et al.* 2011).

In Figure 5, the bold lines represent the bending moments at 5% and 20% of the maximum deflection for the pile only case and the dashed lines show the behaviour of the hybrid system. The results show that adding the footing to the pile reduces the bending moment at any given deflection, and as a result increases the moment capacity of the system at any given applied lateral load. The results indicate about 25% improvement in the bending moment for at both deflections.

Figure 5. Bending moment distribution along the pile length for the hybrid system.

### 3. ANALYSIS

Whilst some advanced numerical modelling of monopiled footings has been undertaken (El-Marassi *et al.* 2008; Stone *et al.* 2010; Arshi *et al.* 2011; Arshi and Stone 2012), the method presented here utilises conventional lateral pile analysis methodology where the hybrid system is idealised to a lateral pile with a resisting moment applied at the mudline. The resisting moment capacity provided by the footings were estimated analytically using conventional bearing capacity theory and applied at the mudline acting in the opposite direction to the loading. This approach only considers the ultimate condition of the system and does not allow the moment

developed by the footing to be generated as a function of the footing rotation.

The results generated by this approach are illustrated in Figure 6 where it is shown how different pile to footing diameter increases the moment capacity of the piles, where this variation lies between a fully free and a fully fixed pile.

The dashed lines in Figure 6 show the ultimate moment capacities of the hybrid system. Although this method successfully leads to obtaining the ultimate load bearing capacity of the hybrid degree of rigidity (D.O.R 75%, 50% and 25% showing the ultimate capacity of the system when 75%, 50% and 25% of the ultimate moment at pile head is applied to the free headed pile) of the system are shown as a benchmark for comparing how different pile to footing diameters relate to the fully fixed moment. As apparent in Figure 6, increasing the size of the footing tends to increase the lateral load bearing capacity. As the footing size increases, it gets close to the fully fixed head condition. This also indicates that there for a given pile diameter and length, there ought to be a footing size after which increasing the footing size further will not enhance the lateral load bearing capacity of the foundation system.

Figure 6. Moment vs. rotation plot for the hybrid system with different pile to footing ratios.

In addition to this, design charts have been developed which relate the pile embedment length to pile and footing diameters. Numerous design charts have been developed covering a wide range of pile diameters, pile lengths, footing diameters and normalized moment capacities an example of which is shown in Figure 8 where the  $L/D$  ratios vary from 1 to 10 and the footing to pile diameter ratios varies from 0 to 1. The moment capacity of the hybrid system has been normalised and is shown against footing to pile diameter ratio. The lines in between represent different pile embedment depth where for a given moment capacity the designer could utilise this graph to choose the appropriate pile length as well as pile and footing diameters. It is also notable that for any given value of normalized moment capacity the designer has the option of choosing a short pile relatively large footing diameter, or long pile with relatively small footing diameter. The flexibility in this design approach is beneficial in particular designing the hybrid system in difficult soil conditions.

Figure 7. Example of a design chart for the hybrid system developed using analytical and numerical methods.

#### 4. DISCUSSION & CONCLUSION

It is apparent that the ultimate lateral response of a single monopile foundation can be enhanced by the presence of a footing resulting in a greater ultimate lateral capacity. This improvement was observed at both load versus deflection as well as the bending moment versus depth plots. Whilst the effect on the initial lateral stiffness may not be significant, the lateral stiffness beyond this initial movement was significantly enhanced through the presence of the footing.

The effect of adding skirts to the hybrid system has been shown to further increase the lateral performance of the hybrid system, and centrifuge tests are planned to investigate the skirted system in more detail.

A simple analytical approach using conventional lateral pile analysis methods is presented from which preliminary design charts can be generated. This approach can be developed to generate realistic design charts where the lateral capacity of the hybrid system is related to the development of bearing capacity coupled to the lateral resistance of the pile shaft.

# Influence of jack-up footprints on mudmat stability – How beneficial are 3D effects?

Influence des dépressions laissées par les jack-ups sur la capacité portante des mudmats – quels sont les effets bénéfiques d'une analyse en 3D?

Ballard J.-C., Charue N.  
*Fugro GeoConsulting Belgium*

**ABSTRACT:** Jacket platforms are piled into the seabed but need to be supported temporarily by mudmats during installation. They sometimes need to be located next to seabed features such as pug marks formed by previous deployments of jack-up rigs. These features may influence the bearing capacity of the mudmats. This is a 3D problem for which simplified approaches are unsatisfactory, simplified 2D plane strain simulations can lead to over-conservative results. This paper presents a project example in very soft clay for which the software package Plaxis 3D has been successfully used. The presence of a pug mark was found to degrade significantly the yield surface in the VHM load space. A comparison between 2D and 3D analyses shows that the beneficial 3D effects are substantial, especially when the pug mark is located at the corner of the mudmat. The zone of influence of the pug mark is also much more limited when the problem is modelled in 3D.

**RÉSUMÉ :** Les plateformes de type « Jacket » sont fondées sur pieux mais nécessitent d'être supportées temporairement pendant l'installation par des mudmats (fondations de type superficiel). Ces jackets sont parfois situées à proximité de dépressions laissées par l'installation antérieure de jack-ups. Ces dépressions peuvent influencer la capacité portante des mudmats. Il s'agit d'un problème 3D typique pour lequel aucune solution simplifiée n'existe. Une approche 2D (en état plan de déformation) peut même mener à des résultats trop conservatifs. Cet article présente un exemple dans de l'argile molle pour lequel la suite de logiciels Plaxis a été utilisée avec succès. Les conclusions sont les suivantes : la présence des dépressions modifie singulièrement la surface de rupture dans l'espace VHM. Une comparaison entre les approches 2D et 3D montre que les avantages à faire appel au 3D sont substantiels, spécialement quand la dépression est située à proximité du coin du mudmat. La zone d'influence de la dépression est aussi bien plus limitée lorsque le problème est modélisé en 3D.

## 1 INTRODUCTION

Jacket platforms are the most common type of offshore structure in the offshore hydrocarbons industry (Dean, 2010). They consist of open-framed steel structures made of tubular leg chords, horizontal bracing, and diagonal bracing. These structures are piled into the seabed but need to be supported temporarily by mudmats during installation. Mudmats are essentially flat stiffened metal plates attached to legs or the lower braces. In soft soils, mudmats can cover the entire surface between the legs to maximise the bearing area. They are generally subjected to combined Vertical, Horizontal and Moment (VHM) loads induced by the jacket weight, wind, waves and currents.

Jacket platforms are not always installed on a virgin seabed and are sometimes located next to features such as pug marks formed by previous deployments of jack-up rigs. A jack-up is a mobile, self-elevating offshore platform consisting of a hull and three or more retractable legs passing through the hull (McClelland et al, 1982). A unit moves onto location, sets its legs onto the seabed, and raises its hull out of the water. The legs are supported on independent foundations called spudcans. Penetration and extraction of spudcans in soft grounds create zones of remoulded soil and seabed depressions (Hossain et al, 2012). These seabed features potentially influence the bearing capacity of the mudmats and need to be accounted for in the stability verification.

Mudmats subjected to combined VHM loads and located next to a jack-up footprint is a 3D problem for which simplified approaches for analysis do not exist. Simplified 2D plane strain simulations are generally performed but they can lead to over-

conservative results. This type of problem is better analysed by means of 3D Finite Element (FE) analyses.

This paper presents a project example in very soft clay for which the software package Plaxis 3D (Plaxis, 2011) has been used successfully. The analysis allowed confidence to be established for the selected location of the mudmat with respect to a pug mark. In contrast, a simplified 2D analysis suggested that the proximity of the mudmat to the pug mark was unacceptable.

It is shown for this particular example how the presence of a pug mark degrades the yield surface in the VHM load space. 3D analyses are compared with 2D analyses to quantify the beneficial 3D effects for different pug mark locations.

## 2 PROBLEM GEOMETRY AND SOIL CONDITIONS

A 30 m by 30 m square mudmat is considered. The mudmat is located next to a circular pug mark of 30 m in diameter. Analyses were performed for 2 positions of the mudmat. The first position considers a pug mark located along the width of the mudmat while the second position considers a pug mark located at the corner of the mudmat, as illustrated on Figure 1. The distance  $d$  between the edges of the mudmat and the pug mark is varied in the analysis.

Soil conditions in this example consist of very soft clay. The soft deposit is considered to be 15 m thick and underlain by stiffer soils, which are not modelled. The intact undrained shear strength increases linearly with depth according to  $s_u = 4 + 0.8z$  (in kPa), where  $z$  is the depth below ground level in meter. This gives a strength heterogeneity  $\kappa = 6$  where  $\kappa = kB/s_{u0}$ ,  $k$  is the

shear strength gradient,  $B$  the mudmat width and  $s_{u0}$  the undrained shear strength at mudline.

A cylinder of soil with remoulded properties is considered to model the pug mark. This cylinder extends to the bottom of the soft layer. A 30 m diameter cylinder corresponds approximately to a 15 m diameter spudcan. The remoulded zone created by the penetration and extraction of a spudcan has indeed been observed to be of the order of 2 times the spudcan diameter (Hossain, 2012). On removal of the jack-up unit, the spudcans leave depressions at the site. The depth and configuration of the depression depends on several factors including soil strength, spudcan final penetration, amount of soil backfill during installation, etc. A seabed depression of 2 m is considered in this paper. To keep the model geometry simple, a horizontal depression with vertical walls is modelled, as illustrated in Figure 1. A remoulded undrained shear strength profile  $s_{ur} = 2 + 0.4z$  (in kPa), where  $z$  is the depth in meter below original ground level, is considered within the pug mark area.

Figure 1. Problem geometry: plan view and cross-section

### 3 FINITE ELEMENT MODEL

2D plane strain and 3D FE simulations were carried out using Plaxis (Plaxis, 2011). The 2D analyses only consider a pug mark along the width of the mudmat while the 3D analyses consider two positions for the pug mark: along the width and at the corner.

An example of 3D finite element mesh is shown on Figure 2. Similar mesh discretization was adopted for the different analyses. The external boundaries were set sufficiently remote so as not to intercept the different failure mechanisms.

Preliminary analyses were first performed for the base case without a pug mark and for which analytical and/or numerical solutions exist. The aim was to check for any effects due to mesh size on the accuracy of the solution. A compromise was found between the accuracy of the solution and computational time. It is estimated that the over-estimation of the true solution due to discretization errors was maximum 10% for the selected mesh, which was judged to be reasonable.

Figure 2. 3D Finite Element meshes

The soil is modelled as an isotropic elasto-perfectly plastic continuum, with failure described by the Mohr-Coulomb yield criterion. It is assumed to behave “undrained” and is characterized by a cohesion equal to the undrained shear strength  $s_u$  with  $\phi_u=0$ . The elastic behaviour was defined by a Poisson’s ratio  $\nu=0.495$ , and a constant ratio of Young’s modulus to undrained shear strength  $E/s_u=300$  for both undisturbed and remoulded clays.

The strength of the mudmat/clay interface is modelled using an interface factor  $\alpha$ , where the maximum shear stress at the interface  $\tau_{max} = \alpha s_u$ . The “rough” and “smooth extremes of interface strength correspond to  $\alpha = 1$  and  $\alpha = 0$  respectively. An intermediate roughness was assumed with  $\alpha = 0.5$ , which is a typical assumption for steel/soft clay interface. A no-tension condition allowing separation of the mudmat from the seabed was permitted at the mudmat/clay interface.

The jacket mudmat is modelled as a 30 m by 30 m rigid plain square plate. The seabed is assumed to be perfectly flat below the mudmat.

### 4 DESIGN PROCESS

The vertical load  $V$  from the mudmat and jacket structure is generally known and well-defined. It should typically be limited to a maximum of 50% the uniaxial vertical capacity. Then, for a given mobilisation ratio of the uniaxial vertical capacity  $v = V/V_{ult}$ , the stability verification consists of ensuring that there is adequate factor of safety on the ‘live’ loading  $M$  and  $H$ . This can be performed by comparing design load combinations to the MH failure envelope. The higher the mobilisation of the uniaxial vertical capacity, the lower the moment and horizontal capacity, i.e. the MH failure envelope shrinks with increasing  $v$ .  $M$  and  $H$  loads are applied in the direction of the pug mark centre, namely perpendicular to the side of the mudmat or along its diagonal.

The presence of a pug mark with remoulded soil conditions in the vicinity of a mudmat has two adverse effects. First, it affects the moment and horizontal capacities for a given  $v$ . Second, it reduces  $V_{ult}$  and therefore increases  $v$ , reducing further the moment and horizontal capacities.

## 5 RESULTS AND DISCUSSION

## 5.1 2D Analyses

The accuracy of the 2D FE model was verified by computing the uniaxial vertical capacity and comparing with results published in the literature. An interface factor at the mudmat/soil interface  $\alpha = 1$  was assumed for this comparison. A normalized vertical capacity  $V_{ult}/s_{uo}B = 10.45$  was found. This compares well with the analyses results published by Salgado (2008) who found 10.42 using ABC program (Martin, 2004). When the interface factor is reduced to  $\alpha = 0.5$ , the vertical capacity  $V_{ult}/s_{uo}B$  reduces to 9.8.

The MH failure envelope for the case without pug mark is shown on Figure 3 assuming a vertical load  $V$  so that  $v = 0.4$ , which is equivalent to a safety factor of 2.5 on the uniaxial vertical capacity. The results are plotted in a non-dimensional way:  $M/s_{uo}B^2$  versus  $H/s_{uo}B$ . This case is for an inter-distance  $d = 2$  m (i.e.  $d/B = 0.07$ ).

Figure 3. Influence of pug mark on MH failure envelope

A few comparison runs were performed with Limitstate:Geo v2 (Limstate, 2009). Limitstate:Geo is designed to analyze the ultimate limit (or “collapse”) state for a wide variety of geotechnical problems. The current version is however limited to 2D plane strain analyses. The ultimate limit state is determined using the Discontinuity Layout Optimization (DLO) algorithm (Smith & Gilbert, 2007). The agreement with the FE results is found to be excellent.

The effect of the pug mark on the MH failure envelope is significant. The normalized uniaxial vertical capacity  $V_{ult}/s_{uo}B$  is reduced to 5.5 leading to a mobilisation ratio  $v = 0.71$  instead of 0.4 (i.e. a safety factor of 1.4 instead of 2.5). The moment capacity is reduced by 55% to 80% depending on the applied horizontal load.

The inter-distance between the mudmat and the pug mark was then progressively increased and results are presented on Figure 4. The maximum moment capacity increases progressively with the inter-distance towards the capacity obtained for the case without a pug mark. From an inter-distance  $d/B = 0.2$ , the difference in mobilisation ratio of the vertical capacity does not affect the maximum moment capacity and, at an inter-distance  $d/B = 0.5$ , the pug mark has no effect at all.

Figure 4. Influence of pugmark / mudmat inter-distance on maximum moment capacity – 2D analyses

## 5.2 3D Analyses

The accuracy of the 3D FE model was also checked by computing the uniaxial vertical capacity for a square footing resting on soft clay, with  $s_u$  constant with depth and  $\alpha = 1$ , and comparing with available literature results. A normalized vertical capacity  $V_{ult}/s_{uo}B^2 = 5.96$  was found. This compares well with the results published by Gourvenec et al. (2006) who found 6.02. When the interface factor is reduced to  $\alpha = 0.5$  and  $s_u$  increases with depth (as defined in Section 2), the vertical capacity  $V_{ult}/s_{uo}B^2$  is about 9.1, which is slightly lower than the 2D plane strain capacity.

Similarly to the 2D plane strain FE analyses, the MH failure envelope for the case without a pug mark assumes a vertical load  $V$  so that  $v = 0.4$ . As discussed above and shown on Figure 1, the 3D analyses consider two positions for the pug mark: along the width and at the corner of the mudmat. The results are plotted on Figures 5 and 6 for the first and second positions, respectively, using the following non-dimensional groups:  $M/s_{uo}B^3$  and  $H/s_{uo}B^2$ . This case is for an inter-distance  $d = 2$  m (i.e.  $d/B = 0.07$ ). The moment capacity is not affected for small mobilisation ratios of the horizontal capacity. However, when  $H/s_{uo}B$  approaches 0.5, the failure mechanism switches rapidly from a general shear mechanism to a sliding mechanism.

For the first position (along the width), the effect of the pug mark on the MH failure envelope is noticeable but not as significant as for the 2D plane strain simulations. The normalized uniaxial vertical capacity  $V_{ult}/s_{uo}B^2$  is reduced to only 8.4 leading to a mobilisation ratio  $v = 0.44$  instead of 0.4 (i.e. a safety factor of 2.29). The moment capacity is reduced by 20% to 28% depending on the applied horizontal load. There is very little difference in the results between a vertical mobilisation factor of 0.4 and 0.44 (Figure 5).

Figure 5. Influence of pug mark on MH failure envelope – Position 1 (along width of mudmat)

For the second position (at the corner), the normalized uniaxial vertical capacity is not affected, meaning that the safety factor for a pure vertical load remains 2.5. The moment capacity is only reduced by 1 to 3 % (Figure 6) depending on the applied horizontal load. This is a negligible difference.

Figure 6. Influence of pug mark on MH failure envelope – Position 2 (at mudmat corner)

Similarly to the 2D plane strain approach, the inter-distance between the mudmat and the pug mark was progressively increased for the position of the pugmark along the width of the mudmat and the results are presented on Figure 7. The maximum moment capacity increases progressively with the inter-distance towards the capacity obtained for the case without pug mark. From an inter-distance  $d/B = 0.25$ , the pug mark has no effect anymore. This result illustrates the benefit of considering a more realistic 3D analysis when facing this kind of problem. The inter-distance required to have no influence of the pug mark in the 3D model is half the inter-distance required in the 2D plane strain model.

Finally, Figures 5 and 6 allow the comparison of the effect of the orientation of the moment and the horizontal loads on the MH envelope. The moment capacity for the loads in the direction of the corner is about 5% lower than for the case where the loads are towards the width of the mudmat. This geometrical effect is however limited.

Figure 7. Influence of pugmark / mudmat inter-distance on maximum moment capacity – 3D analyses

### 5.3 Conservativeness of 2D Analyses

Simplified 2D plane strain and more realistic 3D simulations give similar results if the pug mark is not considered.

In the case where the pug mark is located along the width of the mudmat, the MH failure envelope is degraded in both 2D and 3D analyses. However, the effect is significantly larger in the 2D analyses for which the moment capacity is reduced by

55% to 80% depending on the applied horizontal load. In the more realistic 3D analyses, the moment capacity is only reduced by 20 to 28%. When the pug mark is located at the corner of the mudmat, the 3D analyses show very little impact on the mudmat capacity.

The analyses show also that the distance of influence of the pug mark on the mudmat stability is 2 times less in 3D compared to 2D analyses. The maximum moment capacity is not affected from an inter-distance  $d/B = 0.25$  in 3D analyses while the distance is  $d/B = 0.5$  in 2D analyses.

## 1 CONCLUSION

The presence of a pug mark has been found to degrade significantly the yield surface of a square mudmat in the VHM load space. However, a comparison between simplified 2D plane strain and 3D analyses has shown that the beneficial 3D effects are substantial. If the pug mark is located along the width of the mudmat, the more realistic 3D model shows that the moment capacity is only reduced by 20 to 28% depending on the applied horizontal load. The impact of the pug mark is significantly larger when a more simplified 2D plane strain approach is followed. Moreover, in the particular example treated in this paper, it was observed that a pug mark located at the corner of the mudmat does not influence its stability. The zone of influence of the pug mark is also much more limited when the problem is modeled in 3D and the orientation of a complex VHM loading scheme can be considered in the global stability. Simplified 2D plane strain simulations can lead to over-conservative results for this particular problem.

# Design and installation of buried large diameter HDPE pipelines in a coastal area

## Project et installation de tuyaux enterrés de grand diamètre en zone côtière

SPS - Società Progettazione Servizi s.r.l., Ancona, Italy

**ABSTRACT:** The present paper deals with the main geotechnical aspects of the design and installation of two adjacent HDPE large diameter pipelines along the Adriatic Sea (Italy) coastline. The pipelines -270 m in length and 2 m in diameter - are conceived as buried collectors of polluted runoff water, to convey to sanitation prior to discharge into the sea. Considering that pipes are below the water table uplift analysis is detailed, showing three possible approaches in static conditions, whereas in seismic conditions a method is proposed that include the build-up of pore-water pressures during earthquake. As far as prediction of vertical deflection is concerned, the backfill loosening due to sheet piles extraction has been modelled by assuming no compaction (dumped backfill). Despite this assumption, theoretical short term deflection represents a lower bound of measured deflections.

**RÉSUMÉ :** Cet article décrit les principales problématiques géotechniques du projet et de l'installation de deux tuyaux enterrés adjacents de grand diamètre sur le littoral adriatique italien. Les tuyaux – longs de 270 m - ont la fonction de collecteurs enterrés pour l'eau de ruissellement polluée, pour permettre sa dépollution avant du déchargement dans la mer. En considérant que les tuyaux se trouvent au-dessous du niveau de la nappe d'eau on a analysé le problème du possible soulèvement en conditions statiques utilisant trois différentes méthodes. En conditions sismiques on a proposé une méthode qui considère le développement de pressions interstitielles positives excessives durant le tremblement de terre. L'ovalisation du tuyau a été calculée par une méthode de littérature en considérant un remblai sans compactage pour tenir compte de l'extraction des palplanches utilisées pendant l'excavation de la tranchée. Les valeurs calculées de l'ovalisation initiale représente un limite inférieur de l'ovalisation mesurée.

Keywords : uplift, pipe of large diameter, deflection

## 1 INTRODUCTION

Urban and infrastructural development often involves vulnerable areas such as coastlines. To prevent pollution of the sea from runoff water of a nearby urban area and crowded roads a system of buried collectors are to be built along a stretch of the Italian shoreline of the Adriatic Sea. In such a way, the collected runoff water will be conveyed to sanitation before discharging into the sea. A preliminary hydraulic study allowed to define different drainage basins, and for each basin an adequate collector is required. This paper deals with the design and execution of the first part of the system, concerning a collected water volume of about 1300 m<sup>3</sup>, for which the designers opted to realise the collectors by two adjacent buried pipelines of 2000 mm in internal diameter and 270 m long.

The design and execution of geotechnical works in coastal area must in general face regulatory requirements, environmental and aesthetic concerns, public attention.

As far as engineering problems are concerned, the designer must take into account the objective difficulties connected with the critical location (e.g., underwater excavation, tidal and storm waves, risk of uplift). For the specific case, additional constraints are represented by the closeness of the working area to an important railway (Figure 1), and consequent limited accessibility for materials and machinery. Moreover, local authorities required to minimize the working area, avoiding the occupancy of the beach for the overall length of the collectors through the entire duration of the works. To comply with this requirement, a staged execution was envisaged.

## 2 OUTLINE OF THE DESIGN

### 2.1 Pipe material

Corrugated HDPE pipes were selected (Table 1). HDPE offer in general significant advantages in terms of costs, corrosion resistance, ease of handling and jointing over more traditional materials such spheroidal cast iron. The selected HDPE pipes are manufactured in modules 6.0 m long (less than other materials, e.g., cast iron) which allowed solving the problem linked to area accessibility. In particular with the use of 6 m long modules it is possible to reach the beach area passing through a narrow railway underpass. For longer pipe modules, a more expensive marine transportation would be requested.

Figure 1. Plan view of the working area

Table 1. HDPE Pipe properties

Parameter	
Weight for unit length (kN/m)	2
External diameter (mm)	2240
Internal diameter (mm)	2000
Moment of Inertia (mm <sup>4</sup> /mm)	45899
Young modulus short term(MPa)	1185
Young modulus long term (MPa)	288

## 2.2 Underwater excavation

The soil stratigraphy is essentially composed by a sandy layer 3.5-4.0 m thick overlying a cohesive bed. An open standpipe piezometer installed close to the working area (Fig.1) indicated that the groundwater table is located 1.0-1.5 m below the ground level. Fig.2 shows a typical CPT profile with the characteristic values of geotechnical parameters obtained by laboratory and in situ tests.

Considering the large pipe diameter, the bedding layer and a minimum soil cover to counteract buoyancy (as detailed later), an excavation depth of at least 4.70 m was necessary. Moreover, a minimum inclination of 0.5% to the horizontal is required to ensure gravity flow. This results in an excavation depth ranging from 4.7 m to 6.0 m from ground surface.

Various techniques were considered for the excavation. Unsupported trench with inclined sidewalls was excluded due to excessive breadth to ensure stability and the need for continuous dewatering by well-points. Other equally suitable technologies, (e.g., soil freezing), were incompatible with the budget.

The selected solution consisted in a 6.1 m wide trench supported by strutted sheet piles, embedded in the impervious clay layer. The total length of the sheet piles varied between 8 m and 10 m as depending on excavation depth. Sheet piling allowed retaining the vertical trench walls, minimizing seepage into the trench and protecting the working area from tidal and storm waves (the top of sheet piles was +1 m above g.l., Fig. 2).

To comply with the requirement of minimizing occupation of the area, the installation of the collectors (270 m) was realized in four distinct segments (i.e. the excavation in a zone starts only after the work in the previous zone is completed). For the first segment, sheet piles were preliminarily installed to enclose a rectangular excavation zone, creating a continuous barrier to groundwater along the entire perimeter. For the subsequent segments, the presence of the installed pipes prevented to create rectangular hydraulic barrier by sheet piles only. Therefore, cast-in-place concrete waterproof screens were designed around the protruding edge of the pipes to block seepage due to extraction of sheet piles from the adjacent completed segment.

## 2.3 Pipe uplift

During the service phase the pipelines are expected to be only rarely filled by runoff water but permanently submerged by groundwater and then subjected the buoyancy. Consequently, the design shall be checked against failure by uplift.

Figure 2. Simplified sketch of the excavation geometry with geotechnical soil characterization and a typical cone resistance profile.

According to Italian Building Code (NTC, 2008), as well as Eurocode 7 (2004), for any mass potentially subjected to the failure mechanism, the following inequality must be satisfied:

$$V_d \leq G_d + R_d \quad (1)$$

where  $V_d$  is the design destabilizing action acting upwards (obtained by a partial factor  $\eta_1 = 1.1$  in static conditions),  $G_d$  is the design stabilizing permanent action including the weight of the mass subjected to uplift (obtained by a partial factor  $\eta_2 = 0.9$  in static conditions) and  $R_d$  is the design soil resistance by friction along the vertical contours of the assumed block.

Considering the closeness of pipes to the sea (Fig. 1) it can not be excluded that in the future a portion of the soil above the pipe can be eroded. To confer protection against erosion a cast-in-place concrete slab (6.05 m wide and variable thickness) is realized above the pipes, as illustrated in Figure 3. This solution allows also to increase the average unit weight of the material above the pipes and enlarge the size of the block subjected to uplift. Finally, it represents a protection against accidental damage due to anthropic activities and the superficial sand layer enables to continue the recreational use of the beach.

In the application of Eq. (1) different approaches can be adopted to calculate the term  $V_d$  and in  $G_d$ . Eurocode 7 indicates a total stress analysis for uplift problems (EC7, 2004 §10.2). According to this approach,  $V_d$  is the upward resultant of pore water pressure acting on the lower boundary of the assumed block. Consistently,  $G_d$  includes the total weight of the soil block above the pipes. However, following this approach, the resultant of pore water pressure acting downwards is multiplied by a partial safety factor ( $\eta_1 = 1.1$ ) different to that applied to the vertical upward resultant ( $\eta_2 = 0.9$ ). This results in a violation of the “single source principle” enunciated by Eurocode 7 (EC7, §2.4.2). According to this principle, when destabilising and stabilising permanent actions come from a single source, “a single partial factor may be applied to the sum of these actions or to the sum of their effects”. Based on the above considerations, in the second approach the destabilizing action is assumed to be the buoyancy force on the two submerged pipes (i.e. the weight of the water displaced by the pipes  $W_w$ ). Consistently,  $G_d$  includes the submerged weight of the block above the pipes. Finally, a third approach can be used in which the destabilizing action is assumed to be the resultant buoyant force of the submerged pipes, i.e. the algebraic sum of weight of displaced water  $W_w$  and weight of pipes  $W_p$  (WSSC, 2008). This latter approach implies that the check against failure by uplift is automatically verified when  $W_w < W_p$ .

The three approaches described previously are applied assuming the simplified sliding surface shown in Fig. 3, which implies a failure mechanism involving pipes, slab and soil above and between the pipes as well (hatched zone in Fig.3). The results were obtained for the worst-case scenario of complete erosion of the superficial sand layer ( $h_3 = 0$  in Fig 3) and minimum cover thickness above the pipes ( $h_1 + h_2 = 0.5$  m,  $s = 0.6$  m). The unit weight of concrete and saturated soil were 23.5 kN/m<sup>3</sup> and 20.3 kN/m<sup>3</sup> respectively.

The  $R_d$  term was calculated as the sum of the friction forces along the vertical planes on each side of the assumed block (BC, B’C’, DE, D’E’)

$$R_d = \gamma' K_s \frac{\tan \delta_{BC}}{\eta_3} s^2 + \gamma' K_s \frac{\tan \phi_k}{\eta_3} \left[ (s + h_1 + h_2 + R_e)^2 - s^2 \right] \quad (2)$$

where  $\delta_{BC}$  is the interface friction angle between concrete and the sandy soil ( $\delta_{BC} = 30^\circ$ ),  $\phi$  is the shear resistance angle of the granular backfill,  $\eta_3 = 1.25$  is the partial safety factor applied to the shear strength parameters. The angle  $\phi_k$  after backfilling is assumed to be  $40^\circ - 42^\circ$ , but a reduced value of  $38^\circ$  is assumed in eq. (2) owing to potential loosening induced by sheet pile

extraction.  $K_s$  is the lateral earth pressure coefficient assumed conservatively equal to 0.5 by neglecting the effect of compaction.

Results of static analysis of uplift failure (Table 3) indicate that, as expected, the second and third approaches are less conservative in static conditions; however they appear to better represent the physical reality (i.e. the destabilizing force on a fully submerged pipe is independent of the depth below the water table).

In seismic conditions, Italian Building Code (NTC, 2008 §7.11.1) requires that Eq. (1) shall be checked using  $\eta_1 = \eta_2 = I$ , which result in uniqueness of the approach in seismic analysis (i.e. the difference between  $G_d$  and  $V_d$  is the same using a total stress analysis or an effective stress analysis).

Using a pseudo-static approach the vertical inertial force  $F_V$  acting on pipes, soil, concrete is assumed upwards and proportional to relevant weights by the seismic coefficient  $k_v$  ( $=0.046$ ) defined in Italian Building Code (NTC, §7.11.3.5.2).

It is well recognized that in the presence of earthquake, a build-up of pore water pressures can occur with respect to static conditions. A simplified procedure to account for this phenomenon is the introduction of the pore-pressure coefficient  $r_u = \Delta u / \sigma'_{v0}$  assumed constant with depth (e.g. Ebeling and Morrison, 1992; Kramer, 1996). Accordingly, the unit weight of water and submerged soil are given by:

$$\gamma_{we} = \gamma_w + r_u \gamma' = \gamma_w + r_u (\gamma_{sat} - \gamma_w) \quad (3)$$

$$\gamma'_e = \gamma' (1 - r_u) = (\gamma_{sat} - \gamma_w) (1 - r_u) \quad (4)$$

For  $r_u = 1$  soil liquefaction occurs which implies that (a) upward action acting on pipes is proportional to  $\gamma_{we}$  ( $= \gamma_{sat}$ ) instead of  $\gamma_w$ , and (b) the submerged weight of the soil block and soil resistance  $R_d$  vanish.

In seismic analysis the coefficient  $r_u$  shall be selected on the basis on seismic input (magnitude and maximum acceleration), as well as soil characteristics. In the analyzed case the presence of a coarse backfill (gravel) around the pipes (Fig.3) is expected to strongly limit the build-up of pore water pressure. Hence, the seismic analysis of uplift are performed assuming  $r_u = 0$  and  $r_u = 0.1$ . Results of seismic analysis shown in Table 3 indicate that also for  $r_u = 0.1$  the inequality (2) is satisfied.

## 2.4 Pipe deflection

Flexible conduits fail by excessive deflection rather than by rupture of the pipe wall. It is necessary, therefore, to estimate the deflection of this type of conduit and to establish limits of allowable deflection for the proposed installation.

Table 3. Uplift analysis

Action (kN/m)	Static conditions			Seismic conditions	
	appr.1	appr.2	appr.3	$r_u = 0.1$	$r_u = 1$
$V_d$	174.1	86.6	82.3	86.6	159.9
$W_{pipes}$	4.0	4.0	-	4.0	4.0
$W_{soil}$	87.6	44.4	44.4	40.0	0
$W_{slab}$	85.3	49.0	49.0	45.3	11.6
$F_v$	0	0	0	-8.1	-8.1
$G_d$	159.2	87.7	84.1	81.2	7.5
$R_d$	15.6	15.6	15.6	13.4	0
$R_d + G_d$	174.8	103.3	99.7	94.6	7.5

Figure 3. Details of pipe installation

For flexible conduits the vertical deflection  $\Delta y$  mainly depends on the actual load acting on the pipe and the stiffness of the backfill at the side of the pipes whereas the contribute of pipe stiffness is generally small (i.e. Rogers et al. 1995). In the specific case, the presence of two pipes as well as of the concrete slab makes the analysis more complex than the classical solutions available in the literature.

### 2.4.1 Load on pipes

According to Young and Trott (1984), the pair of pipes can be considered as equivalent to a single pipe of overall width  $D'$  where  $D' = 2D_e + d$ . The load on  $D'$  is calculated by taking the lesser of the two values obtained by the complete ditch condition ( $P_1$ ) and the positive projection condition ( $P_2$ ). This load is taken as being shared equally by the two pipes.

The load acting on a pipe (stiffer than side fill) in a trench with a partially submerged homogeneous backfill (see Fig.3) is given by Bulson (1985):

$$P_1 = \frac{B^2 \gamma}{2\lambda} \left[ 1 - \exp\left(-\lambda \frac{2H}{B}\right) \right] - \frac{B^2 \gamma_w}{2\lambda} \left[ 1 - \exp\left(-\lambda \frac{2H_w}{B}\right) \right] \quad (5)$$

where  $\lambda$  is a coefficient ranging from 0.11 to 0.19 depending on soil type,  $\gamma$  is the total unit weight of backfill. In the analysed case actual backfill unhomogeneity is accounted for by assuming a weighted average unit weight ( $\gamma_{av}$ ).

For a positive projection conduit the  $P_2$  value depends on the relative settlement between the soil prism above the pipe and the adjacent soil, which determines positive or negative arching. In the specific case, the presence of the slab prevents the occurrence of complete ditch or projection conditions. Moreover, considering that the ratio  $H/D'$  is very small, it is reasonable to neglect arching. Therefore, the value of  $P_2$  is assumed to be the weight of overlying prism of width  $D'$ .

Obviously, the maximum deflection is expected to occur at the section with the maximum cover (3.30 m) with the lowest groundwater level (-1.60 m below g.l.). With reference to Figure 3, for  $h_1 = 1$  m,  $s = 0.30$  m,  $h_2 = 1.7$  m,  $h_3 = 0.3$  m,  $H_w = 1.7$  m  $\gamma_{av} = 20.85$  kN/m<sup>3</sup>  $\lambda = 0.19$ ,  $P_1$  and  $P_2$  are calculated as 281 kN/m and 264 kN/m, respectively. Following the suggestion of Young and Trott (1985), the load acting on a single pipe ( $P$ ) is taken as 132 kN/m.

### 2.4.2 Backfill

A large part of ability of flexible pipes to support vertical load must be derived from the passive pressures induced as the sides move outward against the soil. Therefore, any attempt to analyse the behaviour of the flexible conduits must take into account the soil at the sides as an integral part of the structure, since such a large proportion of the total supporting strength is attributable to the side material.

Considering that compactive effort is restricted by the geometry of the trench and the difficult in compacting underneath the pipe in the haunch zone (Fig.3), as well as the

sensitivity of installed flexible pipe to compaction of material around it, a clean gravelly soil has been selected as structural backfill (i.e. the part of backfill that extends from the base of the bedding to a maximum of 30 cm above the pipe, as shown in Fig.3). This coarse-grained soil is preferred over native silty sand for easy of compaction, high earth pressure response and stability when saturated and confined. The same material – well compacted - has been used also as bedding soil (Fig.3).

#### 2.4.3 Calculation of pipe deflection

The pipe deflection is predicted by the method of Spangler (1941) or Iowa formula, although it is well recognized that this method contains some debatable assumptions.

$$\Delta y = \frac{D_L \cdot K \cdot P}{EJ/R^3 + 0.061E'} \quad (6)$$

where  $\Delta y$  = vertical deflection of pipe (m);  $P$  = vertical load on the pipe (MN/m);  $EJ$  = flexural pipe stiffness (MNm<sup>2</sup>/m);  $R$  = mean radius of the pipe (m);  $D_L$  = time-lag factor (-);  $K$  = bedding constant ( $K = 0.1$  for bedding angle  $\alpha = 60^\circ$ , see Fig.3).  $E'$  = horizontal modulus of soil reaction (MPa).

Considering the absence of vehicular loading and the prevalent recreational use of the site, live loads have been neglected. In design the sheet pile extraction is accounted for using the value of  $E'$  relevant to a dumped backfill (Table 4). In long term analysis a time lag factor of 1.5 and a reduced pipe stiffness are considered (see Table 1). With the above assumptions short term and long-term deflections are calculated as 10.1 cm and 20.5 cm, respectively.

Numerous authors have reported that pipes have been distorted by 10-20% and still continue to perform adequately. Therefore the theoretical deflections have been considered acceptable, but a monitoring activity was planned during installation.

### 3 COMPARISON OF ACTUAL AND THEORETICAL DEFLECTIONS

The large diameter of pipelines allowed accessibility and direct measurement of vertical diameter at prescribed positions during the various stages of installation (structural backfilling, slab, final backfilling and sheet piles extraction). The trend of measured vertical deflection versus time is not monotonic, showing an initial small deflection, followed by a slight decrease, a sharp increase and a final stabilisation. The observed trend can be ascribed to the variation of the acting loads (backfill height and groundwater level) and the different lateral support offered by the soil before and after the extraction of sheet piles. Therefore, for the comparison between actual and theoretical deflections, only the stabilised values are considered because they better represent the service conditions of the pipes, with the groundwater level certainly above the crown of the pipes.

With reference to a pipe stretch 45 m long the vertical deflections were measured in sections spaced 3 m apart. Final (stabilized) deflections are shown in Fig. 4. In spite of a quite uniform cover height the measured deflections vary considerably along the pipeline with a minimum of 7 cm to a maximum of 15 cm. This behaviour can be attributed mainly to inherent differences in compacting the soil beside the pipes and variable effect of sheet pile extraction. Moreover, variability in stiffness of native soil can influence the overall response owing to the closeness of pipes to trench sides.

Considering that measurements refer to a design cover height ranging from 2.15 m to 2.37 m, the vertical deflection is calculated by (6) for an average cover height  $H = 2.26$  m. The load on pipe ( $P = 104$  kN/m) is calculated following the suggestion of Young and Trott (1984) discussed previously. The groundwater level was assumed at 1.6 m below the ground

surface ( $H_w = 0.66$  m) based on measurement in the nearby piezometer. As shown in Fig. 4, the theoretical deflection calculated by Spangler method is lower than the actual average deflection. This can be ascribed to effect of sheet pile extraction which results in a loosening of backfill and a probable increase of the load on pipes to due to negative arching.

Table 4. Values of  $E'$  for a clean coarse-grained soil (Howard, 1977)

Degree of compaction	dumped	slight	moderate
$E'$ (MPa)	1.4	6.9	13.8

### 4 CONCLUSIONS

In the present paper some aspects of design and installation of two adjacent large diameter pipelines along the Adriatic Sea coastline in Italy are described.

Uplift analysis is detailed, showing three possible approaches which lead to different results in static conditions, whereas in seismic condition a unified approach is proposed that account for build-up of pore-water pressures.

As far as prediction of vertical deflection is concerned, in the analyzed case the backfill loosening due to sheet piles extraction has been modelled by assuming no compaction (dumped backfill). Despite this assumption, theoretical short term deflection represents a lower bound of measured deflections.

# Geotechnical Exploration for Wind Energy Projects

## Compagnes géotechniques destinées aux parcs éoliens

Ben-Hassine J.

*Renewable Energy Systems Americas Inc., Broomfield, Colorado, USA*

Griffiths D.V.

*Colorado School of Mines, Golden, Colorado, USA*

**ABSTRACT:** Wind energy projects are often fast-paced and cover large terrains. Such conditions result in increased geotechnical risks and require specially adapted geotechnical exploration and data analysis techniques that are designed to manage risks at different stages of project development. Use of geophysical methods, in addition to the traditional subsurface exploration methods, is generally required to collect design critical data. During the early stages of project development, using quick qualitative geophysical methods can prove advantageous for finalization of wind farm layout and preliminary foundation design. However, as project plans progress, a more thorough geotechnical investigation is required. At all stages of a project, an understanding of the available geotechnical tools, along with their associated risks and cost implications is essential to minimize the likelihood of design changes that result in cost over runs. This paper presents geotechnical exploration methods used at different stages of project development and discusses key geotechnical parameters for wind turbine foundation design, available geotechnical tools, and the degree of confidence associated with these tools. The paper makes an attempt to present an exploration approach that is optimized for efficiency and risk.

**RÉSUMÉ :** Les projets d'énergie éolienne sont souvent réalisés dans un contexte d'exécution rapide et couvrent des terrains de grandes envergures. Ces conditions présentent des risques géotechniques accrus et nécessitent des compagnes d'exploration géotechnique et des techniques d'analyse de données spécialement bien adaptées pour gérer les risques à différentes étapes du projet. Le recours à des techniques géophysiques en plus des méthodes d'exploration traditionnelle est généralement requis pour obtenir les données critiques. Durant les premières étapes du projet, le recours à des méthodes géophysiques qualitatives et rapides peut s'avérer plus avantageux pour établir " la faisabilité du projet, " le plan d'implantation du projet et la conception préliminaire des fondations. Toutefois, dans les étapes plus avancées, une étude géotechnique plus poussée doit être réalisée. A toute étape, une connaissance adéquate des méthodes géotechniques disponibles, des risques et coûts qui leurs sont associés est essentielle pour minimiser l'éventualité de changements à la conception résultant en dépassement de coûts. Cet article est un essai de présenter une approche d'exploration optimisant l'efficacité et le risque.

**KEYWORDS:** geotechnical exploration, risk management, wind energy, efficiency.

## 1 INTRODUCTION

The period leading up to an operational wind energy plant starts several years before construction and can be divided into three overlapping phases: project development, engineering design, and project construction (Figure 1). During the development phase, various risk types and sources are evaluated and decisions are made to maintain, modify, or abandon the project. During the engineering design phase, decisions are made to refine the design while maintaining acceptable levels of risk. Any subsequent changes to the design typically result in additional cost. This paper focuses on geotechnical risks, particularly how such risks are being addressed currently and how this process may be improved. The objective is to assess risks and catch flaws as early as possible in the project development phase while there are still opportunities to make changes before significant development funds are spent. As in all large expenditure projects, early decisions have the greatest impact on financial performance. The motivation of this paper is to minimize the cost of civil infrastructure related to wind energy projects (turbine foundations, access roads and facilities such as the substation and the operation and maintenance building) through a rational redistribution of the geotechnical exploration effort. It has been estimated that civil infrastructure accounts for 4 to 10% of the total wind energy project cost. Given the thin profit margins of wind energy projects, a 2% saving can make the difference between whether a project goes ahead or is shelved.

Figure 1. Overlapping phases leading up to a wind energy plant.

## 1 PROJECT REALISATION PHASES

All three project phases (development, design, and construction) involve some level of geotechnical risk assessment and management, with most of this effort currently focused at the engineering design phase. Current and proposed activities related to geotechnical risk assessment for each phase are described below.

### 1.1 Project Development Phase

During the project development phase, the developer is usually focused on wind resource assessment, land agreements, power purchase agreements, and identifying potential investors. The geotechnical aspect is secondary and is typically limited to site visits and reporting of surficial characteristics such as terrain topography, accessibility, proximity to bodies of water, etc. The initial environmental permitting effort presents an opportunity to identify geotechnical conditions that carry cost implications as most environmental permitting efforts include an evaluation of geo-environmental conditions. However, the development phase of a wind project rarely includes geotechnical field investigation activities. However, the development phase is the most opportune time to identify significant geotechnical risks. The findings of a preliminary geotechnical investigation conducted during the development phase rarely render the project non-pursuable. However, preliminary geotechnical investigations are critical to proper planning and allocation of risks to the appropriate stakeholders. The achievement of the benefits of this proposed shift can be formalized through techniques such as geostatistics, Bayesian updating, statistical inference and neural networks (Christian et al. 2006 and Lin and Hung 2011). An immediate benefit of a more holistic development phase exploration is to focus the detailed exploration effort on the critical issues or portions of the project area. In addition to desk studies, recommended development phase exploration techniques include:

- Geophysical surveys using seismic methods such as Multi-Analysis of Surface Waves (MASW) at all proposed turbine locations, possibly excluding locations where rock is at the surface. An MASW survey provides depth profiles of shear and compression wave velocities. The information is used to gain an insight into site stratigraphy and to estimate elastic moduli needed to verify foundation stiffness requirements. The MASW survey, conducted at the project development phase, helps to identify soft locations or locations with potential difficulties as an aid to micrositing of turbines. This exercise lessens the likelihood of needing very large foundations or performing costly ground modifications at soft sites. MASW surveys are also quick and relatively low cost, making them the ideal qualitative tool that is suited for the development phase.
- Preliminary geotechnical exploration borings using a limited number of traditional SPT, SCPT, CPT, or DMT borings spread over different portions of the project area. Exploration pits may also be used along planned access road alignments. Information obtained through site visits and review of available published information and online maps can be used to decide on the locations of the preliminary borings so that the captured range of variability is as wide as possible. Information from the preliminary exploration is used to assess the type and range of variability of site geomaterials, to identify potential foundation types and to plan the full investigation. For example, if a gravity base (shallow) foundation is deemed feasible, an effort should be made at the project development stage to assess the depth range of the stationary groundwater table in order to decide if buoyancy will be a design consideration. If soft materials are encountered requiring consideration of deep foundations, the depth of borings during the full investigation can be adjusted.
- The preliminary geotechnical exploration should also include electrical and thermal resistivity testing as this input is critical to sizing the electrical collection system which is associated with a significant share of project cost.

### 1.2 Engineering Design Phase

During this phase, a full geotechnical investigation must be carried out to finalize the design. The full geotechnical study is designed to complete the investigation and to fill the gaps remaining after the preliminary exploration. The full investigation should confirm and refine the assessment of the

risks identified during the preliminary investigation and should assess any additional risks that may be uncovered. At a minimum, standard practice includes at least one exploratory boring at every turbine location extending to a depth of interest not less than the largest base dimension of the structure (DNV/Risø 2002, GL 2010). For a typical shallow foundation used to support wind turbines, the explored depth is 1 to 1.5 times the foundation diameter. Common current practice is to perform geophysical testing during the full investigation phase at a limited subset (approximately 10%) of turbine locations. In the proposed redistribution of effort, a more extensive geophysical survey is recommended at the development phase. A non-exhaustive list of risks that should be assessed as early as possible during the development and preliminary design phases (but prior to the final design phase) is shown in Table 1. Geotechnical exploration activities help in identifying these risks but are not the sole resource.

Table 1. Non-exhaustive list of potential wind farm geotechnical and geo-environmental risks (in no particular order).

No.	Risk	Identification tools
1	High groundwater	Drilling, excavation pits, monitoring wells and permeability testing.
2	Flooding, storm surge, tsunami	Records, maps
3	Shallow bedrock / blasting	Visual, drilling, MASW
4	Slope stability & landslides	Visual, geologic study
5	Mine subsidence	Records, LiDAR, maps
6	Coal seams	Drilling, records
7	Karst subsidence, caves & voids	Records, drilling, LiDAR, maps, type of underlying rock, groundwater regime
8	Shrink/swell (expansive) soils	Laboratory testing
9	Frost heave	Records, climatic data
10	Permafrost	Records, climatic data
11	Freeze-thaw	Climatic records
12	Collapsible soils	Laboratory testing
13	Excessive consolidation / tilt	Laboratory testing
14	Aggressive environments: high sulfates, high salinity, corrosion	Laboratory testing
15	Alkali-Silica Reaction (ASR)	Testing, local information
16	Peat bogs and soft grounds	Visual, drilling, MASW
17	High seismicity / liquefaction	Exploration, design codes
18	Hurricanes	Records, design codes
19	Volcanic activity	Records, geologic study
20	Scarcity of gravel / road base	Visual, local information
21	Buried pipelines & infrastructure	Records
22	Forest logging roads	Drilling, excavation pits
23	Drifting sands	Visual, local information
24	High soil electrical resistivity	Field and lab testing
25	High soil thermal resistivity	Field and lab testing

### 1.3 Project Construction Phase

During the construction phase, geotechnical activity is typically limited to quality assurance testing which serves to confirm and ensure that the design assumptions remain valid. This is the phase where risks missed during the earlier phases may become apparent with the potential for project cost overruns.

Rarely would geotechnical input in this phase result in cost savings. However, *value engineering* where the balance of plant (BOP) contractor is provided an opportunity to redesign is becoming more popular. Value engineering often occurs shortly before construction or as the BOP contractor is mobilizing to construct the project. Ironically, the likely reason for value engineering is the tendency of the original designer to err on the conservative side because of compressed schedules and/or lack of substantive geotechnical basis of design at the end of the development phase, creating opportunities for the BOP contractor to cut costs at the last minute.

### 1.4 Summary of Current and Proposed Practice

Table 2 shows a summary of current and proposed practice. The essence of the proposed redistribution of the geotechnical exploration effort is to advance the geophysical survey and the preliminary investigation to the development phase (P1). Details of the geotechnical activities for the proposed redistribution are shown in Table 3.

Table 2. Common and proposed geotechnical effort.

Phase	Common			Proposed		
	P1	P2	P3	P1	P2	P3
Desk study	X			X		
Geophysical survey		X		X		
Preliminary investigation		X		X		
Full investigation		X			X	
Assurance & validation			X			X

## 2 SOURCES OF UNCERTAINTY

Wind energy projects differ from most traditional projects in that they cover large terrains. Wind turbines are typically placed 5 to 10 rotor diameters apart to optimize energy extraction (Denholm et al. 2009). Nowadays, typical rotor diameter for large wind turbine generators is around 120 meters, signifying turbine spacing of 0.5 to 1 kilometer just for energy extraction efficiency. Therefore, wind turbines are too far apart to consider any relationship between ground conditions from one turbine location to another. This is separate from regional or larger scale characteristics which may be applicable to the project area or portions of it, such as those related to different geologic settings or terrains. Turbine structures themselves are also unique due to the nature of loading they impart to foundations and supporting soils in terms of type, magnitude and variation. Thus, in addition to increased uncertainty due to essentially independent conditions at turbine locations, these projects also require parameters unique to these structures such as those needed to ensure adequate foundation stiffness.

Generally, there are three main sources of uncertainty in a geotechnical design property: i) inherent soil variability, ii) measurement error, and iii) transformation error (see Baecher and Christian 2003, Phoon and Kulhawy 1999). Often, a design parameter is not measured directly in-situ or in a laboratory test but is calculated based on other measured properties. Two of the above sources (inherent variability and measurement error) are associated with the measured property. The third source is associated with uncertainty in the selected transformation model, i.e., the empirical or theoretical relationship used to calculate the design property from the measured properties. Point estimates, as well as spatial variability of various shear strength, mechanical and index properties, are available in the literature (e.g., Lee et al. 1983). This information can be used to select the test methods that result in lowest variability depending on the soil type. In this section, uncertainty sources are discussed in more detail as they relate to wind energy projects.

### 2.1 Uncertainty Due to Inherent Soil Variability

Inherent soil variability is related to the natural geologic processes that produced the soil and should not include the influence of deterministic trends (e.g., trends due to depth), mixing of soils from different geologic units, or measurement errors. In the case of wind projects, inherent variability should be considered at each individual turbine location.

Another source of uncertainty is related to spatial variability extending vertically and horizontally to dimensions of influence. Uncertainty related to spatial variability is affected by the scale of fluctuation or correlation distance which is an important statistical parameter loosely defined as the distance within which the values of a given parameter are significantly correlated (Fenton and Griffiths 2008). Due to the often layered nature of soils, the correlation distance is typically shorter in the vertical direction than in the horizontal direction. Engineering design practice, including that within the wind energy industry, considers single (or point) variables to represent properties of an

entire soil mass. Thus, in designing a shallow foundation for a wind turbine, for example, traditional practice assumes an infinite horizontal correlation length where a single value is assumed for the soil in each layer. Furthermore, while focus is on variation in the vertical direction, geotechnical exploration rarely goes beyond one boring at the center of the foundation unless there is strong reason to believe conditions are non-uniform in the lateral directions, such as in cavitate terrain. Thus, knowledge of the vertical spatial variation is often limited to the line of the boring. On the other hand, knowledge in the horizontal direction is limited to the observation and verification of the exposed foundation bearing surface. This is very limited information but standard practice. This is also why at least two forms of exploration should be carried out at each turbine location: a traditional boring and a seismic survey (MASW).

## 2.2 Uncertainty Caused by Measurement Error

Measurement uncertainty is related to the equipment being used, in-situ or laboratory test procedures, and random data scatter. Naturally, measurement error is different for different test procedures. Reported measurement error data have been summarized for various laboratory and field tests by various investigators (e.g. Phoon and Kulhawy 1999). It is worthwhile to note that the highest variability attributed to in-situ test measurement error is that corresponding to the Standard Penetration Test (SPT). The error introduced by sample size is sometimes considered as a measurement error. Normally, the greater the number of data points or sample size, the smaller the error. However, beyond a rather low number of samples, it is more important to capture the full range of variability than to obtain more data points. There are numerous simplified rules to estimate standard deviation and variability based on the range and number of samples (Tippett 1925, Withiam et al. 1997, Whitman 2000 and Foye et al. 2006). For this reason, the effort to capture the full range of variability as early as possible is very important to the early assessment of risks.

## 2.3 Uncertainty Caused by Transformation Error

Transformation or model errors are introduced when test measurements are used to calculate the desired design properties using empirical or theoretical relationships. The sources of the error include the fitting errors in the case of empirical equations and the simplification/idealization errors in the case of theoretical relationships. The transformation errors for several design properties (undrained shear strength, effective stress friction angle, Young's modulus, horizontal stress coefficient, etc.) have been compiled (e.g. Phoon and Kulhawy 1999) for various laboratory and in-situ test methods. Noteworthy remarks from these compilations include:

- Higher variability (as expressed in higher coefficients of variation) result for sand properties obtained through correlations with SPT blow counts, especially if "universal" empirical relationships are used; i.e., relationship not calibrated to a specific geology. Hence, "local knowledge" seems to be important for interpretation of SPT results.
- Higher variability is typically obtained for sand properties than for clay properties.

## 3 CONCLUSIONS

Wind energy projects are almost always developed and built under compressed schedules where project realization phases overlap. They also cover large terrains that involve wide variability of geotechnical and geo-environmental conditions. For these reasons, geotechnical risks must be addressed as early as possible during the development phase to avoid overlooking fatal hazards that can shelve or financially devastate the project. This paper proposes to conduct extensive, low cost and quick

geophysical surveys during the development phase to help with turbine micro-siting and to gain an insight into the variability of the entire project area. The paper lists potential hazards that should be assessed and discusses sources of geotechnical uncertainty and how they relate to wind energy projects.

## 4 ACKNOWLEDGEMENTS

The author would like to acknowledge his employer, Renewable Energy Systems Americas Inc, for support in the preparation and presentation of this paper.

# Essais cycliques axiaux sur des pieux forés dans des sables denses

## Cyclic axial load tests on bored piles in dense sands

Benzaria O.

Fugro GeoConsulting, Nanterre, France – IFSTTAR, Paris, France

Puech A.

Fugro GeoConsulting, Nanterre, France

Le Kouby A.

IFSTTAR, Paris, France

**RÉSUMÉ :** Dans le cadre du projet national SOLCYP, cinq pieux forés instrumentés ont été installés dans les sables denses des Flandres. Deux pieux de 8 mètres de fiche et 420 mm de diamètre ont été soumis à des séries d'essais de chargements statiques et cycliques axiaux en compression. Cette communication présente les résultats les plus significatifs des essais statiques conventionnels et des essais cycliques en compression.

**ABSTRACT:** As part of the national project SOLCYP, five bored piles were installed in dense Flanders sands. Two 8m long, 420mm diameter instrumented piles were submitted to extensive series of static and cyclic load tests in compression. This paper presents key results from conventional static tests and cyclic one-way tests in compression.

**MOTS-CLÉS :** SOLCYP, pieux forés, sables denses, chargements cycliques.

**KEYWORDS :** SOLCYP, bored piles, dense sands, cyclic loading.

## 1 INTRODUCTION

Le projet national SOLCYP (Puech et al., 2012) a pour objectif principal le développement d'une méthodologie pour le dimensionnement des pieux soumis à des chargements cycliques. Dans ce cadre, des essais sur pieux réels ont été conduits sur deux sites expérimentaux du Nord de la France: le site de Merville constitué d'argile des Flandres et le site de Loon-Plage constitué de sables denses. Sur le site de Loon-Plage ont été installés cinq pieux forés et deux pieux métalliques battus.

Les résultats obtenus sur les pieux battus et forés de Merville ont été partiellement publiés (Benzaria et al., 2012, 2013 ; Puech et Benzaria, 2013). Cette communication est centrée sur les résultats des essais statiques et cycliques en compression exécutés sur les pieux forés sur le site de Loon-Plage.

## 2 SABLE DES FLANDRES

Le site expérimental se situe sur la commune de Loon-Plage (59) près de Dunkerque dans le Nord de la France. Il se caractérise par une couverture de remblais récents (0-0,6m) et d'argile sableuse (0,6-2,2m) sous laquelle on rencontre la formation de sable des Flandres. La nappe phréatique au moment des essais se situait à environ 2m sous le niveau du terrain naturel.

Une campagne spécifique d'investigations a été réalisée au droit du plot d'essais comportant 4 essais au piézocône (CPTu), 2 essais au pressiomètre Ménard (PMT), 3 carottages continus et une série d'essais de laboratoire sur carottes (Figures 1 et 2). Le sable est un sable siliceux très fin ( $D_{50}$  voisin de 0,15mm) et mal gradué (coefficient d'uniformité  $CU=0,98$ ). La formation est latéralement homogène et se caractérise par des valeurs de résistance au cône  $q_n$  croissant de 5 à 40MPa vers 8 m de profondeur pour se stabiliser ensuite entre 30 et 50MPa jusque vers 11,5m. Entre 12 et 16,5m se trouve une couche d'argile molle qui fait brutalement chuter les caractéristiques mécaniques. L'interprétation des CPT par la méthode de Jamiolkowski et al. (2003) (Figure 2) conduit à un indice de densité  $I_D$  compris entre 0,7 et 0,9 (sable dense à très dense).

Une série d'essais triaxiaux monotones a donné un angle de frottement interne  $\phi_{cv}$  voisin de  $31^\circ$  en bon accord avec les valeurs trouvées par Kuwano sur le sable de Dunkerque (Kuwano, 1999 ; Jardine et Standing, 2000)

Figure 1. Profils stratigraphiques et pressiométriques à Loon-Plage

## 3 INSTALLATION ET CHARGEMENT DES PIEUX

Les deux pieux, F4 et F5, sont géométriquement identiques ( $D=420$ mm, fiche 8m). Ils ont été exécutés par l'entreprise Botte Fondations à l'aide d'une tarière à axe creux vissée dans le sol sans extraction notable de matériau (Figure 3a) puis extraite sans dévissage tandis que le béton est injecté simultanément par l'axe creux. Les pieux sont équipés d'un train d'extensomètres amovibles de type LCPC introduits dans

un tube de réservation positionné entre les armatures (Figure 3b).

Figure 2. Profils pénétrométriques à Loon-Plage : résistance au cône  $q_c$  et indice de densité  $I_D$ .

Les pieux ont été testés trois mois environ après leur mise en place. Les programmes de chargement comportaient des essais statiques de référence à paliers d'une heure selon la norme NF P 94-150, des essais de chargement rapides (réduction des paliers à 3mm) et des essais de chargements cycliques axiaux de type répété. Une description plus précise des modes de chargement est indiquée dans Benzaria et al. (2012).

La caractérisation complète d'un chargement cyclique suppose la définition des paramètres suivants :

$Q_m$ : valeur moyenne de la charge sous chargement cyclique,

$Q_c$ : demi-amplitude du chargement cyclique,

$Q_{max}$ : charge maximale ( $Q_{max} = Q_m + Q_c$ )

$N$ : nombre de cycles (les essais ont été conduits à la rupture ou à grand nombre de cycles  $N > 1000$ )

$f$ : fréquence des cycles (en général 0,5Hz)

$Q_u$ : capacité statique ultime selon le mode considéré.

L'essai est dit répété si  $Q_c < Q_m$  et alterné si  $Q_c > Q_m$ .

Figure 3. a) réalisation d'un pieu foré à l'aide d'une tarière à axe creux b) schéma d'instrumentation d'un pieu foré à l'aide d'extensomètres amovibles de type LCPC

Le dispositif de chargement des pieux est similaire à celui utilisé pour les pieux de Merville et décrit dans Benzaria et al. (2012).

Figure 4. Dispositif d'essais de chargement utilisé à Loon-Plage

#### 4 ESSAIS STATIQUES

La Figure 5 montre la courbe charge-déplacement en tête obtenue pour l'essai statique de référence sur le pieu F4, vierge de tout chargement, ainsi que la courbe de mobilisation de l'effort en pointe et la courbe de fluage (représentant la vitesse de déplacement du pieu lors de chaque palier de chargement).

On note :

- une rupture de type ductile,
- une entrée du pieu en grands déplacements pour un déplacement en tête de l'ordre de 5% du diamètre. La charge de rupture  $Q_{uc}$  conventionnelle pour 10% de déplacement de la tête (42mm) peut être estimée à environ 1 100kN,
- une charge de fluage  $Q_F$  vers 850kN soit  $Q_F/Q_{uc} \approx 0,77$ ,
- une mobilisation de l'effort de pointe retardée puis quasi linéaire jusqu'à 8% de déplacement relatif de la tête laissant préjuger d'une croissance de l'effort de pointe au-delà de la valeur conventionnelle à 0,1D.

Figure 5. Essai statique de référence sur le pieu F4. Courbes de charge-déplacement en tête, de mobilisation de l'effort de pointe et de fluage.

Les mesures extensométriques ont permis de déterminer la distribution des charges le long du pieu (par éléments de 1m) ainsi que les courbes locales de mobilisation du frottement latéral selon la procédure décrite dans Benzaria et al. (2012). Les courbes locales de transfert de charges (dites aussi courbes t-z) sont données sur la Figure 6 pour les seuls niveaux correspondant au sable des Flandres. La mobilisation du frottement est très progressive : le déplacement local à la

rupture est de l'ordre de 3 à 5% du diamètre du pieu. Le caractère ductile de la rupture est confirmé. Les frottements sont modestes ( $f < 45\text{kPa}$ ).

Figure 6. Courbes de mobilisation des frottements locaux obtenues lors de l'essai statique de référence sur le pieu F4.

## 5 ESSAIS CYCLIQUES

### 5.1 Essais cycliques sur pieu vierge

La Figure 7 représente la séquence d'essais de chargements réalisés sur le pieu F5 vierge de tout chargement. Leurs caractéristiques sont données dans le Tableau 1

Tableau 1 : Caractéristiques des chargements appliqués au pieu F5  
C : cyclique  $Q_{uc}$  : 1100 kN (pieu F1)

Test F5-	Type	Date	f (Hz)	$Q_m / Q_{uc}$	$Q_c / Q_{uc}$	N
Installation		25/11/11				
CC1	C	08/03/12	0,5	0,36	0,27	14
CC2	C	08/03/12	0,5	0,27	0,09	5000
CC3	C	08/03/12	0,5	0,36	0,18	280

L'essai CC1 a été réalisé avec un taux de chargement relativement modeste ( $Q_{max}/Q_{uc} = 0,63$ ). Il a été arrêté prématurément en raison de l'instabilité d'un pieu de réaction mais il est manifeste que la rupture était imminente après seulement 14 cycles. La rupture est définie pour un déplacement cyclique permanent de la tête du pieu de 3% du diamètre soit 12mm.

L'essai CC2, enchaîné avec un taux nettement plus faible ( $Q_{max}/Q_{uc} = 0,35$ ), a pu être conduit à 5000 cycles mais pour un déplacement additionnel permanent de plus de 16mm.

L'essai CC3 ( $Q_{max}/Q_{uc} = 0,54$ ) a provoqué un déplacement supplémentaire de 6mm pour seulement 280 cycles.

Figure 7. Courbes charges-déplacements en tête obtenues lors des essais de chargements réalisés sur le pieu F5.

Il est à noter que la vitesse d'évolution des déplacements en tête pour un nombre de cycles donné augmente avec le taux de chargement. Cependant pour chacun des essais cette vitesse décroît avec le nombre de cycles (Figure 8). Cette observation peut paraître contradictoire avec le constat de rupture.

Figure 8. Courbes déplacement en tête en fonction du nombre de cycles obtenues lors des essais de chargements réalisés sur le pieu F5.

Une observation fine des phénomènes générés par les chargements cycliques sur un pieu dans un sable permet de mieux comprendre cet apparent paradoxe. Les cycles provoquent une succession de petits glissements relatifs sol-pieu dont le cumul détermine le déplacement global. La vitesse de déplacement est fonction de l'amplitude et du niveau de chargement mais ces paramètres conditionnent également l'évolution du frottement qui peut se détériorer (cycles sévères) ou s'améliorer (petits cycles). Sur un pieu sollicité en traction, la vitesse initiale se modifie pour conduire vers la rupture de plus en plus rapide ou vers la stabilisation (Tsuha et al., 2012). La rupture peut être indifféremment définie de manière conventionnelle (par exemple 0,1D) ou en terme de déplacement acceptable. Sur un pieu en compression, le déplacement s'accompagne d'une mobilisation progressive de l'effort de pointe de sorte que dans tous les cas le pieu tend vers la stabilisation. Il en résulte que le critère de rupture doit être défini en terme de déplacement acceptable et non de manière conventionnelle. Le critère peut être alors atteint aussi bien en phase de vitesse de déplacement croissante que décroissante. Dans le premier cas, le nombre de cycles amenant à la rupture est faible. Dans le deuxième cas il peut être très élevé. On peut alors introduire la notion de zones instables et métastables (e.g. Puech et al, 2013).

## 5.2 Effet de l'histoire des chargements

La Figure 9 montre l'histoire des chargements du pieu F4, détaillée dans le Tableau 2.

L'essai CC1 a été exécuté après que le pieu ait été amené à la rupture (essai S1). Malgré son faible taux de chargement ( $Q_{max}/Q_{uc} = 0,31$ ) le critère de rupture est atteint avant 2000 cycles. La capacité post cyclique (essai R1) ne semble toutefois pas affectée par cette série de cycles de faible amplitude.

Tableau 2 : Caractéristiques des chargements appliqués au pieu F4  
S : statique conventionnel R : statique rapide C : cyclique

Test F4-	Type	Date 2012	f (Hz)	$Q_m / Q_{uc}$	$Q_c / Q_{uc}$	N
Installation		25/11/11				
CS1	S	01/03/12				
CC1	C	02/03/12	0,5	0,18	0,13	1819
CR1	R	02/03/12				
CC2	C	02/03/12	0,5	0,36	0,18	200
CC3	C	02/03/12	0,5	0,36	0,27	200
CC4	C	02/03/12	0,5	0,47	0,25	100
CC5	C	02/03/12	0,5	0,45	0,36	200
CR2	R	02/03/12				
CR3	R	27/03/12				

Une série de quatre essais d'amplitudes et taux moyens croissants (CC2 à CC5) est ensuite enchaînée, provoquant des déplacements significatifs (environ 25mm pour seulement 700 cycles cumulés). L'essai statique rapide R2 indique que la rigidité du pieu a fortement augmenté. L'essai statique R3 confirme ce résultat et montre que la capacité post cyclique du pieu est maintenant de 1480 kN soit un accroissement de 27% par rapport à l'essai S1 sur le pieu vierge.

Figure 9. Courbes charge-déplacement en tête obtenues lors des essais de chargements réalisés sur le pieu F4.

## 6 CONCLUSIONS

On a présenté les résultats des essais statiques et cycliques en compression effectués sur les pieux forés à la tarière creuse installés sur le site de Loon-Plage constitué de sable dense des Flandres.

Sous chargement statique la rupture est ductile et la mobilisation du frottement nécessite des déplacements globaux et locaux importants entre 3 et 5% du diamètre du pieu.

Le comportement cyclique est très fortement dépendant de l'histoire des chargements. D'une manière générale, les pieux forés apparaissent très sensibles aux chargements répétés. Des déplacements importants peuvent être générés avant de pouvoir bénéficier d'une capacité en pointe suffisante pour stabiliser le pieu. La rupture doit donc être définie par un critère en déplacement et non de manière conventionnelle.

Une interprétation plus approfondie des résultats reste à proposer après traitement complet des autres données recueillies (essais alternés et essais en traction) et en liaison avec le comportement mécanique du sable des Flandres.

## 7 REMERCIEMENTS

Les résultats présentés dans cette communication ont été acquis dans le cadre du Projet National Français SOLCYP. SOLCYP est un projet de recherche sur le comportement des pieux soumis à des sollicitations cycliques, regroupant 12 entreprises et bureaux d'études du génie civil et 6 organismes universitaires et de recherche. Il est piloté par l'IREX et financé par les partenaires, l'Agence Nationale de la Recherche, le Ministère de l'Écologie, du Développement Durable et de l'Énergie et la Fédération Nationale des Travaux Publics. Les auteurs remercient les partenaires du projet d'avoir autorisé la publication de ces données.

**RÉSUMÉ :** Dans le cadre du projet national SOLCYP, quatre pieux forés instrumentés ont été installés dans l'argile fortement surconsolidée des Flandres. Ces pieux de 13 mètres de fiche et 420mm de diamètre ont été soumis à des séries d'essais de chargements statiques et cycliques axiaux. Cette communication présente les principaux résultats des essais statiques conventionnels et des essais cycliques en compression répétés et alternés.

**ABSTRACT:** As part of the national project SOLCYP, four bored piles were installed in the high OCR Flanders clay. The 13m long, 420mm diameter instrumented piles were submitted to extensive series of static and cyclic load tests. This paper presents key results from conventional static tests and cyclic one-way and two-way tests in compression.

**MOTS-CLES:** SOLCYP, pieux forés, argile surconsolidée, chargements cycliques.

**KEYWORDS :** SOLCYP, bored piles, overconsolidated clay, cyclic loading

## 1 INTRODUCTION

Le projet national SOLCYP (Puech et al., 2012) a pour objectif principal le développement d'une méthodologie pour le dimensionnement des pieux soumis à des chargements cycliques. Dans ce cadre, des essais sur pieux réels ont été conduits sur deux sites expérimentaux du Nord de la France: le site de Merville constitué d'argile des Flandres et le site de Loon-Plage constitué de sable dense. Sur le site de Merville ont été installés quatre pieux métalliques battus, quatre pieux forés et deux pieux vissés moulés.

Un précédent article (Benzaria et al., 2012) était consacré à la description du contexte expérimental et à la présentation des résultats obtenus sur les pieux battus. Cette communication présente les résultats des essais statiques et cycliques exécutés sur les pieux forés.

## 2 ARGILE DES FLANDRES

Le site expérimental se situe sur la commune de Merville (59) dans le Nord de la France. Il se caractérise par une couverture de limons sableux à argileux de 3,5m d'épaisseur dans lequel fluctue la nappe phréatique (-2m environ lors des essais) sous laquelle on rencontre la formation d'argile des Flandres, particulièrement homogène sur toute la zone, et d'une puissance de 40m environ.

L'argile des Flandres, géologiquement comparable à l'argile de Londres et à l'argile de Boom, s'est déposée il y a 50 millions d'années (Eocène) dans un golfe marin qui couvrait toute la zone Nord de la France, de la Belgique et du Sud Est de l'Angleterre. Elle a été recouverte par des formations tertiaires dont la sédimentation s'est poursuivie jusqu'au Pleistocène supérieur. Le niveau du sol se situait alors probablement à 200m au-dessus du niveau actuel. Les formations sus-jacentes se sont érodées. Le processus d'érosion a été suivi au Quaternaire par le dépôt d'alluvions du Flandrien. Le matériau a été soumis à des cycles de chargement/déchargement et à des processus périglaciaires qui associés à des phénomènes de cimentation

chimique et de vieillissement ont fortement conditionné son degré de surconsolidation (OCR) apparent (Josseaume, 1998)

L'argile des Flandres présente des caractéristiques voisines de celles des argiles de Londres et de Boom (Borel et Reiffsteck, 2005) :

- faible teneur en eau (de l'ordre de 30%)
- forte plasticité (IP voisin de 50)
- forte fissuration notamment au-delà de 5m de profondeur

Figure 1. Profils de résistance au cône  $q_t$  et OCR sur le site de Merville

Une campagne spécifique d'investigations a été réalisée au droit du plot d'essais comportant des essais au piezocône (CPTU), des essais au pressiomètre Ménard (PMT), des carottages continus et une série d'essais de laboratoire sur carottes.

L'OCR a été estimé à partir du CPT et de la relation de Mayne (1991) :  $OCR = k \cdot (q_t - \sigma_{v0}) / \sigma'_{v0}$  avec  $k=0,5$ . Le facteur  $k$  est fonction du type de matériau. La valeur de 0,5 a été retenue car elle donne des valeurs d'OCR compatibles avec l'épaisseur de surcharge supposée et le gradient de  $q_n = q_t - \sigma_{v0}$  dans l'argile profonde (au-delà de 8m). A noter que pour l'argile de Londres, Powell et al., 1989 suggèrent des valeurs de  $k$  supérieures à 1.

Figure 2. Conditions de sol au niveau du plot d'essais de Merville

Les essais triaxiaux de type UU (non consolidé, non drainé) ou CIU (consolidé isotropiquement, non drainé) montrent des ruptures prématurées de type fragile, caractéristiques de ce type d'argile plastique fissurée et fortement surconsolidée. La rupture se caractérise par la formation de plans de cisaillement contenant des particules réorientées, comme noté par Bond et Jardine (1991). Les valeurs de la résistance au cisaillement non drainée  $C_u$  sont corrélées à la résistance au cône par un facteur  $N_{kt}$  élevé,  $[N_{kt} = (q_t - \sigma_{v0}) / C_u = 20]$ , compatible avec la nature du matériau. Les valeurs de pression limite pressiométrique nette sont assez bien reliées à  $C_u$  par la relation d'Amar et Jezequel (1998) :  $C_u = p_l^* / 12 + 30$ , avec  $C_u$  en kPa et  $p_l^*$  en MPa

### 3 INSTALLATION ET CHARGEMENT DES PIEUX

Les quatre pieux sont géométriquement identiques ( $D=420$ mm, fiche 13m). Ils ont été exécutés à l'aide d'une tarière à axe creux vissée dans le sol sans extraction notable de matériau (Figure 3a) puis extraite sans dévissage tandis que le béton est injecté simultanément par l'axe creux. La partie basse est munie d'un manchon télescopique. Les pieux sont équipés d'un train d'extensomètres amovibles de type LCPC introduits dans un tube de réservation positionné entre les armatures (Figure 3b).

Les pieux ont été testés deux mois après leur mise en place. Les programmes de chargement comportaient des essais statiques de référence à paliers d'une heure selon la norme NF P 94-150 (1999), des essais de chargement rapides (réduction des paliers à 3mm) et des essais de chargement cycliques axiaux de type répété ou alterné. Une description plus précise des dispositifs (Figure 4) et modes de chargement est indiquée dans (Benzaria et al., 2012).

La caractérisation complète d'un chargement cyclique suppose la définition des paramètres suivants :

$Q_m$ : valeur moyenne de la charge sous chargement cyclique,

$Q_c$ : demi-amplitude du chargement cyclique,

$Q_{max}$ : charge maximale ( $Q_{max} = Q_m + Q_c$ )

$N$  : nombre de cycles (les essais ont été conduits à la rupture ou à grand nombre de cycles  $N > 1000$ )

Figure 3. Pieux forés a) tarière à axe creux. b) schéma d'instrumentation à l'aide d'extensomètres amovibles de type LCPC.

Figure 4 : Dispositif de chargement des pieux en compression.

$f$  : fréquence des cycles (en général 0,5Hz)

$Q_u$  : capacité statique ultime selon le mode considéré.

L'essai est dit répété si  $Q_c < Q_m$  et alterné si  $Q_c > Q_m$ .

### 4 ESSAIS STATIQUES

La Figure 5 montre la courbe charge-déplacement en tête obtenue pour l'essai statique de référence sur le pieu F1, vierge de tout chargement, ainsi que la courbe de fluage représentant la vitesse de déplacement du pieu lors de chaque palier de chargement.

Figure 5. Courbe charge-déplacement en tête et courbe de fluage obtenues pour l'essai statique de référence sur le pieu F1.

On note :

- une rupture de type ductile (contrairement aux observations de Benzaria et al., 2012 sur le pieu battu) ;
- une entrée du pieu en grands déplacements pour un déplacement en tête de l'ordre de 3% du diamètre. La charge de rupture  $Q_{uc}$  conventionnelle pour 10% de déplacement de la tête peut être extrapolée avec confiance à 900kN ;
- une charge de fluage  $Q_F$  nette vers 670kN soit  $Q_F/Q_{uc} \approx 0,75$ .

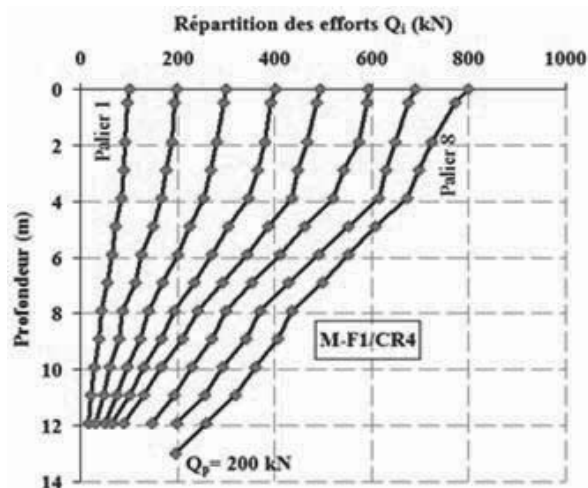

Figure 6. Distributions des charges obtenues pour l'essai statique de référence sur le pieu F1.

Figure 7. Courbes locales de mobilisation du frottement latéral obtenues pour l'essai statique de référence sur le pieu F1.

Les mesures extensométriques ont permis de déterminer la distribution des charges le long du pieu (Figure 6) ainsi que les courbes locales de mobilisation du frottement latéral selon la procédure décrite dans Benzaria et al. (2012). Les courbes locales de transfert de charges (dites aussi courbes t-z) sont données sur la Figure 7. La mobilisation du frottement est très rapide (entre 1 et 2%) du diamètre du pieu. Le caractère ductile de la rupture est confirmé. Les frottements sont modestes ( $f < 50$ kPa) et très inférieurs à ceux observés sur les pieux métalliques battus installés sur ce même site.

## 5 ESSAIS CYCLIQUES

### 5.1 Essais cycliques répétés

La Figure 8 représente la séquence d'essais de chargements réalisés sur le pieu F2. Leurs caractéristiques sont données dans la Tableau 1.

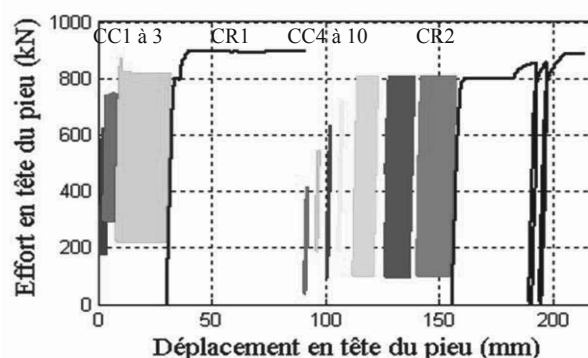

Figure 8. Courbes charge-déplacement en tête obtenues lors d'essais de chargements statiques et cycliques sur le pieu F2.

On observe que :

- le taux de chargement maximal contrôle la réponse du pieu ;
- lorsque ce taux demeure inférieur à un seuil critique, les déplacements restent non significatifs y compris pour de grands nombres de cycles ( $N > 1000$ ). Les boucles d'hystérésis sont fermées (Figure 9) ;
- lorsque le seuil critique est franchi, le pieu cumule rapidement des déplacements le conduisant vers la rupture. Les essais CC3, CC8, CC9 et CC10 ont dépassé 12mm (3%D) de déplacement cyclique permanent considéré comme critère de rupture (Figure 8) ;
- le seuil critique est très voisin de  $Q_{max}/Q_{uc} = 0,9$
- les chargements cycliques, y compris lorsqu'ils conduisent à la rupture, n'ont pas significativement affecté la capacité statique du pieu.

Tableau 1 : Caractéristiques des chargements appliqués au pieu F2  
C : cyclique R : statique rapide  $Q_{uc} = 900$ kN (pieu F1)

Test F2-	Type	Date	f (Hz)	$Q_m/Q_{uc}$	$Q_c/Q_{uc}$	N
Installation		16/03/2011				
CC1	C	16/05/2011	0,5	0,50	0,25	3408
CC2	C	17/05/2011	0,5	0,58	0,25	4834
CC3	C	17/05/2011	0,5	0,58	0,33	2021
CR1	R	17/05/2011				
CC4	C	17/05/2011	0,5	0,25	0,20	1013
CC5	C	17/05/2011	0,5	0,40	0,20	1000
CC6	C	17/05/2011	0,5	0,40	0,30	1088
CC7	C	17/05/2011	0,5	0,50	0,30	602
CC8	C	17/05/2011	0,5	0,50	0,40	81
CC9	C	17/05/2011	0,1	0,50	0,40	24
CC10	C	17/05/2011	0,5	0,50	0,40	85
CR2	R	17/05/2011				

La comparaison des essais CC9 et CC10 effectués à mêmes taux de chargement met en outre en évidence un effet de fréquence dans le domaine proche de la rupture : la rupture est accélérée lorsque la fréquence diminue.

Figure 9. Courbes charge-déplacement en tête obtenues d'essais de chargements réalisés sur le pieu F2.

### 5.2 Essais cycliques alternés

Neuf essais cycliques alternés ont été effectués sur le pieu F3. Les caractéristiques de ces essais sont telles que  $Q_m/Q_{uc} < 0,2$  et  $0,2 < Q_c/Q_{uc} < 0,5$ . Pour des raisons de montage hydraulique (deux vérins en opposition de phase), il n'a pas été possible d'appliquer une charge maximale  $Q_{max}$  supérieure à  $0,7 Q_{uc}$ .

Tous les essais effectués dans ces conditions sont du type stable avec des boucles d'hystérésis fermées comme illustré sur la Figure 10.

Figure 10, Courbe charge-déplacement en tête obtenue lors de l'essai de chargement CC9 réalisé sur le pieu F3.

### 5.3 Notion de stabilité cyclique

L'ensemble des résultats obtenus en compression pure et en compression alternée (mais également en traction pure et en traction alternée) suggèrent que pour le type de matériau et de pieu considéré il existe deux zones de fonctionnement bien différenciées :

- une zone dans laquelle les chargements cycliques même en grand nombre ( $N > 1000$ ) ont peu d'effet sur le comportement du pieu : accumulation non significative des déplacements permanents, rigidité cyclique constante ;
- une zone dans laquelle le pieu évolue très rapidement vers la rupture.

La zone de stabilité cyclique est étendue mais pourrait être affectée par le caractère répété ou alterné des chargements.

L'analyse complète des résultats et la définition de critères de rupture précis devrait permettre de proposer ultérieurement des diagrammes de stabilité cyclique au sens de Poulos (1988) ou Karlsrud et al. (1986)

## 6 CONCLUSIONS

On a présenté des résultats d'essais statiques et cycliques en compression pure et alternée effectués sur des pieux forés à la tarière creuse installés sur le site de Merville constitué d'argile surconsolidée des Flandres.

Sous chargement statique la rupture n'est pas fragile contrairement aux observations faites sur les pieux battus. Les frottements mobilisés sont nettement inférieurs (Benzaria et al., 2012).

Il semble exister sous chargement cyclique une zone étendue à l'intérieur de laquelle la stabilité est assurée pour un grand nombre de cycles. Le seuil critique, au moins pour les essais répétés, semble voisin de  $Q_{max}/Q_{uc} = 0,9$ . Les chargements cycliques, y compris lorsqu'ils conduisent à la rupture, n'affectent pas significativement la capacité statique du pieu.

Un article à cette même conférence (Puech et Benzaria, 2013) analyse le comportement statique des deux types de pieux battus et forés en liaison avec la nature et le comportement mécanique de l'argile des Flandres.

## 7 REMERCIEMENTS

Les résultats présentés dans cette communication ont été acquis dans le cadre du Projet National Français SOLCYP. SOLCYP est un projet de recherche sur le comportement des pieux soumis à des sollicitations cycliques, regroupant 12 entreprises et bureaux d'études du génie civil et 6 organismes universitaires et de recherche. Il est piloté par l'IREX et financé par les partenaires, l'Agence Nationale de la Recherche, le Ministère de l'Écologie, du Développement Durable et de l'Énergie et la Fédération Nationale des Travaux Publics. Les auteurs remercient les partenaires du projet d'avoir autorisé la publication de ces données.

# Fondations superficielles glissantes pour l'offshore profond – Méthodologie de dimensionnement

## Deep Offshore Sliding Footings – Design Methodology

Bretelle S.  
GHD, Perth, Australie

Wallerand R.  
Subsea7, Paris, France

**RÉSUMÉ :** Les caractéristiques géotechniques des sols rencontrés en offshore profond conduisent de manière récurrente à des fondations de très grandes dimensions. Ceci induit des difficultés d'installation qui stimulent la recherche de solutions audacieuses pour les fondations dont le dimensionnement intègre des sollicitations horizontales transitoires. Les efforts horizontaux résultent de conditions transitoires pour les pipelines (arrêt et redémarrage de l'exploitation induisant des changements de température dans les pipelines). Ceux-ci induisent un glissement de la fondation. Ces efforts horizontaux étant variables dans le temps, le sol est soumis à des sollicitations cycliques. Cet article détaille les différentes étapes proposées pour le dimensionnement des fondations glissantes, destinées au support des structures liées aux pipelines, en prenant en compte les effets de la dégradation cyclique sur la capacité portante, et l'évaluation des tassements.

**ABSTRACT:** Due to the geotechnical characteristics of offshore deep-water soils, footing size can become very large. This may induce installation challenges, which in turn stimulates smart design solutions allowing for horizontal displacement of the footing. Horizontal loads results from flow lines expansion during start-up and shut-down of the production, as large temperature changes will induce dilatation. If horizontal loads are above the horizontal capacity of the footing, the foundation will slide. Horizontal loads varying with time, soil cyclic loadings are induced. This paper presents the different steps of the design for the proposed concept, allowing the footing to slide. This design includes cyclic soil degradation effects on bearing capacity and settlements.

**MOTS-CLÉS:** Offshore, fondation, glissante, pipeline, cyclique, dégradation, tassement.

**KEYWORDS:** Offshore, footing, sliding, pipeline, cyclic, degradation, settlement.

### 1 INTRODUCTION

Les caractéristiques géotechniques des argiles molles rencontrées en offshore profond conduisent de manière récurrente à des fondations de très grandes dimensions. Ceci induit des difficultés d'installation qui stimulent la recherche de solutions audacieuses pour les fondations dont le dimensionnement intègre des sollicitations horizontales transitoires.

Les efforts horizontaux résultent des sollicitations horizontales transitoires. C'est le cas notamment des structures intermédiaires ou des structures fin de ligne, qui permettent la connexion entre les pipelines et les différents éléments de l'architecture du champ (puits, risers, manifolds). Les efforts appliqués à ces structures sont transmis au sol par l'intermédiaire de fondations superficielles faites de tôles d'acier. Les efforts verticaux proviennent du poids propre de la structure, de la section de conduite qu'elle supporte, des différents connecteurs et vannes associées. Les efforts horizontaux sont eux provoqués par la dilatation ou la contraction de la conduite (arrêt et redémarrage de l'exploitation induisant des changements de température et de pression dans les pipelines). Ceux-ci induisent un glissement de la fondation (le coefficient de sécurité au glissement est inférieur à 1). Ces efforts horizontaux étant variables dans le temps, le sol est soumis à des sollicitations cycliques.

L'évaluation des effets résultants de la dégradation cyclique des propriétés des sols (ici la résistance au cisaillement) permettra d'assurer que la fondation reste stable sous efforts verticaux et moments.

L'évaluation des tassements est nécessaire. Le cisaillement cyclique (environ 2000 cycles sur la durée de vie de l'ouvrage)

est source de tassements spécifiques, qui sont dus aux déplacements répétés de la fondation.

Cet article détaille les différentes étapes proposées pour le dimensionnement des fondations glissantes, destinées au support des structures liées aux pipelines, et posées sur des argiles molles.

### 2 COMPARAISON PIPELINES-FONDATIONS

Le tableau 1 rappelle les concepts d'interaction sol-pipeline et sol-fondation. Il permet d'illustrer les différences entre les comportements admis pour les pipelines et ceux généralement requis pour les fondations superficielles (White - Cathie 2010).

Les grandes familles de différences qui sont décrites ci-dessous affectent directement la perception du dimensionnement, qui intègre naturellement les déplacements pour les pipelines, et qui par contre recommande des coefficients de sécurité importants sur la capacité portante (incluant les efforts horizontaux) des fondations pour se prémunir des déplacements.

Pour ce qui concerne les pipelines, il peut s'avérer économiquement impossible d'empêcher le pipeline de se déplacer, en l'enfouissant par exemple, sur des dizaines de kilomètres, et à des profondeurs d'eau de plus de 1000m. Par contre, des modèles d'interaction sol-pipeline intégrant le déplacement permettent d'optimiser les dimensions des pipelines (les épaisseurs des tubes en particulier).

Pour ce qui concerne les fondations, même liées aux pipelines, il reste d'usage de les dimensionner sans autoriser leur déplacement.

Ce choix conduit à des fondations de très grandes dimensions, en particulier sur les argiles marines en grande

profondeur. Il pose aussi des problèmes structuraux au niveau de la connexion du pipeline et de la fondation.

Tableau 1. Comparaison des comportements admis pour les pipelines et pour les fondations.

Paramètre	Pipeline	Fondation
Géométrie de l'interface sol-fondation	Incertaine, la pénétration dépend des méthodes d'installation, de la forme du fond marin	Connue, contrôlée
Critère de dimensionnement en service	Déplacement autorisé, lois de comportement spécifiques	Fixe, déplacements minimales de la fondation
Sol	Perturbé pendant l'installation et les cycles	Similaire à l'état initial
Charges	La réponse du pipeline est affectée par l'interaction avec le sol	Les charges ne sont pas affectées par le sol de fondation
Méthodes de dimensionnement	Non disponible (ou encore contestées), les hypothèses de sol enveloppes (hautes ou basses) doivent être considérées	Disponibles, les hypothèses de sol basses sont conservatives pour la stabilité

### 3 DIMENSIONNEMENT SOUS CHARGES PERMANENTES

La première étape traite du dimensionnement sous charges permanentes qui requiert un coefficient de sécurité supérieur à 1 avec la prise en compte concomitante des efforts verticaux et moments (Cathie 2008).

Figure 1 : Mécanismes de rupture

La stabilité au sens usuel du terme doit être assurée. Les charges permanentes sont essentiellement liées au poids de la structure.

La problématique du dimensionnement des fondations superficielles connaît de nombreux développements récents et il existe une normalisation (ISO 19901-4 2011) afférente. Celle-ci permet la prise en compte de manière concomitante des efforts verticaux N, horizontaux T ainsi que des moments M.

On rappelle en préambule les principes du dimensionnement intégrant ces efforts M, N, T, sous la forme d'enveloppes 3D (Randolph 2005).

Les mécanismes de rupture sont rappelés sur la figure 1.

L'approche traditionnelle de dimensionnement de fondations superficielles consiste à simplifier le chargement (M, N, T) en un chargement (N, T) appliqué sur une surface réduite. Cette approche conduit à des surdimensionnements quand ils sont comparés à des calculs par éléments finis tridimensionnels.

L'approche proposée dans l'API-ISO permet l'utilisation d'enveloppes de rupture 3D, utilisant les valeurs de :

- ✓ Nult charge verticale de rupture sous chargement vertical seul (M=0 et T=0) ;
- ✓ Tult charge horizontale de rupture sous chargement horizontal seul (M=0 et N=0) ;
- ✓ Mult moment de renversement ultime en condition de renversement seul (T=0 et V=0).

La surface limite dans l'espace (N/N<sub>ult</sub>, M/M<sub>ult</sub>, T/T<sub>ult</sub>) est alors définie par des calculs spécifiques 3D ou disponibles dans certaines références pour des formes de fondation types. Un exemple est proposé sur la figure 2.

Figure 2 : Enveloppe de rupture (Gourvenec 2007)

### 4 DIMENSIONNEMENT SOUS CHARGES HORIZONTALES

Les efforts horizontaux résultent de conditions transitoires pour les pipelines (arrêt et redémarrage de l'exploitation induisant des changements de température dans les pipelines).

Un coefficient de sécurité suffisant doit être obtenu pour que la fondation soit stable (pas de rupture sous charges verticales et moments), tout en autorisant son déplacement horizontal.

L'évaluation présentée dans cet article se limite au cas des argiles molles trouvées dans les grands fonds.

#### 4.1 Vérifications de stabilité

L'évaluation des effets résultants de la dégradation cyclique des propriétés des sols (ici la résistance au cisaillement) se décompose en trois étapes :

- ✓ Une évaluation des contraintes de cisaillement est effectuée sous la fondation le long de surfaces de rupture ;
- ✓ l'effet des cycles est intégré en utilisant des résultats usuels d'essais de laboratoire caractérisant la dégradation cyclique ;
- ✓ une vérification de la stabilité de la fondation est effectuée le long des surfaces de rupture précédentes, avec les caractéristiques réduites déterminées précédemment.

#### 4.1.1 Évaluation des contraintes de cisaillement

Il est suggéré d'utiliser un programme de calcul aux éléments finis pour obtenir les contraintes de cisaillement sous la fondation.

Il n'est pas requis d'utiliser un modèle autorisant des grands déplacements (2 à 3 mètres sont observés pour les pipelines), ni

de représenter fidèlement les cycles (les structures concernées subissent 1000 à 5000 cycles), ce qui nécessiterait des temps de calculs importants et des outils complexes.

La modélisation proposée ici applique un effort vertical représentatif du poids de la structure, et un effort horizontal « à la rupture », c'est-à-dire saturant les contraintes de cisaillement à l'interface sol fondation.

La figure 3 présente un modèle type de calcul.

Figure 3 : Modèle de calcul

Ce calcul permet de déterminer l'étendue des zones sollicitées sous la fondation et les contraintes de cisaillement appliquées au sol de fondation.

A partir de ce calcul, on détermine le taux de cisaillement moyen ( $\tau$ ) à différentes profondeurs sous la fondation (en général de 0 à B, où B est la largeur de la fondation).

#### 4.1.2 Dégradation cyclique

La dégradation cyclique est déterminée à partir d'essais de laboratoire cycliques, qui permettent d'obtenir des enveloppes de dégradation en fonction du nombre de cycles.

Figure 4 : Dégradation cyclique (Argile de Drammen, OCR=1, d'après Andersen 2004)

On lit sur l'axe horizontal le rapport  $\tau_0/s_u$  et sur l'axe vertical le ratio  $\tau_{cy}/s_u$ . Le nombre de cycles correspond aux différentes courbes sur l'abaque.

Les notations suivantes sont utilisées :

$\tau_0$  = cisaillement moyen sans cycles

$\tau_{cy}$  = cisaillement dégradé, après N cycles

$s_u$  = résistance au cisaillement moyen

#### 4.1.3 Vérification de la stabilité après dégradation cyclique

Le calcul présenté en 4.1.1 peut être repris en modifiant les valeurs de  $S_u$  pour tenir compte de la dégradation cyclique.

Le coefficient de sécurité obtenu est alors représentatif de la stabilité de la fondation après un grand nombre de cycles.

#### 4.2 Calculs des tassements

L'évaluation des tassements (élastique, consolidation, fluage) est nécessaire. Le cisaillement cyclique (environ 2000 cycles sur la durée de vie de l'ouvrage) est source de tassements additionnels, qui sont dus aux déplacements répétés de la fondation. Les tassements additionnels suivants sont considérés :

- ✓ Tassements induits par le chargement cyclique de l'argile profonde (données de triaxiaux DSS publiées),
- ✓ Dégradation de la couche en contact avec la fondation du fait du glissement répété,
- ✓ Erosion par les bords de la fondation (cause potentielle de réduction de la surface effective sous la fondation).

##### 4.2.1 Tassements élastiques, consolidation, fluage

Les tassements élastiques de consolidation et de fluage peuvent être déterminés à partir des méthodes usuelles analytiques, ou à partir du modèle éléments finis décrit plus haut (avec des modèles de type Soft Soil pour Plaxis).

##### 4.2.2 Réduction cyclique du module d'élasticité

Pour les tassements cycliques, il faudra tenir compte :

- ✓ Des déformations dues aux cycles ;
- ✓ Du développement de surpressions interstitielles dû aux cycles.

Dans les deux cas, on utilisera les résultats des calculs décrits plus haut, et les enveloppes obtenues par essais de laboratoire.

Les notations suivantes sont utilisées (différentes de celles du chapitre précédent) :

$\tau_{av}$  = cisaillement moyen sans efforts horizontaux

$\tau_{cy}$  = cisaillement moyen avec efforts horizontaux

$s_u$  = résistance au cisaillement moyen

La figure 5 présente des résultats types pour la détermination des déformations ( $\gamma$ ) dues au cisaillement cyclique.

Figure 5 : Déformations moyennes de cisaillement cyclique (Argile de Drammen, OCR=1, d'après Andersen 2004)

La déformation ci-dessus est multipliée par l'épaisseur de la couche concernée pour obtenir le tassement supplémentaire.

La figure 6 présente l'augmentation de pression interstitielle en fonction du nombre de cycles.

La déformation supplémentaire est alors obtenue par :

$$\varepsilon = (\Delta u / \sigma'_v) * \sigma'_v / M$$

Avec

$\Delta u / \sigma'_v$  : lu sur la figure 6

$\sigma'_v$  : contrainte effective verticale

M : module de déformation

Figure 6 : augmentation de pression interstitielle due au cisaillement de 1000 cycles (Argile de Drammen, OCR=1, d'après Andersen 2004)

#### 4.2.3 Dégradation de la couche de contact

La couche de contact (les 20 à 30 cm d'argile directement en contact avec la face inférieure de la fondation) subit de façon répétée un état de rupture, sous l'effet du glissement.

Cet état de rupture reste en général confiné au niveau de cette couche d'interface, car une couche de meilleures caractéristiques (crouete) est souvent présente entre 0 et 2 m de profondeur. La crouete agit comme une barrière de protection qui limite le transfert des ruptures par cisaillement vers les couches inférieures.

Il est très difficile, voire impossible de modéliser le processus cyclique dans cette couche supérieure, du fait des redistributions de contraintes entre les bords et le centre de la fondation et bien entendu du fait des sollicitations cycliques.

Il est donc proposé de retenir une approche simplifiée qui considère les différents aspects de la dégradation.

Le modèle éléments finis décrit plus haut permet de considérer le moment maximum qui sollicite la fondation, associé au poids de la fondation et à l'effort horizontal qui sature le frottement au niveau de l'interface. Ce calcul peut être mené avec les caractéristiques « intactes » dans la couche de contact, puis avec les caractéristiques remaniées dans cette même couche.

La comparaison directe des résultats permet d'estimer un tassement et une rotation supplémentaire à considérer dans le dimensionnement.

#### 4.2.4 Erosion par les bords

La concentration de contraintes est un phénomène bien connu qui dans ce cas particulier peut créer des tassements supplémentaires par érosion près des angles.

Les skis ont depuis longtemps apporté une réponse appropriée en relevant les bords pour limiter l'effet de l'angle.

Les fondations glissantes devront comporter un dispositif similaire pour éviter de racler progressivement toute une bande de sol.

L'estimation par le calcul de ce phénomène reste à développer, par contre, les conséquences peuvent être évaluées en retirant arbitrairement les éléments de sol de l'interface sous une partie de la fondation. On pourra enlever les éléments sur une bande correspondant au mouvement calculé des pipelines qui se connectent sur la fondation, puisque ce mode de comportement est disponible dans les modèles de pipelines.

Une autre méthode, moins pénalisante consiste à reprendre les résultats du calcul avec les moments présentés au paragraphe précédent 4.2.3, pour déterminer les contraintes dans la couche d'interface.

En comparant ces contraintes à la contrainte ultime ( $N_c * S_u$ )

Figure 7 : Exemple de calcul avec dégradation sous les bords (cercleées).

## 5 CONCLUSION

Cet article a détaillé les différentes étapes proposées pour le dimensionnement des fondations glissantes, destinées au support des structures liées aux pipelines, dans des conditions géotechniques d'argiles grands fonds.

Le tassement à long terme et sous un nombre de cycle représentatif de la vie de la structure sera obtenu par cumul des différentes valeurs de tassements calculées suivant la démarche proposée. La stabilité de la structure sera ainsi assurée, et son fonctionnement ne sera pas altéré par les tassements ou rotations dus au chargement cyclique.

## 6 REMERCIEMENTS

Je tiens à remercier mon mari et mon fils pour leur patience pendant la période de rédaction de cet article, ainsi que pour leur relecture.

Bien entendu, cet article n'aurait pas vu le jour sans mon expérience en France, à Terrasol pour la maîtrise des fondamentaux géotechniques, chez Saipem, pour l'ouverture Internationale et offshore, chez Cathie Associates pour la pratique continue des projets liés aux grands fonds et enfin en Australie, où GHD me donne l'opportunité de travailler sur des grands projets d'infrastructure.

# Proposition d'une loi t-z cyclique au moyen d'expérimentations en centrifugeuse

## Proposal of cyclic t-z law by means of centrifuge experiments

Burlon S., Thorel L.

Université Paris-Est, IFSTTAR, Département GERS, Paris, France

Mroueh H.

LGCgE, Lille, France

**RÉSUMÉ :** Cet article propose une extension de la loi t-z de Frank et Zhao (1982) pour le calcul des déplacements d'un pieu soumis à des charges axiales cycliques. Les potentialités de cette nouvelle loi sont présentées et une comparaison est effectuée entre des résultats expérimentaux issus d'essais en centrifugeuse pour quatre pieux soumis à des charges cycliques et des résultats numériques obtenus au moyen de cette nouvelle loi. Pour chaque cas, le déplacement de la tête de pieu en fonction du nombre de cycles de chargement est analysé. Une discussion est menée pour mieux cerner l'influence de chaque paramètre de la nouvelle loi t-z cyclique développée et envisager les développements futurs à mettre en œuvre.

**ABSTRACT:** This paper includes an extension of the t-z law proposed by Frank and Zhao (1982) for the displacements calculation of a pile subjected to cyclic axial loads. The potential of this new law are presented and a comparison is made between experimental results obtained from centrifuge tests for four piles subjected to cyclic loads and numerical results obtained by this new law. For each case, the displacement of the pile head according to the number of load cycles is analyzed. A discussion is conducted to better understand the influence of each parameter of the new cyclic t-z law and to consider future developments to implement.

**MOTS-CLÉS :** Fondation profonde, charge axiale, sollicitations cycliques, centrifugeuse, loi t-z.

**KEYWORDS:** Deep foundations, axial load, cyclic load, centrifuge tests t-z curve.

## 1 INTRODUCTION

Le comportement des pieux soumis à des charges axiales monotones peut être appréhendé par des calculs mettant en œuvre des lois d'interaction locale de type t-z. Ces lois permettent, pour chaque section d'un pieu, d'associer le déplacement relatif de l'interface sol-pieu à la contrainte de cisaillement mobilisée. Cette approche de calcul du comportement des pieux est généralement mise en œuvre, comme le recommande l'Eurocode7 Partie 1 (Eurocode 7 2005), lorsque les exigences de la structure portée en termes de déplacement sont essentielles. En France, ces lois sont très largement utilisées et s'appuient essentiellement sur les propositions de Frank et Zhao (1982) à la fois pour les sols fins et les sols grenus. Elles sont toutefois limitées au cas de charges axiales monotones ne dépassant la charge de fluage du pieu et ne permettent pas de rendre compte des phénomènes observés dans le cas où le pieu est soumis à des charges cycliques (fondations d'éoliennes, de structures pétrolières, etc.). Toutefois, des lois t-z cycliques, développées notamment pour l'ingénierie pétrolière, existent pour rendre compte des effets de tels chargements (Chin et Poulos 1992 et Randolph 1986).

Sur la base de ces lois, cet article propose une extension de la loi t-z formulée par Frank et Zhao. Les aptitudes de cette nouvelle loi, pour rendre compte des phénomènes de durcissement ou de radoucissement cyclique ou de rochet et de relaxation (Lemaître et Chaboche 2009), sont présentées à l'échelle locale. Une comparaison entre des résultats expérimentaux issus d'essais sur modèles réduits centrifugés pour quatre pieux soumis à des charges cycliques et des résultats numériques obtenus au moyen de cette nouvelle loi est ensuite proposée. Cette comparaison concerne l'évolution du déplacement en tête de pieu en fonction du nombre de cycles. Une discussion des résultats est ensuite présentée de manière à mieux cerner l'influence de chaque paramètre de la nouvelle loi t-z cyclique développée et à esquisser les développements futurs à mener.

## 2 MISE AU POINT D'UNE LOI T-Z CYCLIQUE

### 2.1 Principes

Dans sa version la plus générale, la loi t-z cyclique entre le frottement  $q_s$  et le déplacement tangentiel  $u_t$  est traduite par l'équation 1. Les neuf paramètres de cette loi sont présentés dans le tableau 1.

$$q_s(u_t) = q_{s,i} + A(-1)^{n_{\text{cyl}}+1} \left[ \left( q_{s,0} + \Delta q_s \left( 1 - e^{-\frac{u_{ti}}{\alpha}} \right) \right) \left( 1 - e^{-R \left| \frac{u_t - u_{ti}}{\alpha} \right|} \right) + \left[ \beta e^{-\frac{u_{ti}}{\alpha}} |u_t - u_{ti}|^\delta e^{-\left| \frac{u_t - u_{ti}}{\gamma} \right|^\delta} \right] \right] \quad (1)$$

Les paramètres auxiliaires A et R sont définis de la manière suivante :

- le paramètre A contrôle l'augmentation de la raideur de l'interface sol-pieu lors des déchargements. Cette augmentation est d'autant plus importante que le déchargement est réalisé à un niveau de chargement élevé ;
- le paramètre R gère l'augmentation de la raideur de l'interface sol-pieu à chaque inversion de cycle. Il comprend les paramètres  $\rho$  et  $\xi$  définis dans le tableau 1.

Lors du premier cycle de chargement, la relation entre le frottement  $q_s$  et le déplacement relatif  $u_t$  peut être simplifiée :

$$q_s = q_{s,0} \left( 1 - e^{-\frac{u_t}{\alpha}} \right) + \beta u_t^\delta e^{-\left( \frac{u_t}{\gamma} \right)^\delta} \quad (2)$$

Le second terme comprenant les paramètres  $\beta$ ,  $\delta$  et  $\gamma$  traduit le durcissement monotone. Il est maximal lorsque le

déplacement relatif  $u_t$  atteint la valeur  $\gamma$ . En l'absence de durcissement, la relation se simplifie sous la forme suivante :

$$q_s = q_{s0} \left( 1 - e^{-\frac{u_t}{\alpha}} \right) \quad (3)$$

On peut remarquer que le paramètre  $\alpha$  correspond au déplacement relatif de l'interface sol-pieu permettant de mobiliser environ 63 % du frottement maximal en l'absence de durcissement. Pour des chargements monotones, les paramètres  $q_{s0}$  et  $\alpha$  peuvent être déterminés respectivement selon la norme française d'application de l'Eurocode 7 (AFNOR 2012) relative aux fondations profondes et selon les lois de Frank et Zhao (1982) (Figure 1). Les autres paramètres sont à caler sur des essais cycliques de chargements de pieu. Actuellement, ils ne peuvent pas être déduits à partir de propriétés usuelles du sol comme le module pressiométrique, la pression limite ou la résistance de cône.

Tableau 1. Définition des paramètres de la loi t-z cyclique

Paramètres généraux	
$i$	nombre d'inversion de cycle de chargement ( $i \geq 1$ )
$q_{s,i}$	frottement mobilisé à l'inversion de charge ( $q_{s,i} = 0$ pour $i = 1$ )
$u_{t,i}$	déplacement relatif de l'interface sol-pieu au cycle $i$ ( $u_{t,i} = 0$ pour $i = 1$ )
$u_{ts} = \sum  u_{t,i} - u_{t,i-1} $	somme des valeurs absolues des déplacements relatifs
Paramètres auxiliaires	
$A = abs \left  \frac{q_{s,i} - (-1)^{(n_{cycl} + 1)} (q_{s0} + \Delta q_s (1 - e^{-u_{ts}/\varepsilon}))}{(q_{s0} + \Delta q_s (1 - e^{-u_{ts}/\varepsilon}))} \right $	
$R = e^{-(n_{cycl}-1)\xi} + \rho (1 - e^{-(n_{cycl}-1)\xi})$	
Mobilisation du frottement sous chargement monotone – 2 paramètres	
$q_{s0}$ [kPa]	frottement mobilisable sous chargement monotone pour de grands déplacements
$\alpha$ [cm]	paramètre de mobilisation du frottement (plus ce paramètre est faible, plus le déplacement pour mobiliser un frottement important est faible et plus l'interface sol-pieu est rigide)
Radoucissement/durcissement monotone – 3 paramètres	
$\gamma$ [cm]	paramètre fixant le déplacement pour laquelle le durcissement est maximal
$\beta$ [kPa]	paramètre contrôlant l'amplitude du durcissement
$\delta$	paramètre de calage égal à 2
Phénomènes cycliques – 4 paramètres	
$\Delta q_s$ [kPa]	amplitude de radoucissement ou de durcissement cyclique
$\varepsilon$ [cm]	paramètre contrôlant la vitesse de radoucissement ou de durcissement cyclique
$\rho$	paramètre contrôlant l'adaptation, l'accommodation et le rochet ou la relaxation
$\xi$	paramètre contrôlant la vitesse d'adaptation, d'accommodation et de rochet ou de relaxation

Figure 1. Comparaison entre la loi de Frank et Zhao et la loi t-z cyclique pour une sollicitation monotone.

## 2.2 Potentialités de la loi t-z cyclique

La loi t-z cyclique a été élaborée de manière à rendre compte les principaux phénomènes cycliques observés lors d'essais de cisaillement cyclique en laboratoire :

- le durcissement ou le radoucissement cyclique pour des essais de cisaillement en déplacement symétrique (Figure 2a) ;
- la relaxation ou non pour des essais de cisaillement en déplacement non symétrique (Figures 2b et 2c) ;
- le rochet plus ou moins important pour des essais de cisaillement en contrainte non symétrique.

Figures 2. Modélisation d'essai de cisaillement suivant différentes conditions (a : déplacement symétrique, b : déplacement non symétrique – relaxation, c : déplacement non symétrique – relaxation nulle)

### 2.3 Comportement de la base du pieu

La loi utilisée pour modéliser l'enfoncement de la base d'un pieu  $u_p$  a été développée sur le même modèle que la loi précédente. Elle est formulée directement en termes d'effort axial mobilisable sous la base du pieu et comprend neuf paramètres dans sa version la plus évoluée. Pour des chargements monotones, les paramètres  $Q_{p0}$  et  $\alpha$  sont toujours calés respectivement selon la norme française d'application de l'Eurocode 7 relative aux fondations profondes (AFNOR 2012) et selon les lois de Frank et Zhao (1982).

Un paramètre complémentaire  $p_r$  (variant entre 0 et 1) a été introduit de manière à prendre en compte le fait que la pointe d'un pieu sollicitée axialement peut se trouver au-dessus de sa position d'origine. Plus il est faible, moins l'effort mobilisé sous la pointe du pieu, tant que ce dernier est au-dessus de sa position initiale, est important (Figure 3).

Figure 3. Modélisation de la mobilisation de l'effort de pointe

## 3 PRÉSENTATION DES ESSAIS EN CENTRIFUGEUSE

Le modèle réduit considéré, à l'échelle du  $1/23^{\text{ème}}$ , est soumis à une accélération centrifuge de  $23 \times g$ . Les propriétés du sable sont les suivantes (Jardine *et al.* 2009, Andria-Ntoanina *et al.* 2010) :  $\rho_{\text{dmin}} = 1395\text{-}1408 \text{ kg/m}^3$ ,  $\rho_{\text{dmax}} = 1755 \text{ kg/m}^3$ ,  $\rho_s = 2650 \text{ kg/m}^3$ ,  $d_{10} = 0,15 \text{ mm}$ ,  $d_{50} = 0,207\text{-}0,210 \text{ mm}$ ,  $d_{60} = 0,23 \text{ mm}$  et  $CU = 1,49\text{-}1,43$ . Le pieu modèle a les caractéristiques suivantes : forme cylindrique « pointe » plate, diamètre de 18 mm, longueur de 590 mm, fiche de 560 mm, barreau d'aluminium de masse totale 0,405 kg, rugosité à l'état « neuf » définie par  $R_t = 112 \mu\text{m}$ ,  $R_a = 25,9 \mu\text{m}$  soit  $R_t/d_{50} = 0,54$  et  $R_a/d_{50} = 0,13$ , rugosité à l'état « usé » (après 10 essais) définie par  $R_t = 90 \mu\text{m}$ ,  $R_a = 23,9 \mu\text{m}$  soit  $R_t/d_{50} = 0,44$ ,  $R_a/d_{50} = 0,12$ . Les massifs sont

reconstitués par pluviage de sable sec dans un conteneur double (Figure 4).

Les expérimentations réalisées comprennent deux séries d'essais monotones permettant de déterminer la résistance ultime du pieu en compression ( $Q_p$ ) et en traction ( $Q_s$ ). Quatre essais cycliques ont ensuite été réalisés : la charge atteint d'abord la valeur  $V_m$  puis oscille entre  $V_{\text{max}} = V_m + V_c$  et  $V_{\text{min}} = V_m - V_c$  (Tableau 2).

Tableau 2. Programme de chargement des essais cycliques

	$V_m/Q_p$	$V_c/Q_p$
Essai 1 (traction cyclique)	-0,33	0,05
Essai 2 (traction cyclique)	-0,133	0,133
Essai 3 (cyclique alterné – compression dominante)	0,3	0,4
Essai 4 (cyclique alterné)	0	0,133

## 4 ANALYSE DES RÉSULTATS OBTENUS

### 4.1 Présentation des résultats

Les paramètres de calcul (Tableau 3) sont calés sur les deux essais monotones en traction (Figure 4) et en compression (Figure 5) en supposant le module de Young du pieu égal à 10 GPa et sur l'essai cyclique 3 qui présente le comportement *a priori* le plus complexe à modéliser.

Tableau 3. Propriétés des paramètres de la loi t-z pour le frottement axial et pour la résistance de pointe

Frottement axial		Résistance de pointe	
$q_{s0}$	102 kPa	$Q_{p0}$	1615 kN
$\alpha$	1 cm	$\alpha$	0,1 cm
$\beta$	30 kPa	$\beta$	
$\gamma$	1,8 cm	$\gamma$	
$\delta$	2	$\delta$	
$\Delta q_s$	- 83 kPa	$\Delta Q_p$	300 kN
$\varepsilon$	25 cm	$\varepsilon$	5 cm
$\rho$	20	$\rho$	6
$\xi$	0,05	$\xi$	0,1
		$p_r$	0,05

### 4.2 Analyse des résultats

La figure 6 propose, pour les quatre essais, la comparaison entre les résultats expérimentaux et les résultats numériques. Expérimentalement, la rupture du pieu est obtenue pour les essais 2, 3 et 4 avec un défaut de résistance à la traction du sol. Pour l'essai 1, alors que l'effort de traction appliqué est plus important de tous les essais réalisés, la rupture n'a pas été atteinte pour le nombre de cycles effectués. Il est néanmoins très probable que le nombre de cycles effectués est insuffisant. Pour l'essai 3, la rupture en compression peut être observée puisque l'enfoncement du pieu est supérieur à 10 % de son diamètre. Les efforts de traction atteints traduisant la rupture du pieu pour les essais 2, 3 et 4 sont très différents : 1204,6 kN, 843,22 kN et 317 kN. Ce résultat montre que le frottement mobilisable le long du fût du pieu, après un grand nombre de cycles de chargement, varie en fonction du chargement appliqué. Dans l'état actuel, la loi t-z proposée n'est pas en mesure de rendre compte ce phénomène car les paramètres  $\Delta q_s$  et  $u_s$  ne traduisent pas suffisamment les effets des cycles sur la résistance de l'interface.

Les résultats obtenus indiquent toutefois que le modèle développé rend compte de manière plutôt satisfaisante des déplacements du pieu lors des premiers cycles de chargement. Pour des nombres de cycles élevés, les tendances restent plutôt bien appréhendées même si les amplitudes de déplacement ne sont pas correctes.

Figure 4. Modélisation de l'essai de traction

Figure 5. Modélisation de l'essai de compression

## 5 CONCLUSION

Une loi d'interaction  $t$ - $z$  cyclique a été développée pour le calcul des pieux sous charge axiale. Des tentatives de validation ont été effectuées en confrontant des résultats numériques obtenus avec cette loi et des expérimentations en centrifugeuse pour des chargements cycliques en traction et en compression alternés ou non. Des améliorations significatives restent à apporter. Les premiers résultats sont encourageants car ils traduisent au moins dans leurs grandes lignes les principaux comportements du pieu.

## 6 REMERCIEMENTS

Les résultats présentés dans cette communication ont été acquis dans le cadre du Projet ANR et du Projet National Français SOLCYP (SOLlicitations Cycliques sur les Pieux).

# Deformation behavior of single pile in silt under long-term cyclic axial loading

## Comportement d'un pieu isolé sous chargement axial cyclique de longue durée dans un limon

Chen R.P., Ren Y., Zhu B., Chen Y.M.

*MOE Key Laboratory of Soft Soils and Geoenvironmental Engineering, Zhejiang University, Hangzhou, China*

**ABSTRACT:** Evaluating the response of piles to cyclic loading is a crucial part in the design of piled-embankment over soft ground. In this paper, a series of large-scale model tests were performed to investigate the response of pile in silt under cyclic axial loading. Heavily instrumented piles were used in the tests. The study is focused on the accumulation of permanent displacement of the piles under long-term cyclic loading. Piles were tested at different cyclic loading levels and subjected up to 50,000 cycles of loading in each test. The accumulated settlement was found to be strongly dependent on the characteristics of the applied cyclic loads. The piles were found not to produce any increase in accumulated settlement if the cyclic loading amplitude is less than a certain threshold value. A simple method is proposed to predict the accumulated settlement of single pile due to very large number of loading cycles. The idea of a cyclic deformation diagram for analyzing the influence of characteristics of cyclic loads on the deformation behavior was also developed.

**RÉSUMÉ :** L'évaluation de la réponse des pieux vis-à-vis d'un chargement cyclique est un élément essentiel dans la conception des remblais sur sols mous. Dans cet article, une série d'essais sur maquette à grande échelle a été réalisée pour étudier la réponse de pieux sous chargement axial cyclique dans le limon. L'étude est centrée sur l'accumulation des déplacements permanents des pieux sous chargement cyclique de longue durée. Les pieux ont été testés à différents niveaux de charge cyclique et soumis à 50000 cycles pour chaque test. Les tassements accumulés sont fortement dépendants des charges cycliques appliquées. Aucune augmentation de tassements n'est constatée si l'amplitude de chargement cyclique est inférieure à un certain seuil. Une méthode simple est proposée pour prédire le tassement cumulé d'un pieu isolé en fonction d'un très grand nombre de cycles de chargement. L'idée d'un diagramme de déformation cyclique pour analyser l'influence des caractéristiques des charges cycliques sur le comportement en déformation a également été développée.

**KEYWORDS:** Pile; model test; accumulated settlement; cyclic loading

## 1 INTRODUCTION

Piles are commonly used to support high-speed railway embankment in soft ground, which are exposed not only to the heavy loads from superstructure self-weight, but also to the long-term "one-way" cyclic loads induced by high-speed trains throughout their service life. However, available design experiences on the long-term response of the pile in silt to cyclic axial loading are very limited, due to the fact that the existing data obtained from laboratory tests and field measurement are insufficient. This results in uncertainty in the design and always leads to an over-conservative design of the pile foundation.

The response of pile subjected to cyclic loading is very complex and model test is the most effective and reliable way to study it and its influencing factors. Laboratory and field tests (Chan and Hanna 1980; Lee and Poulos 1991; Karlsrud et al. 1993) have shown that there are two main effects of cyclic axial loading on piles: (1). a reduction in load capacity and pile-soil system stiffness; (2). an increase in settlement of piles. Poulos (1989) reviewed several cyclic loading tests performed in sand and stated that the accumulation of permanent displacement with increasing load cycles was expected to dominate under "one-way" cyclic loading, particularly if "strain-softening" behavior can occur at the pile-soil interface. The accumulation of the permanent displacement principally depends on the cyclic load level. Briaud and Felio (1986) analyzed the published data and concluded that a load threshold exists above which failure occurs by plunging due to cyclic loading and the value of this threshold is 80% of the ultimate pile capacity on average.

In previous studies, most of the piles were loaded less than 500 cycles of loading. There have been few researches on the response of pile to long-term cyclic loading at present.

This paper describes the results of a series of large-scale model tests on single stiff piles in saturated silt to study the accumulation of permanent displacement of the piles. The tests have been performed using heavily instrumented model piles. A simple method for predicting the accumulation of permanent displacement of pile to long-term cyclic axial loading is proposed. The idea of a cyclic deformation diagram for analyzing the influence of characteristics of cyclic loads on the deformation behavior was also developed.

## 2 DESCRIPTIONS OF EXPERIMENTS

### 2.1 Test site and soil characteristics

The present large-scale model tests were carried out in a big soil tank at Zhejiang University (Fig 1). This soil tank has a dimension of 15×5m in plan view and a depth of 6m.

The soil used in the tests is low cohesive silt. Grading tests showed that the soil contains 10% sand, 85% silt and 5% clay. The characteristics of the soil are summarized in Table 1. Laboratory tests show that the prepared soil had an average water content of 28.5% and an effective internal friction angle of 30°.

Figure 1. The big soil tank at Zhejiang University

Table 1. Main soil properties

Property	Value
D <sub>50</sub> particle size (mm)	0.032
Specific gravity, G <sub>s</sub>	2.69
Plastic limit, W <sub>L</sub>	22.6
Liquid limit, I <sub>L</sub>	31.7
Plasticity index, PI	9.1

### 2.2 Model pile

The used instrumented model pile was closed-ended steel tube pile with an outer diameter (*d*) of 168 mm, a wall thickness of 7 mm. The pile had a cone-shaped tip end with a cone angle of 60°. The model pile was designed to be assembled from four segments to give a full length of 4.2 m. The instrumentation consisted of axial load cells (ALC), total pressure transducers (TPT) and pore pressure transducers (PPT).

Figure 2. Schematic diagram of the model pile (Unit: mm)

### 2.3 Characteristics of cyclic loading

The characteristics of the applied cyclic load are uniquely defined using two independent parameters:

$$SLR = P_s / P_u \quad (1)$$

$$CLR = P_c / P_u \quad (2)$$

in which  $P_u$  refers to the static ultimate capacity of the pile in compression, and  $P_s$  is the minimum in a load cycle and  $P_c$  is the cyclic load amplitude. In present study,  $P_s$  and  $P_c$  simulated the self-weight from the superstructure and the cyclic load induced by the high-speed trains, respectively. A visual interpretation of the load ratios is given in Fig. 3.

Figure 3. The characteristics of cyclic loading

In this study, the cyclic load frequency of 3Hz was used for the tests and the sampling frequency was of 50 Hz.

## 3 TEST RESULTS

### 3.1 Accumulated settlement

The overall pattern of accumulated settlement of the pile with SLR of 0.3 is presented in Fig. 4 by normalizing the accumulated permanent displacement *s* by the pile diameter *d*. The values of the CLR in this series ranged from 0.1 to 0.6. It can be found that the ways in which displacement developed is highly dependent on the amplitudes of cyclic load which can be represented by the cyclic load ratio (CLR).

In the test with the smallest CLR of 0.1, extreme small permanent displacement, of approximately 0.04%*d* was produced in the first three cycles and remained nearly constant from cycle No. 3 to 50,000. For the CLR's ranging from 0.2 to 0.5, the permanent accumulated displacement increased gradually with the increasing number of cycles and also with the increasing magnitude of cyclic load. For the tests with the CLR of 0.2, 0.3, 0.4 and 0.5, the permanent displacements at the end of the tests were 0.15%*d*, 0.35%*d*, 0.56%*d* and 1.26%*d*, respectively. The permanent displacement increased rapidly at initial stage and had the highest rate of displacement increase in the first few cycles, and then it kept increasing continuously with a decreased rate of displacement increase and seemed to increase without a final and constant value. For the test with very large cyclic load, such as CLR=0.6, the pile head moved downward in a very "unstable" way marked by a quick plunging during the test and the pile failed with a total accumulated displacement of 10%*d* in 2,147 cycles.

Figure 4. Normalized permanent displacement (*s/d*) with number of cycles (SLR=0.3)

The aforementioned patterns of behavior shown in Fig. 4 can also be found in other tests with SLR of different values. The accumulated displacement for each test fell qualitatively into any of the three distinct patterns shown in Fig. 4:

(1) no accumulated displacement, as exhibited during the test with CLR of 0.1;

(2) continuing displacement, as exhibited during the tests with CLR ranging from 0.2 to 0.5;

(3) failure, as exhibited during the test with CLR of 0.6.

For the first case, the pile-soil system seems not to be influenced by the cyclic loading and is in elastic range; only small accumulated displacement was produced during the first few cycles. For the second case, the pile-soil system was influenced to some degree and partially entered plastic range; the pile head showed continuing downward movement without any apparent limit and the accumulation of displacement depended on both of cyclic load level and number of load cycles, and high cyclic load level and large number of cycles produced larger permanent displacement. For the last case, the cyclic loading had brought severe damage to the pile-soil system and the pile fully entered the plastic range; the pile head moved continuously downward at a rapid rate up to the end of the test and a plunging failure might occur in some cases.

Thus, to divide the accumulated displacement responses for the tests with a given SLR two critical values of CLR are defined here, named minimum cyclic load ratio (MCLR) and failure cyclic load ratio (FCLR), respectively. For CLR smaller than the MCLR, the pile was in elastic range; for CLR greater than the FCLR, the damage to the pile-soil system was severe and the always caused "failure".

The MCLR was found to be of 0.1 in all the tests and shown to be unaffected by the SLR, and it can be inferred that if the applied cyclic loads remained less than 10% of the ultimate pile static capacity, the response of the pile can be considered to be total elastic and the permanent displacement was negligible after first several cycles.

The FCLR was found to be of 0.5 for the tests with SLR ranging from 0.2 to 0.4. However, in the case of the test with SLR of 0.1, the pile produced large permanent displacement with CLR of 0.4, and it showed the tendency that lesser cyclic loads were required to cause large permanent displacement for the pile with very small SLR. Briaud and Felio (1986) reviewed the previous cyclic load tests and concluded that a threshold of peak load ratio (CLR+SLR) existed above which large permanent displacement occurred and the value of that threshold was about 0.8 on average. However, the tests results suggest that the large permanent displacement depended more on the magnitude of the cyclic load rather than the peak cyclic load. It can be inferred from the results that large permanent displacement occurred if the magnitude of the applied cyclic load exceeds the 50% of the ultimate pile static capacity.

### 3.2 Prediction method

To investigate the evolution of the permanent displacement in the tests in which the permanent displacement are identified as "continuing displacement", the results are replotted on double logarithmic scales and the evolution of the permanent displacement is evaluated in terms of the dimensionless ratio

$$\frac{\Delta s(N)}{s_s} = \frac{s_N - s_0}{s_s} \quad (3)$$

which expresses the magnitude of the permanent displacement  $\Delta s(N)$  caused by cyclic loading in terms of the displacement  $s_s$  that would occur in a static load test when the load is equivalent to the maximum cyclic load (as defined by  $(SLR + CLR) \times P_u$ ). The  $s_0$  and  $s_N$  refer to the permanent displacement in first and  $N$ 'th cycle, respectively.

The results, plotted in Fig. 5, show that the trend in the data follows the exponential behavior which appears as straight lines in double logarithmic axes. This suggests that the permanent displacement due to cyclic loading can be predicted by the following power model:

$$\frac{\Delta s(N)}{s_s} = AN^b \quad (4)$$

where  $A$  and  $b$  are two parameters. It is observed in Fig. 5 that all slopes are almost equal. This suggests that  $b$  is independent of the load characteristics within the observed range. It is introduced into (4) to represent the influence of load characteristics on parameter  $A$  in the following form:

$$A = a(SLR + 1)^m (CLR)^n \quad (5)$$

where  $a$ ,  $m$  and  $n$  are three calibration parameters. Clearly, when  $CLR = 0$ , then  $A = 0$  and no accumulated displacement will occur under static load. Also, when  $SLR = 0$  then  $A = a(CLR)^n$  indicates that the accumulated displacement depends only on CLR. Thus, substituting (5) into (4) gives the following model for accumulated permanent displacement:

$$\frac{\Delta s(N)}{s_s} = a(SLR + 1)^m (CLR)^n N^b \quad (6)$$

The expression in Equation (6) was fitted to the data in Fig. 5 to empirically determine values of these parameters and back-calculated parameters  $a$ ,  $m$ ,  $n$  and  $b$  for the tests are 0.054, 0.68, 1.24 and 0.23. The predicted results are shown by the dotted lines in Fig. 5 and it appears that the influences of the load characteristics on permanent displacement are reflected well in the prediction. The closeness of the fit up to  $5 \times 10^4$  cycles indicates that, in the absence of further experimental data, it might be reasonable to extrapolate beyond  $N > 5 \times 10^4$ . Further data are, of course, required to confirm this hypothesis.

Figure 5. Measured and predicted accumulated displacement  
The dotted lines are obtained using Equation (6)

## 4 CYCLIC DEFORMATION DIAGRAM

Poulos (1988) proposed the idea of cyclic stability diagram to investigate the capacity degradation caused by cyclic loading. In this study, similar concept is used and the idea of a diagram named cyclic deformation diagram is developed. The cyclic deformation diagram for the model piles is shown in Fig. 6. In the diagram, the aforementioned three types of displacement response are represented by different symbols. Therefore, three main regions can be identified on the diagram shown in Fig. 6:

(1) A stable (elastic) region I in which the cyclic loading has no influence on the pile responses and the displacement response is the type of "no accumulated displacement".

(2) A serviceability region II in which the cyclic loading has some influence on the pile response and the displacement response can be identified as “continuing displacement”.

(3) A unstable region III in which cyclic loading causes severe damage for the pile to produce very large permanent displacement and in some cases a plunging failure occurs.

Figure 6. Cyclic deformation diagram for pile in silt ( $N=50,000$ )

The upper boundary to the cyclic permanent displacement is the straight line (CS:  $SLR+CLR=1$ ) that represent the combinations of SLR and CLR necessary to cause a failure of pile without cyclic effects being considered. The other two lines plotted in this diagram represent the approximate boundaries between the stable region, the serviceability region and the unstable region. These lines are defined by the following relations:

Upper boundary of stable zone (line AB and BC):

$$\begin{cases} CLR = 0.5 & 0 \leq SLR \leq 0.4 \\ 1.2CLR + SLR = 1 & 0.4 < SLR \leq 1.0 \end{cases} \quad (7)$$

Lower boundary of unstable zone (line DC):

$$5CLR + SLR = 1, \quad 0 \leq SLR \leq 1 \quad (8)$$

Fig. 6 also plots the other test results of field or model tests on axial cyclically loaded pile. It can be seen that these proposed lines are consistent with the experimental data and thus it is indicated that the proposed three regions are capable of reasonably identifying the deformation behavior of pile under various load combinations. A diagram such as shown in Fig. 6 represents the permanent displacement of a pile for a specified number of cycles,  $N$ . As  $N$  increases, the stable region will remain unchanged and the unstable region may increase as the permanent displacement increases.

In the pile design, it is very convenient to determine the deformation behavior of the pile to cyclic loading using this diagram. The most conservative design is to have the cyclic loads in the stable region which means that pile will not be affected by cyclic loading and issues of the permanent displacement can be totally ignored. If the designed cyclic load is in the serviceability region, the permanent displacement accumulates in “stable” way and depends on both of the number of cycles and the load characteristics; and it can be predicted using the proposed simple method mentioned above. For a safe design, it should avoid the cyclic load to be in the unstable region in which cyclic loading will result in very large permanent displacement and even a plunging failure.

## 5 CONCLUSION

A series of tests were conducted on large-scale model piles subjected to long-term cyclic axial loading. The deformation behavior of the piles in silt to cyclic loading was investigated.

The evolution of permanent displacement highly depends on the magnitude of cyclic load. In general, the accumulation of permanent displacement increases with increasing cyclic load amplitude and increasing number of cycles. However, the pile behaves in an elastic manner and does not accumulate any deformation after the first few cycles of loading if the magnitude of cyclic load is less than 10% of the ultimate pile capacity. Very large permanent displacement, even plunging failure, occurs when magnitude of cyclic load exceeds 50% of the ultimate pile capacity. This suggests that the magnitude of the cyclic load be kept below 50% of the ultimate capacity to avoid large permanent displacement in the design.

These results provide a better understanding of the deformation behavior of pile in silt to long-term cyclic axial loading, and can be used to optimize the designs of pile foundations that resist cyclic loads in service.

# Time-Varying Dynamic Properties of Offshore Wind Turbines Evaluated by Modal Testing

Étude expérimentale de l'évolution temporelle des propriétés dynamiques d'éoliennes maritimes

Damgaard M., Andersen J.K.F.  
*Vestas Turbines R&D, Denmark*

Ibsen L.B., Andersen L.V.  
*Department of Civil Engineering, Aalborg University, Denmark*

**ABSTRACT:** Modal frequencies and damping ratios of civil engineering structures are often used as damage-sensitive features, since changes in the dynamic characteristics of the structures may indicate structural damage. For offshore wind turbine structures, the modal parameters are influenced by environmental impacts that change boundary conditions, irreversible soil deformations and inherent structural properties. The excitation frequencies related to the environmental loads and the passage of blades past the tower are so low that a proper estimate of the modal parameters are needed in order to avoid strong resonance of the wind turbine structure. In this paper, free vibration tests and a numerical Winkler type approach are used to evaluate the dynamic properties of a total of 30 offshore wind turbines located in the North Sea. Analyses indicate time-varying eigenfrequencies and damping ratios of the lowest structural eigenmode. Isolating the oscillation oil damper performance, moveable seabed conditions may lead to the observed time dependency.

**RÉSUMÉ:** Les fréquences modales et les taux d'amortissement des structures de génie civil sont souvent utilisés comme indicateur de dommages car l'évolution de la réponse dynamique des structures peut indiquer des dégâts structuraux. Pour des structures comme les éoliennes maritimes, les paramètres modaux sont influencés par la déformation irréversible des sols, les propriétés structurelles inhérentes et les conditions environnementales qui peuvent changer les conditions aux limites. Les fréquences d'excitations liées aux charges environnementales et aux passages des pales sont si basses qu'une estimation correcte des paramètres modaux est nécessaire pour éviter une forte résonance de la structure de l'éolienne. Dans cet article, des tests vibratoires et une approche numérique du type Winkler sont utilisés afin d'évaluer les propriétés dynamiques de 30 éoliennes maritimes situées en mer du Nord. Les analyses révèlent le changement des fréquences propres et des taux d'amortissement de la plus basse fréquence propre structurelle en fonction du temps. En isolant la performance de l'amortisseur oscillant à huile, les changements de conditions du fond marin peuvent démontrer une dépendance temporelle.

**KEYWORDS:** Free vibration; modal; offshore wind turbine;  $p$ - $y$  curve; scour; winkler approach.

## 1 INTRODUCTION

Recently, offshore wind turbine towers and blades have increased significantly in height and length, respectively, with only a small increase in weight. Therefore, the dynamic response of the wind turbine structure occurs in a frequency range close to the excitation frequencies related to environmental and structural harmonic loads. In this context, sufficient geometrical and material damping in the structure and soil are required to counteract large amplitudes of vibration. Especially for wind parks characterised by a large degree of wind-wave misalignment, a proper estimate of the inherent damping is needed due to low aerodynamic forces out of the rotor plane.

The aim of this paper is to investigate the time-varying eigenfrequency  $f_1$  and inherent modal damping  $\delta_1$  of the lowest eigenmode  $\Phi^{(1)}$  for offshore wind turbines installed on a monopile foundation. Experimental modal analysis of offshore wind turbines have been studied by several researchers. Based on free vibration tests, Tarp-Johansen *et al.* 2009 and Damgaard *et al.* 2011 have used "rotor-stop" tests to determine each damping contributor to the measured inherent modal damping  $\delta_1$  of an offshore wind turbine. Versteijlen *et al.* 2011 and Devriendt *et al.* 2012 used the same modal approach to obtain reliable damping estimates. In addition, Versteijlen *et al.* 2011 considered operational modal analysis in order to include the aerodynamic effects on the structure. The theory has been widely used for civil engineering structures like bridges and buildings. However, in the last years the application of

operational modal analysis on wind turbines has been published in many excellent papers, see for instance Hansen *et al.* 2006 and Tcherniak *et al.* 2010. A thorough data processing of more than 650 free vibration tests on 30 offshore wind turbine structures are presented in the paper. The variation in the dynamic properties is supported by a numerical Winkler approach that estimates the modal parameters for different environmental conditions.

## 2 STRUCTURE AND SITE CONDITIONS

A total of 30 Vestas V90-3MW turbines located in the North Sea are considered. Each tower is installed on a monopile connected by a grouted transition piece to the tower base. The tower height is approximately 60 m, the monopile diameter 4.3 m and the water depth 8 m w.r.t. LAT. For each turbine an oscillation damper is placed in the top of the tower. It consists of a pendulum partly immersed in highly viscous oil, capable of oscillating in the horizontal directions. The soil consists mainly of cohesionless soil in the top layers with friction angles  $\phi_k$  higher than 30° followed by cohesive soils with undrained shear strength  $c_u$  higher than 90 kPa.

## 3 MODAL PARAMETER ESTIMATION

By use of two accelerometers placed in the nacelle, the modal parameters of each wind turbine are experimentally estimated

from the acceleration decay when the turbine generator shuts down and the blades pitch out of the wind, see Figure 1. Hence, assuming that the wind turbine structure behaves as a single-degree-of-freedom (SDOF) system, the eigenfrequency  $f_1$  and modal damping  $\delta_1$  are determined by least-squares fitting of a linear function to the zero crossings and to the natural logarithm of the rate of decay of the vibration, respectively. It should be noticed that a wind turbine structure has two closely spaced modes occurring at nearly identical frequencies (Damgaard *et al.* 2012), where vibrational energy is transferred from the highest to the lowest damped mode. Hence, for the damping estimation of each free vibration test it is ensured that the acceleration of the structure only takes place in the fore-aft direction  $y$ .

Figure 1. Raw output acceleration signal during a “rotor-stop”.

### 3.1 Winkler Approach

Offshore wind turbines supported by pile foundations are subjected to lateral cyclic loads. The load-deflection behaviour is often evaluated by a Beam on Nonlinear Winkler Foundation (BNWF) model due to its computationally efficiency and practical versatility. The tower and pile are modelled as Bernoulli-Euler beams and the soil-structure interaction is incorporated via so-called  $p$ - $y$  curves suggested by DNV 2011, see Fig. 2. The soil consists of a series of independent soil layers with smooth horizontal boundaries, *i.e.* no shearing can be transmitted across the boundaries. Rather than modelling the soil as a number of discrete springs connected to the element nodes, this paper uses a consistent approach, where the soil is modelled as a continuous spring over each element. The nodal forces are then obtained via numerical integration. The reader is referred to Damgaard *et al.* 2011 for more information about the computational model.

Figure 2. Beam on nonlinear Winkler foundation (BNWF) model.

#### 3.1.1 Soil Damping Estimation

In general, attenuation of wave propagation in the soil is determined from geometric damping, *i.e.* the radiation of waves into the subsoil, and material damping caused by the slippage of soil grains with respect to each other. However, extensive studies of wind turbines on a homogeneous or layered ground made by Andersen 2008 show that geometric dissipation is

insignificant at frequencies below 1 Hz. From the continuum mechanics it is known that material damping is related to the relative motion of material points, and the energy dissipation is frequency-dependent. For a given frequency and deformation level, the soil material damping can be approximated to an equivalent viscosity. Based on a static deformation analysis, using the Winkler approach, the following procedure is used to determine the soil damping ratio  $\zeta_{soil}$  of the lowest eigenmode  $\Phi^{(1)}$ :

- A 10-minutes time-domain simulation of the wind turbine structure is conducted for a power production situation with a normal turbulence model (IEC 2005) using the aeroelastic code FLEX (Øye 1996). A correct estimate of the structural eigenfrequency  $f_1$  in the FLEX model is ensured by extending the tower until the eigenfrequency  $f_1$  of the Winkler model is reached.
- Based on the maximum overturning moment at the tower/foundation interface from the FLEX simulation and including wave loads, the horizontal pile deformation in each nodal point below the seabed is evaluated.
- Assuming a load-displacement cycle after the generator shuts down, as indicated in Figure 3a, the irreversible soil deformations are a measure of energy dissipation. Hence, the energy dissipation in Figure 3a can be transformed to an equivalent viscous damping model as shown in Figure 3b.
- Using the theory of linear structural dynamics, the soil damping  $\zeta_{soil}$  of the lowest eigenmode  $\Phi^{(1)}$  is determined from the global damping matrix  $C$ , the angular eigenfrequency  $\omega_1$ , the eigenmode  $\Phi^{(1)}$  and the modal mass  $M_1$  given by

$$\zeta_{soil} = \frac{\Phi^{(1)T} C \Phi^{(1)}}{2\omega_1 M_1} \quad (1)$$

The virgin curve in Figure 3a is determined by the  $p$ - $y$  curve formulation given by DNV 2011. The unloading phase is determined by the initial stiffness  $E_{py}^*$ . Assuming separation between the pile and the soil, a shear drag  $p_{drag}$  is introduced. For cohesionless soils, the shear drag depends on the vertical effective stress  $\sigma_v$  (Ovesen *et al.* 2006) given by  $p_{drag} = 0.6D \sigma_v$ , whereas for cohesive soils the undrained shear strength  $c_u$  must be considered, *i.e.*  $p_{drag} = 0.7Dc_u$ .

Figure 3. Hysteresis Loop Method (Nielsen 2004): (a) Load-displacement curve after the wind turbine generator shuts down, (b) Hysteresis loop implied by viscous damping in a harmonic motion with the amplitude  $A$  and the angular eigenfrequency  $\omega_1$ .

## 4 INTERPRETATION OF RESULTS

Experimental modal testing of 30 offshore wind turbines in the period 2006-2011 is presented in Figure 4a and Figure 4b in terms of the modal damping  $\delta_1$  and the eigenperiod  $T_1$  of the lowest eigenmode  $\Phi^{(1)}$ , respectively. Using a lognormal probability distribution, the 5% quantile of the modal damping  $\delta_1$  and the eigenperiod  $T_1$  are estimated to 0.11 and 2.94 s, respectively. This corresponds to an eigenfrequency  $f_1$  of 0.34 Hz. As indicated in Figure 4a and Figure 4b, the scatter of the estimated parameters is high. Increasing the R-square value from 0.95 to 0.99, meaning that the fit of the acceleration amplitude peaks and zero crossings explains 99% of the total variation in the data about the average, seems to reduce the scatter to a certain extent, see Figure 4c and Figure 4d. Overall,

a tendency of decreasing modal damping and eigenfrequency is observed for increasing acceleration level. High structural accelerations induce irreversible soil deformations and thereby soil damping activation. However, the oil damper performance is characterised by optimal damping for low levels of accelerations, which may explain the observed behaviour. In addition, distinct non-linear soil behaviour occurs for high accelerations, which reduces the secant stiffness  $E_s$  and thereby the eigenfrequency  $f_1$ .

An almost identical mean value and standard deviation of the modal parameters have been observed for each wind turbine. Hence, the variation of the modal parameters in Figure 4c and Figure 4d might be caused by the following conditions:

Figure 4. Free vibration tests for a total of 30 offshore wind turbines: (a) Damping histogram, (b) Eigenperiod histogram, (c) Damping vs. acceleration level, (d) Eigenfrequency vs. acceleration level.

- Tower damper performance
- Tidal variation
- Wind variation
- Temperature dependent modal parameters
- Moveable seabed and scour around the foundation

Figure 5. Selected turbine investigation: (a) Tidal and wind variation as a function of time, (b) Modal parameters as a function of time. Data are collected with same acceleration level and slope of generator speed.

It has been observed that the mass pendulum of the tower damper in some tests moves exactly with a phase identical to the phase of the wind turbine, resulting in almost no additional damping. To eliminate the variation of the tower damper performance, data for each turbine is investigated for the same slope of generator speed when the blades pitch out of the wind and for the same acceleration level. As an example, Figure 5 shows the comparison of the measured 10-minutes wind speed

and tidal variation together with the modal parameters for a selected turbine. One one-year measurements of the tidal levels at the wind park show only a maximum difference between highest and lowest astronomical tide of 2 m. It might then be assumed that the tidal variation at the wind park has negligible impact on the magnitude of the modal parameters. The same conclusion can be drawn regarding the variation in the wind speed and temperature during the tests. The aerodynamic damping is very low, when the blades pitch out of the wind, and a temperature change from  $-73^\circ$  to  $93^\circ$  only changes the Young's modulus of elasticity  $E_{\text{steel}}$  with 5% (Nielsen 2004). Based on a Winkler model this corresponds to a change in the eigenfrequency  $f_1$  of only 0.5%. In conclusion, assuming that the tower damper contributes with the same damping value in Figure 5b, the time-dependent modal parameters might be caused by erosion of soil particles near the monopile foundation.

Figure 6. Scour and backfilling analysis based on a Beam on Nonlinear Winkler Foundation model: (a) Eigenfrequency  $f_1$  as a function of scour depth and backfilling height, (b) Soil damping  $\delta_{\text{soil}}$  as a function of scour depth and backfilling height.

### 1.1 Scour and Backfilling

When a pile is installed in a loose sedimentary bed, a scour hole will form around the pile. The phenomenon is of high importance, since the structural eigenfrequency and soil damping contribution will change and in worst case lead to fatigue damage and, eventually, failure. Based on experimental tests, Sumer *et al.* 1992 stated that the mean value of the equilibrium scour depth for a vertical cylinder in steady current is given by  $1.3D$ , where  $D$  is the diameter of the cylinder. However, for combined current and wave conditions the scour depth is difficult to determine, since wave action tends to reduce the scour depth (Høgedal and Hald 2005).

As no scour protection is present for the investigated wind turbine structures in this paper, the variation of the eigenfrequency  $f_1$  and soil damping  $\delta_{\text{soil}}$ , caused by sediment transportation at seabed, is estimated using a Winkler approach. Different scour depths and backfill heights are considered for a wind speed of 13 m/s with maximum depth and height equal to  $1.3D$ , respectively. The vertical effective stress  $p_0$  is reduced linearly with depth to a depth equal to  $3D$  below the base of the current scour hole. As expected, Figure 6a shows a decreasing eigenfrequency  $f_1$  for increasing scour depth. Assuming cohesionless backfill material with a friction angle  $\phi_k$  of  $28^\circ$ ,

the eigenfrequency  $f_1$  tends to increase for increasing backfill height. The material soil damping  $\delta_{\text{soil}}$  highly depends on the pile deflection and the initial stiffness  $E_{\text{py}}^*$  for each soil layer, see Figure 3. However, the pile deflection at the base of the scour hole only increases to a certain scour depth, and the initial stiffness  $E_{\text{py}}^*$  depends on the strength of each soil layer and the scour depth. Hence, for increasing scour depth the pile deflection and initial soil stiffness might increase or decrease relative to each other. This may in turn explain the observed behaviour of the soil damping  $\delta_{\text{soil}}$  in Figure 6b.

Over a period of time the relative density  $I_d$  of the backfill material might be increased due to the presence of waves inducing depth compaction (Sørensen *et al.* 2010). Hansson *et al.* 2005 have reported friction angles above 40° for Frederikshavn sand. Figure 7 shows the eigenfrequency  $f_1$  and soil damping  $\delta_{\text{soil}}$  as a function of the strength of the backfill material after the scour hole is replaced by the backfill material.

In conclusion, the Winkler approach shows a variation of the eigenfrequency  $f_1$  caused by sediment transportation at the seabed level of 8%. The model indicates a soil damping  $\delta_{\text{soil}}$  in the range of 0.05-0.08 logarithmic decrement. Hence, comparing these results with the experimental findings in Figure 5, the time-varying modal parameters of the investigated offshore wind turbines might be caused by sediment transportation at seabed.

## 2 CONCLUSION

Wind energy is a rapidly growing interdisciplinary field that involves many different disciplines within civil engineering. The dynamic behaviour of the wind turbine structure is determined by a complex interaction of components and sub-systems. A full understanding of the structural modal parameters is crucial in order to assess the fatigue damage accumulation during the lifetime of the wind turbine structure.

Experimental and numerical investigations of the dynamic properties of offshore wind turbine structures installed on a monopile foundation have been presented in this paper. Based on a total of 665 free vibration tests, time-varying modal parameters are observed, which is supported by a Winkler approach. Several interesting observations can be made:

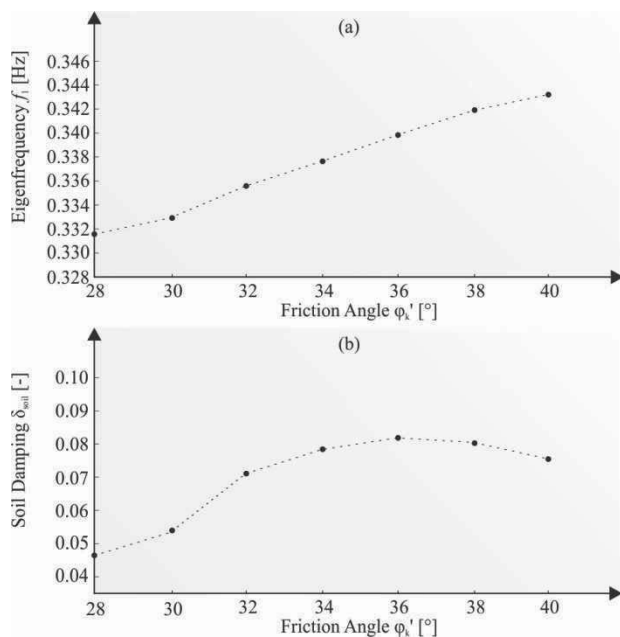

Figure 7. Strength of backfilled material based on a Beam on Nonlinear Winkler Foundation model: (a) Eigenfrequency  $f_1$  as a function of the friction angle  $\phi_k'$  of the backfill material, (b) Soil damping  $\delta_{\text{soil}}$  as a function of the friction angle  $\phi_k'$  of the backfill material.

- Experimental testing indicates a high variation in the eigenfrequency  $f_1$  and the modal damping  $\delta_1$ . A 5% quantile of 0.11 logarithmic decrement is observed, which corresponds very well with the findings for each considered turbine.
- Eliminating the tower damper performance tends to reduce the large variation of the modal parameters. However, distinctly time-varying eigenfrequencies  $f_1$  and modal damping values  $\delta_1$  are still obtained.
- A Beam on a Winkler foundation model indicates that the observed time-dependencies might be caused by sediment transportation at seabed. Scour development and backfilling change the eigenfrequency  $f_1$  with 8%, and the soil damping  $\delta_{\text{soil}}$  varies in the range 0.05-0.08.

# Numerical investigation of dynamic embedment of offshore pipelines

## Étude numérique de l'ancrage dynamique de conduites enterrées maritimes

Dutta S., Hawlader B.  
Memorial University, St. John's, Canada.

Phillips R.  
C-CORE, St. John's, Canada.

**ABSTRACT:** Pipelines are one of the key components of offshore oil and gas development programs. Deep water pipelines are often laid on the seabed and penetrate into soil a fraction of their diameter. High operating temperature and pressure generate axial stress that could buckle the pipeline laterally. The embedment and formation of soil berm have a significant effect on lateral resistance. The embedment of a pipeline depends on stress concentration at the touchdown point (TDP) and dynamic laying effects. In this study, large deformation finite element modelling of dynamic penetration of offshore pipeline is presented. The Coupled Eulerian Lagrangian (CEL) technique is used to develop finite element model. The pipe is first penetrated into the seabed followed by a small amplitude cyclic lateral motion. Results from the finite element models are compared with centrifuge test results. High plastic shear strain is obtained around the pipeline during cyclic loading which causes significant pipe embedment. The shape of soil berm is different from that of monotonic pipe penetration.

**RÉSUMÉ :** Les conduites enterrées sont un des éléments clés des programmes de développement de pétrole et de gaz. Des conduites enterrées en eau profonde sont souvent mises sur le plancher océanique et pénètrent dans le sol sur une fraction de leur diamètre. La température et la pression de fonctionnement élevées génèrent une contrainte axiale qui peuvent déformer la conduite latéralement. L'ancrage et le sol encaissant ont un effet significatif sur la résistance latérale. L'enfouissement d'une conduite dépend des concentrations de contraintes et des effets dynamiques de la pose. Dans cette étude, une modélisation par éléments finis en grande déformation de la pénétration dynamique de la conduite est présentée. Une technique de type Eulérien Lagrangien (CEL) est utilisée pour développer le modèle éléments finis. Le tuyau est d'abord mis en place dans le fond marin puis subit un mouvement cyclique de faible amplitude latérale. Les résultats des modèles éléments finis sont comparés avec les résultats d'essais en centrifugeuses. D'importantes valeurs de la déformation plastique sont obtenues autour de la canalisation lors du chargement cyclique ce qui nécessite un ancrage suffisant de la conduite. La forme du sol encaissant est différente de celle du tuyau mis en place statiquement.

**KEYWORDS:** pipelines, dynamic embedment, clay, large deformation analysis.

## 1 INTRODUCTION

As-laid pipelines are commonly used in deepwater. During installation the as-laid pipeline could be penetrated a fraction of its diameter into the seabed (Bruton et al. 2006), and a soil berm could be formed. The soil around the pipelines provides not only the thermal insulation and hydrodynamic stability to the pipe but also resistance to pipeline walking and lateral buckling during high operating temperature and pressure. Accurate assessment of as-laid pipe embedment is extremely difficult. Depending upon sea state, vessel conditions, pipe stiffness and soil conditions, the pipeline might experience both in-plane and out-of-plane cyclic motion during installation (Westgate et al. 2010, 2012), which causes dynamic embedment of the pipeline.

The penetration of a pipeline under static load can be obtained using bearing capacity theory, analytical solution or finite element techniques. In the current engineering practice, two additional factors are used to estimate the embedment of pipelines: (a) additional vertical force near the TDP (the point where the pipe first touches the soil) due to catenary effects and (b) dynamic lay effects. A number of methods have been proposed in the past to estimate these factors (Carneiro et al. 2010, Oliphant and Yun 2011). For example, Randolph and White (2008) proposed an empirical equation to calculate the touchdown lay factor ( $f_{lay}$ ) using pipe submerged weight, bending rigidity, horizontal component of effective tension, lay angle, water depth and seabed stiffness. The embedment factor for dynamic lay effects ( $f_{dyn}$ ) varies between 2 and 10 (Lund 2000, Bruton et al. 2006). This wide range of variation in this factor makes the assessment of pipe embedment very difficult.

During installation, both vertical and lateral pipe motions can soften the seabed soil near the pipe. Soil softening/remolding together with water entrainment can reduce the undrained shear strength of soil. Field observation (Westgate et al. 2010) and physical modeling using geotechnical centrifuge (Cheuk and White 2011) show that the horizontal cyclic motion, although small amplitude, has a significant effect on pipe embedment.

The main purpose of this study is to conduct large deformation finite element (FE) analysis for dynamic events during the installation of pipeline. Coupled Eulerian Lagrangian (CEL) technique is adopted in the analysis using ABAQUS FE software. Four FE models are developed for two different soils: kaolin and high plasticity clays (plasticity index for kaolin is 34 and for high plastic clay is 100-130, Cheuk and White 2011). The results are compared with the centrifuge test results available in the literature.

## 2 PROBLEM DEFINITION.

The problem considered in the present finite element (FE) modelling is shown in Fig.1. During laying, offshore pipelines usually penetrate vertically into the seabed due to its self-weight and catenary effect near the touchdown zone (TDZ). The vessel movement from wave loading could cause small amplitude cyclic motions in the  $x$ -direction. As the pipeline is under a vertical load ( $p_0$ ), the lateral movement in the  $x$ -direction could cause additional vertical penetration as shown by Stage-II and III in Fig. 1.

Figure 1. Problem statement.

### 3 FINITE ELEMENT MODELLING.

ABAQUS 6.10 EF-1 is used in the present finite element analysis. As the embedment of pipe in the seabed is large deformation problem, the conventional finite element techniques in Lagrangian approach cannot simulate the complete process realistically as numerical difficulties are generally encountered for such large displacements. Therefore, in this study the Coupled Eulerian Lagrangian (CEL) technique currently available in ABAQUS FE software is used. In CEL, the soil flows through the fixed mesh without having any numerical issues. The FE modeling using CEL for pipe embedment into the seabed is presented by the authors previously (Dutta et al. 2012 a&b). A soil domain of  $8\text{m} \times 3\text{m} \times 0.04\text{m}$  (length  $\times$  height  $\times$  thickness) is used in this study. The soil is modelled as Eulerian elements and the pipe is modelled as Lagrangian elements. The 1.5 m void space above the soil is required to accommodate the displaced soil mass (Eulerian materials) during pipe displacement. Zero velocity boundary conditions are applied at all faces of the Eulerian domain to make sure that Eulerian materials are within the domain and cannot move outside. However, at the seabed-void interface, no boundary condition is provided so that the soil can flow to the void. That means, the bottom of the model is restrained from any vertical movement, while all the vertical faces are restrained from any lateral movement. The pipe is modeled as a rigid body. During penetration, especially in cyclic loading, the remolding of soil near the pipe could cause significant reduction in undrained shear strength. Smooth pipe/soil interface condition is used for the present analysis. Mesh sensitivity analysis is also performed and an optimum mesh size of  $0.04\text{m} \times 0.04\text{m}$  is used (Dutta et al. 2012 a).

The loading is performed in three different stages. First, the geostatic conditions are applied to bring the seabed to in-situ condition. Second, the pipe is penetrated applying a vertical load ( $p$ ) which is the combined effect of submerged unit weight of the pipe and laying effects. In the third step, 40 cycles of small amplitude ( $\pm 0.05D$ ) lateral displacement are applied using displacement boundary conditions under the constant vertical load  $p_0$ . Plastic shear strain develops near the pipe during penetration. In the present FE analyses the degradation of undrained shear strength as a function of plastic shear strain is adopted using the following model (Einav and Randolph 2005 Wang et al. 2009 and Zhou and Randolph 2009).

$$s_u = [\delta_{rem} + (1 - \delta_{rem}) \exp(-3\xi/\xi_{95})] s_{u0} \quad (1)$$

where  $\delta_{rem} = 1/S_r$ ,  $S_r$  is the soil sensitivity,  $\xi$  is the accumulated equivalent plastic shear strain,  $s_{u0}$  is the intact undrained shear strength of soil and  $\xi_{95}$  is the accumulated plastic shear strain at 95% undrained shear strength degradation. The variation of  $s_{u0}$  with depth is shown in Fig. 1 and the von-Mises yield criteria is adopted.

In this study four cases are simulated and the results are compared with centrifuge test results of Cheuk and White (2008). Two tests (KC-04 & KC-05) are in kaolin clay and two

(HP-06 & HP-07) are in high plasticity clay. Table 1 shows the parameters used in the FE analyses. The vertical load  $p$  for initial static penetration and during cyclic motion are also shown in Table 2.

Table 1. Parameters for finite element modelling.

Pipe	Soil Properties	
	Kaolin Clay	High Plasticity Clay
Pipe diameter, $D$ (mm)	800	
Lateral displacement during cyclic motion	$\pm 0.05D$	
Undrained modulus of elasticity, $E_u$	$500s_u$	$500s_u$
Poisson's ratio, $\nu_u$	0.495	0.495
Undrained shear strength at mudline, $s_{um}$ (kPa)	0.75	0.40
Gradient of shear strength increase, $k$ (kPa/m)	1.6	2.5
Submerged unit weight of soil, $\gamma'$ (kN/m <sup>3</sup> )	6.0	3.0
Remoulded soil sensitivity, $S_r$	4.0	1.7
Accumulate absolute plastic shear strain for 95% degradation of soil strength, $\xi_{95}$	10	10

Table 2. Centrifuge test conditions (Cheuk and White 2011).

	KC-04	KC-05	HP-06	HP-07
Pipe vertical load, $p$ (kN/m)	1.17	2.23	1.47	2.61
Initial static embedment, $w_{in}/D$	0.08	0.12	0.10	0.22
Pipe vertical load at cyclic motion, $p_0$ (kN/m)	1.13	2.17	1.43	2.52

### 4 RESULTS.

The pipe was initially penetrated under a static vertical load  $p$ . The initial static embedment ( $w_{in}$ ) for this load is shown in Table 2. After initial penetration a small amplitude cyclic lateral load is applied (e.g. Fig. 2 for KC-05,  $u$  = pipe lateral displacement) to simulate the first 40 cycles (Stage-I) of centrifuge tests. The normalized lateral resistance for KC-05, where  $s_{u0(i)}$  in the horizontal axis is the intact undrained shear strength at pipe invert, is shown in Fig. 3(a) and compared with centrifuge test results Fig.3(b). The lateral resistance is slightly higher than that obtained in centrifuge test. This might be due to the limitation of the soil shear strength degradation model (Eq. 1). It is very difficult to measure and model the behaviour of soil near the pipeline under cyclic loading. However, using this simplified model (Eq. 1) in ABAQUS CEL the lateral resistance during cyclic movement is reasonably simulated.

Figure 2. Pipe embedment during lateral motions

Figures 4(a),4(b) and 4(c) show the lateral resistance for other three simulations. As shown, the shape of the lateral resistance plot is different, which mainly depends on soil shear strength profile, shear strength degradation, sensitivity of soil, and applied vertical load. The depth of the invert of the pipe normalized by pipe diameter ( $D$ ) with number of load cycle is shown in Fig. 5 for comparison the centrifuge test. the present FE model reasonably simulates the embedment

of the pipe with the soil parameters listed in Table 1. Figure 5(a) shows that the depth of embedment does not increase

significantly after 20-30 load cycles for kaolin clay. However, the pattern is somehow different for high plastic clay as shown in Fig. 5(b) where the pipes continue to penetrate even after 20-30 load cycles.

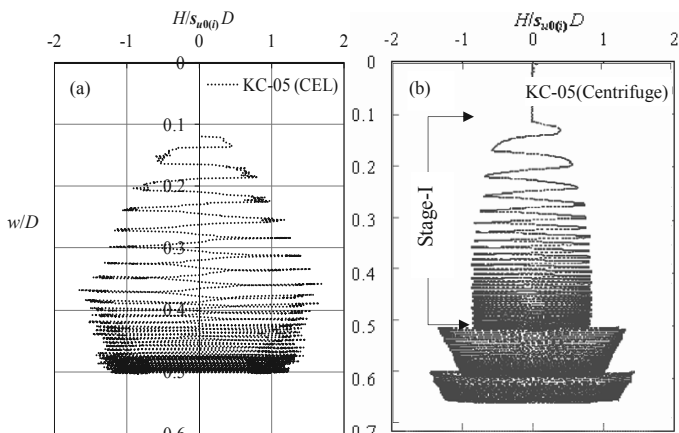

Figure 3. Test KC-05 (a) present study (b) centrifuge test.

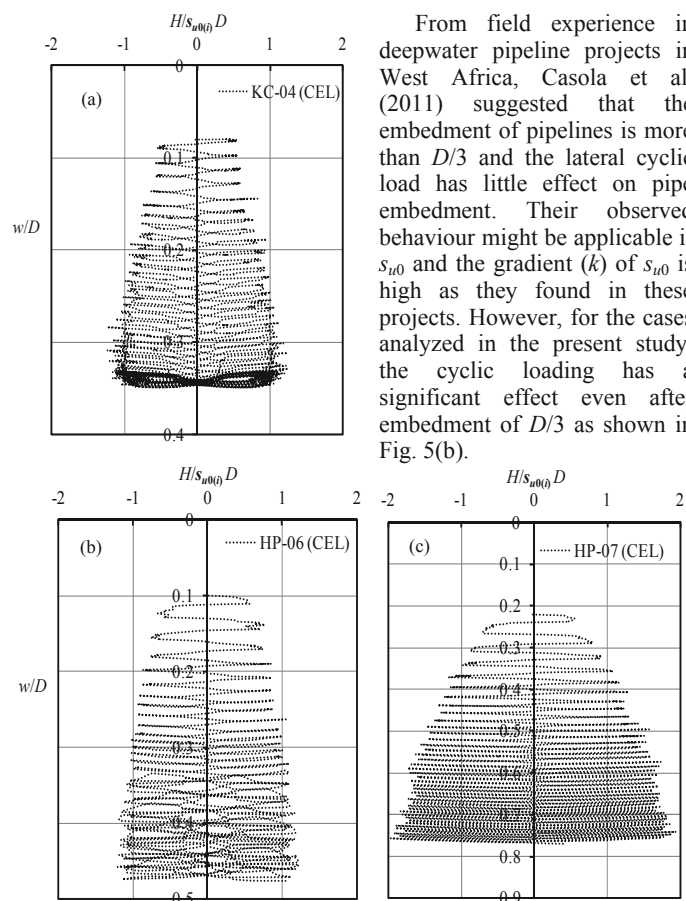

Figure 4. FE results (a) KC-04 (b) HP-06 and (d) HP-07.

## 5 DYNAMIC EMBEDMENT

In the current engineering practice the effects of laying and dynamic embedment are assessed separately. The lay effect on vertical load ( $p$ ) is obtained by multiplying the submerged unit weight of the pipe by an empirical lay factor ( $f_{lay}$ ). The monotonic embedment ( $w_{mon}$ ) for this load  $p$  is calculated using the bearing capacity theory. The effect of small amplitude cyclic lateral motion is incorporated using another empirical factor known as dynamic embedment factor ( $f_{dyn}$ ). Finally, the total embedment ( $w_f$ ) is calculated as  $w_f = f_{dyn} w_{mon}$ . In some projects

(e.g. Oliphant and Yun 2011) a combined empirical factor ( $=f_{lay} \times f_{dyn}$ ) is also used that accounts for both laying and dynamic effects. Table 3 shows the calculated values of  $f_{dyn}$  for the four tests simulated in this study. Analyzing field data of a 200 km offshore pipeline in shallow to deep water, Oliphant and Yun (2011) showed that an average value of  $f_{dyn}$  of approximately 7 could be used for estimation of pipeline embedment. Lund (2000) suggested that the value of  $f_{dyn}$  in the field varies between 2 and 10.

## 6 EQUIVALENT PLASTIC STRAIN AND BERM SHAPE.

During penetration the soil around the pipeline is softened as a function of plastic shear strain as shown in Eq. 1. The equivalent plastic shear strain at the end of penetration for two

Figure 5. Pipeline embedment with horizontal cyclic motions (a) Kaolin clay (b) High plasticity clay.

cases (KC-04 and KC-05) are shown in Figs. 6(a) & 6(b). A significant plastic strain ( $>500\%$ ) is developed near the pipe. The white broken lines in Figs. 6(a) & 6(b) show the boundary above which the equivalent plastic shear strain is greater than  $\xi_{95}$  ( $=10$ ). That means 95% degradation of undrained shear strength occurred in the soil above this line (see Eq. 1). In other words, the undrained shear strength of the soil in the zone above this line is almost near the remoulded undrained shear strength. In order to show the effects of lateral cyclic loading on penetration, an analysis is performed for monotonic penetration as shown in Fig. 6(c). The geometry and soil property used in this analysis is same as KC-05 in Fig. 6(b), except the pipe moved monotonically downward to the depth of final embedment in KC-05 using a displacement boundary condition. The shear strain and berm formation for monotonic penetration is shown in Fig. 6(c). The equivalent plastic shear strain near the pipe in monotonic loading is significantly lower (Fig. 6c) than that obtain in lateral cyclic loading (Figs. 6a&b). The maximum plastic shear strain developed near the pipe in cyclic loading is almost 5 times higher than that of monotonic loading. Also the maximum equivalent plastic shear strain is less than  $\xi_{95}$ , which means that the shear strength reduction due to softening is less

than 95%. The softening has a significant effect on the shape of the berm and soil movement around the pipe. The highly softened displaced soil mass formed flat berms on the top of the seabed extended over a large distance in cyclic loading. In addition, the soil is in contact with the pipe almost up to the top of the berm. However, for monotonic loading the displaced soil mass formed a berm mainly near the pipe and the berm height is more than that of in cyclic loading. That means, the soil deformation in monotonic and cyclic loading is significantly different.

In a parametric study Dutta et al. (2012 b) showed that the effect of softening on the vertical penetration resistance in monotonic loading is not very significant, which is because of less plastic strain developed near the pipe. However, for cyclic loading huge plastic strain is developed in a zone near the pipe which causes significant reduction in undrained shear strength. That means, the zone of considerable softening is higher in cyclic loading. As in offshore the small amplitude lateral cyclic loading near the touchdown zone is commonly encountered from the motion of the vessel, the analyses for cyclic motion with strain softening behaviour of soil will provide more accurate results.

Table 3. Dynamic embedment factor,  $f_{dyn}$ .

	KC-04	KC-05	HP-06	HP-07
Initial static embedment ( $w_{in}/D$ )	0.08	0.12	0.10	0.22
Final embedment ( $w/D$ )	0.34	0.50	0.48	0.77
$f_{dyn}$	4.25	4.16	4.8	3.5

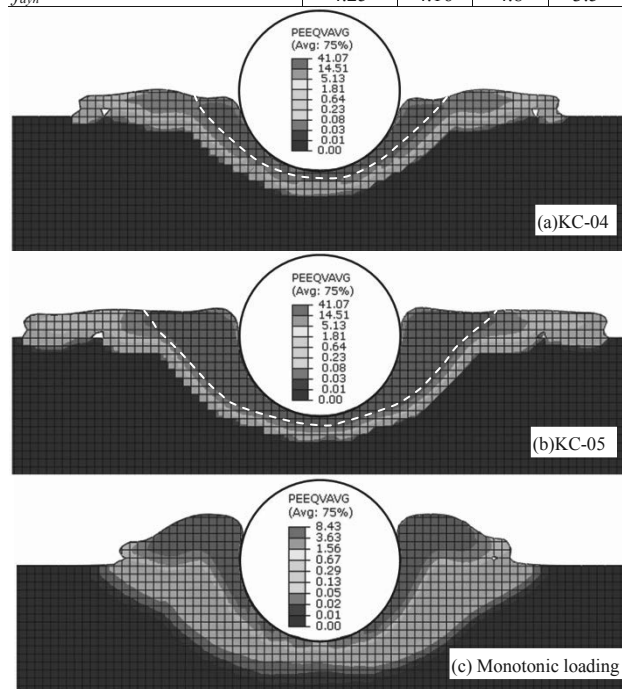

Figure 6. Equivalent plastic strain.

## 7 CONCLUSION

Large deformation finite element analyses are conducted to assess the embedment of as-laid offshore pipelines in clay. The effects of small amplitude cyclic lateral loading are investigated. The following conclusions can be drawn from this study.

- The Coupled Eulerian Lagrangian (CEL) method currently available in ABAQUS FE software can simulate the pipeline embedment.
- The plastic shear strain near the pipeline in cyclic loading is significantly higher than that of in monotonic loading.

- The shape of the berm depends on type of loading; spread over a large area in cyclic and mounted near the pipe in monotonic loading.
- The softening of soil in a zone near the pipe is significantly higher in cyclic loading compared to monotonic loading.
- Forty cycles of small amplitude lateral loading increased the embedment by a factor of 4-5 of initial static embedment. The embedment is higher in initial loading cycles.

# Post Cyclic Behaviour of Singapore Marine Clay

## Le comportement post-cyclique de l'argile marine de Singapour

Ho J., Goh S.H., Lee F.H.  
*National University of Singapore*

**ABSTRACT:** In this paper, the post-cyclic behaviour of remoulded Singapore Marine Clay is examined. Cyclic triaxial tests, followed by monotonic loading to failure, were performed on normally consolidated specimens (38mm diameter by 76mm height) within a cyclic strain range of approximately 0.7% to 1.4%. Results herein reveal that the effective stress paths under post-cyclic monotonic loading may take on different forms depending on the mean effective stress state of the specimen at the end of the cyclic loading phase. By normalizing the mean effective stress ( $p'$ ) against the effective consolidation pressure ( $p_c'$ ) of the specimen, the effective stress paths during the post-cyclic monotonic loading may be approximately grouped into three different regimes, according to the normalized mean stress ( $p'/p_c'$ ). Within each normalized mean stress regime, the monotonic soil response is independent of the effective consolidation pressure, the cyclic strain amplitude and number of cycles applied during cyclic loading. The results suggest that the normalized mean stress after cyclic loading may be an important parameter in determining the subsequent stress path under undrained monotonic loading to failure.

**RÉSUMÉ :** Dans ce papier, le comportement post-cyclique de l'argile marine remaniée de Singapour est étudié. Des essais triaxiaux cycliques suivis de chargement monotone jusqu'à la rupture ont été effectués pour des déformations cycliques comprises entre 0,7% et 1,4% sur des échantillons normalement consolidés. Les résultats démontrent que les chemins de contrainte durant le chargement monotone post-cyclique peuvent être de formes différentes et dépendent de l'état de contrainte moyenne effective de l'échantillon à la fin de la phase du chargement cyclique. En normalisant la contrainte moyenne effective ( $p'$ ) par la contrainte de consolidation ( $p_c'$ ), les chemins de contrainte pendant le chargement monotone post-cyclique peuvent être regroupés en trois différents groupes selon la contrainte moyenne normalisée ( $p'/p_c'$ ). Dans tous les cas, la réponse monotone du sol est indépendante de la contrainte effective de consolidation, de l'amplitude de la déformation cyclique et du nombre de cycles appliqué pendant le chargement cyclique. Les résultats suggèrent que la contrainte moyenne normalisée après le chargement cyclique pourrait être un paramètre important pour déterminer, sous chargement monotone non-drainé, les chemins de contrainte jusqu'à la rupture.

**KEYWORDS:** Post-cyclic clay behaviour, Mean effective stress, Cyclic stress reversal

### 1 INTRODUCTION

Previous studies have shown that, during undrained compression loading, the effective stress path of a normally consolidated clay after cyclic loading is similar to the effective stress path of an overconsolidated clay (Hyde and Ward 1985, Matsui et al. 1992, Yasuhara et al. 1992). Researchers have adopted different frameworks in the analysis of the post-cyclic undrained shear strength of clays. One common approach is to estimate the undrained shear strength based on the maximum shear strain during the applied cyclic loading (Thiers and Seed 1969, Sangrey and France 1980). Another method of analysis is to relate the post-cyclic undrained shear strength with the apparent overconsolidation ratio induced by the cyclic loading (Matsui et al. 1992, Yasuhara et al. 1992). Apart from the post-cyclic undrained shear strength, this induced apparent overconsolidation ratio from cyclic loading was also used to determine how the subsequent monotonic effective stress path approaches the critical state line (Yasuhara et al. 1992).

However, one possible limitation in past studies is the relatively fast rates of cyclic loading used, which typically ranges from 0.5Hz to 1 Hz. At such loading rates, it is uncertain if excess pore pressure in the clay specimens will be able to dissipate. For this reason, the reliability of pore pressure measurements during cyclic loading phase may be doubtful. Fast loading rates on normally consolidated clays during undrained triaxial tests prevents equilibration of excess pore pressure within test specimens, which results in a higher pore pressure within the middle one-third portion of the specimen

(Wood 1982). This can lead to errors in effective stress calculations. Few attempts had been made to overcome the issue of unequalized pore pressures during cyclic loading. For example, Matsui et al (1992) the specimen to stand in an undrained state for 1 hour after cyclic loading and prior to post-cyclic monotonic loading to allow for equalization of pore pressures. On the other hand, Diaz-Rodriguez et al (2000) used a longer equalization period of 12 hours. Another approach is to allow drainage before post-cyclic loading to allow for pore pressures accumulated during cyclic loading to be dissipated (Yasuhara et al. 1992). The drawback of this approach is that it alters the pore pressures within specimens, leading to discontinuities in effective stress paths between the cyclic loading and post-cyclic loading phases. Intuitively, the effective stress response of a clay undergoing cyclic loading should be indicative of its post-cyclic behavior if post-cyclic monotonic loading is conducted immediately after cyclic loading. Due to possible errors effective stress measurements and discontinuities between cyclic and post-cyclic effective stress paths, a direct comparison between the cyclic and post-cyclic behavior of clays has hitherto not been possible. This objective of the study reported herein is to re-visit the issue of post-cyclic behaviour of soft clay, while ensuring adequate equilibration of excess pore pressure.

### 2 CYCLIC AND POST CYCLIC TESTING PROGRAM

A series of two way strain-controlled undrained cyclic triaxial tests were performed on remoulded specimens (38mm diameter by 76mm height) of normally consolidated Singapore Upper

Marine Clay, the standard properties of which have been reported by Tan (1983). After cyclic loading, the specimens were immediately subjected to standard consolidated undrained triaxial monotonic loading to failure. According to Ho et al. (2012), when undrained cyclic triaxial tests on clays are conducted at a sufficiently slow rate for pore pressure equilibration, intrinsic strain rate effects on pore pressure measurements, effective stress paths and stress-strain relationships are negligible. Since the focus of this study is not on strain rate effects, all tests were conducted at relatively slow rates. Both mid-plane and base pore pressure transducers were used and pore pressure equilibration is considered to be achieved when both transducers produce similar excess pore pressure measurements. All cyclic and post-cyclic triaxial tests were performed using the GDS Enterprise Level Dynamic Triaxial Testing System. Table 1 shows the experimental matrix. Experimental data presented in this study was recorded at 2-second intervals.

### 3 EXPERIMENTAL RESULTS AND DISCUSSION

#### 3.1 Cyclic Loading

Normalized stress plots and stress-strain relationships during the cyclic tests are summarized in Figure 1. The stress path parameters, i.e. deviator stress ( $q$ ) and mean effective stress ( $p'$ ), are normalized against the effective consolidation pressure ( $p_c'$ ) for easy comparison between specimens subjected to different consolidation pressures. Post-cyclic effective stress paths are included in Figure 1. The critical state line is also plotted based on data from monotonic triaxial compression tests where the effective angle of friction for Singapore Upper Marine Clay is found to be 25.4 degrees. The initial yield locus and the state boundary surface are assumed to be elliptical.

For Singapore Upper Marine Clay specimens subjected to the same effective confining pressure, the stress paths and stress-strain relationships shown on Figure 1 for different number of applied cycles are similar, reflecting consistency among the specimens. Due to positive excess pore water

pressure generated during cyclic loading, the mean effective stress generally decreases during the reloading phase of each cycle. However, after a certain number of load cycles, the mean effective stress is observed to increase at the later part of the loading, just before the maximum deviator stress is reached, as illustrated in Figure 2. The turning point marking this change in mean effective stress is hereby termed as "stress reversal" point. These stress reversal points correspond to a decrease in shear-induced excess pore water pressure, which would seem to imply dilative behavior. As the stress reversal points appear after the normalized mean effective stress decreases beyond a certain value, post-cyclic monotonic tests are conducted after different number of load cycles to investigate the factors governing the onset of this stress reversal behaviour.

#### 3.2 Post-cyclic Loading

Normalized stress plots and stress-strain relationships during the post-cyclic monotonic tests are summarized in Figure 3, for the tests listed in Table 1. From Figure 3, the form of the effective stress paths under post-cyclic monotonic loading depends on the normalized mean effective stress state of the specimen at the start of the post-cyclic loading phase. These post-cyclic effective stress paths may be approximately grouped into three different regimes, according to the normalized mean effective stress.

When the normalized mean effective stress state of the clay specimen at the start of post-cyclic monotonic loading is greater than 0.6, stress reversal is generally absent and post-cyclic shearing shows either a decrease or no change in mean effective stress. This is akin to that of lightly over-consolidated and normally consolidated clays which tend to increase in density when sheared.

On the other hand, when the normalized mean effective stress state of the clay specimen at the start of post-cyclic monotonic loading falls below 0.5, stress reversal becomes evident and the effective stress path becomes similar to that of heavily over-consolidated clays.

Within the range of 0.5 to 0.6, the effective stress path is approximately vertical indicating that this is a boundary zone between occurrence or otherwise, of stress reversal.

Unlike the effective stress paths, the normalized stress-strain relationships are relatively similar. The post-cyclic undrained strength is almost equal to that without cyclic loading. This means that the undrained shear strength of Singapore Upper Marine Clay is not significantly influenced by cyclic loading. This observation agrees with the findings of Yasuhara et al. (1992).

#### 3.3 Effect of Cyclic Strain Amplitude

In this section, the results of four additional tests conducted at a lower strain amplitude are presented; the aim being to investigate whether strain amplitude has any effect on the stress reversal. Table 2 summarizes the four additional tests conducted.

Table 2. Additional Cyclic and Post-cyclic Tests.

No	Effective Consolidation Pressure, $p_c'$ (kPa)	Cyclic Amplitude		Period (min)	No. of Cycles
		Amplitude (mm)	Strain (%)		
1	100	0.5	≈0.7	14	10
2					15
3					20
4					110

Figure 4 presents the normalized stress plots and stress-strain relationships obtained from the additional tests. As the applied cyclic strain amplitude for these four tests has reduced by half to 0.7%, the number of load cycles required to reach the same mean effective stress state as previous tests with strain amplitude of 1.4% has increased proportionally. However, as Figure 4 shows, the post-cyclic effective stress paths of these four tests can still be categorized under the three normalized mean effective stress regimes previously discussed. The boundaries of these three regimes remain the same despite the

increase in number of load cycles and reduction in applied cyclic strain amplitude. This implies that the form of the effective stress paths of Singapore Upper Marine Clay under post-cyclic monotonic loading is dependent primarily on the mean effective stress state at the end of the cyclic loading phase.

#### 4 CONCLUSIONS

The effective stress paths of Singapore Upper Marine Clay under post-cyclic monotonic loading takes on three different forms depending on the mean effective stress state of the specimen at the end of the cyclic loading phase. Although it is commonly accepted that the undrained post-cyclic effective stress path of a normally consolidated clay is similar to the effective stress path of an overconsolidated clay (Matsui and Abe 1981, Hyde and Ward 1985, Yasuhara et al. 1992), this study shows that this condition holds only when the normalized mean effective stress state of the clay specimen at the start of

post-cyclic monotonic loading falls below 0.5. When the normalized mean effective stress state of the clay specimen at the start of post-cyclic monotonic loading is greater than 0.6, the effective stress path of the specimen still follows that of lightly over-consolidated and normally consolidated clays. Within each of these normalized mean effective stress regimes, the post-cyclic clay behavior is governed by the normalized mean effective stress after cyclic loading and independent of the effective consolidation pressure, the cyclic strain amplitude and number of cycles applied during cyclic loading.

Furthermore, stress reversal points observed during cyclic loading phase becomes evident when mean effective stress state of the clay specimen at the start of post-cyclic monotonic loading falls below 0.5. Thus, the occurrence of stress reversal during cyclic loading is indicative of dilative behavior and post-cyclic monotonic loading in this regime exhibits effective stress path of an overconsolidated clay.

**ABSTRACT:** A centrifuge load test for a preliminary design of a monopod suction bucket foundation was performed. The target site was the Yellow Sea of Korea and the prototype foundation was a steel monopod caisson with a diameter of 15.5m for a 3MW turbine. The seabed conditions comprised of a dense silty sand above layers of sandy silt were reproduced to a model soil profile using soil samples collected at nearby seashores. Horizontal load and overturning moment were applied and monitored in the test, with vertical load being simulated by self-weight of the bucket model. Series of numerical analysis were performed in order to validate test conditions and compare the effects of soil parameters.

**RÉSUMÉ :** Un test de chargement en centrifugeuse pour étudier le design préliminaire d'une fondation de type « caisson à succion » a été réalisé. Le site cible était la mer Jaune de Corée et la fondation prototype était un caisson unique en acier caisson de 15.5 m de diamètre pour une éolienne de 3 MW. La stratigraphie du fond marin, sable limoneux dense et limon sableux, a été reproduite pour faire un profil de sol modèle en utilisant des échantillons de sol prélevés sur le rivage à proximité. Un chargement horizontal et un moment de renversement ont été appliqués et contrôlés pendant l'essai, le chargement vertical était simulé en utilisant le poids propre du modèle. La modélisation numérique a été réalisée afin de valider les conditions d'essai et de comparer les effets du choix des paramètres de sol.

## 1 INTRODUCTION

Suction bucket (also termed as suction caisson or suction pile) has been considered as a viable alternative to conventional foundations for offshore wind turbines, because it has features appropriate for installing large foundations in offshore environment with minimal environmental problems (Byrne and Houlby 2003, Houlby et al. 2005, Villalobos 2006, LeBlanc et al. 2009, Hung and Kim 2012, Oh et al. 2012). In Korea, major offshore wind farm projects are planned in the Yellow Sea near the south western coast of Korea. The soil profiles are mainly composed of layers of silty sand and sandy silt.

A preliminary design was performed for field testing of suction bucket foundations, and centrifuge load tests were performed to verify and compare alternative designs. In this paper, a centrifuge test for a steel monopod with a diameter of 15.5 m and a length of 10.5 m is described. Expected horizontal load combined with moment load was applied in the test.

Numerical analyses were performed to validate the centrifuge test model conditions such as model weight and soil boundary distance. In addition, the effects of soil parameters such as elastic modulus, internal friction angle, dilation angle, cohesion and wall interface friction angle, on foundation behaviour were evaluated.

## 2 CENTRIFUGE MODELING

A centrifuge test was performed with a geotechnical centrifuge at KAIST (Korea Advanced Institute of Science and Technology) in South Korea. It has a maximum capacity of 240 g-ton and 5 m radius (Kim et al. 2012). Detailed description of the centrifuge test for this study can be found in Choo et al. (2012) and Kim et al (2013). The procedures and results are briefly described here.

The soil conditions at the target site were replicated in the model soil container for the centrifuge test. Natural soil samples collected at the Western coastal areas near the target site were used after verifying that the properties of model materials were comparable the soil samples from the target site (Figure 2). The model profile was formed in two layers of dense silty sand and medium dense sandy silt up to the depth of 32 m, which was about two times the diameter of the foundation.

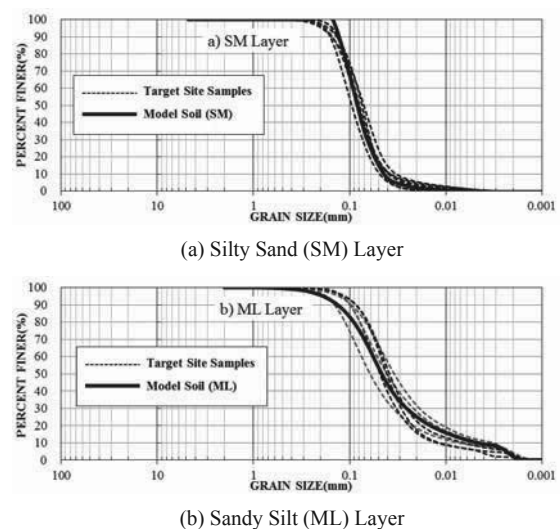

Figure 1. Comparison of grain size distributions between target site samples and model soil

A 1/70 scaled model was used for the test. Horizontal load by a displacement controlled actuator was applied and

monitored at the model tower which was located at 33.0 m height from the foundation top in prototype scale. The horizontal displacement of the tower was measured at multiple points so as to calculate the horizontal displacement and rotation of the foundation.

The load – displacement curve of the test are shown in figure 2. The load is presented in moment, which is the horizontal load multiplied by the vertical eccentricity of the load from the foundation top. The displacement is shown in terms of the rotation of the foundation. Gradual decrease in the slope was observed and the method by Villalobos (2006) was used to define the yield load, which was 198 MN-m.

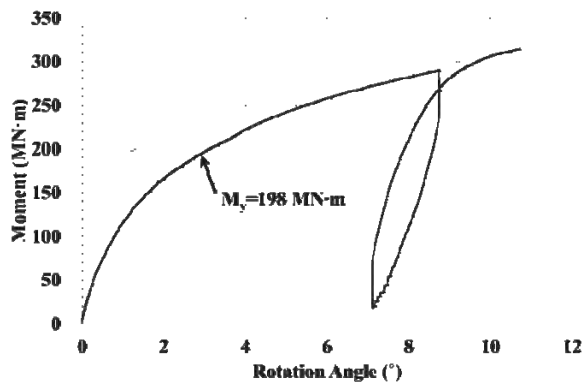

Figure 2. Moment – rotation angle curve of the centrifuge test

The model and nearby soil after the test are shown in Figure 3. Tilting of the foundation by the horizontal and moment load induced several mm of heave in the passive side and 20 to 30 mm of subsidence behind the bucket. Positions of the model before and after the load test are shown in Figure 4.

Figure 3. Model and nearby soil after the test

Figure 4. Comparison between positions before and after the test

### 3 NUMERICAL ANALYSIS

#### 3.1 Model setup and analysis procedures

Numerical modeling in this study was performed using FLAC 3D V 5.0 based on the finite-difference method and explicit scheme (Itasca, 2012). The numerical model was modified from a model used in Kim et al. (2013) and detailed descriptions are given for modeling and analysis procedures.

Soil elements were modeled by Mohr-Coulomb failure criterion with linear elasticity up to plastic yield and the bucket body and tower parts were modeled by linear elastic solid elements. In order to represent the load conditions, a solid circular tower was additionally modeled on top of the bucket top lid and horizontal displacement was applied on the top face of the tower. Half section model mesh and boundary conditions were used for the analysis because of the symmetry of the foundations and load conditions. Approximately 4800 elements were used in the model. Actual steel deformation properties were used in the analysis ( $E = 200 \text{ GPa}$ ,  $\nu = 0.30$ ). The mesh for the analysis is shown in Figure 5.

Figure 5. Mesh for numerical model (Bucket body shown in magnified scale)

The base properties for the model are shown in Table 1. The submerged unit weight of the steel used for the bucket body was modified from actual value, because the weight of the centrifuge model bucket was increased by the connection between the bucket body and the vertical rod.

Table 1. Base properties for numerical analysis

Items	Parameters		
	Bucket	SM Layer	ML Layer
Submerged unit weight ( $\gamma_{sub}$ , $\text{kN/m}^3$ )	75.9	9.50	8.60
Elastic modulus ( $E$ , MPa)	200,000	10	10
Poisson ratio ( $\nu$ )	0.3	0.3	0.3
Internal friction angle ( $\phi$ )	-	33.7	34.5
Dilation angle ( $\psi$ )	-	11.7	0
Cohesion ( $c$ , kPa)	-	16.1	5.2
Friction angle between bucket wall and soil ( $\delta$ , )	-	22.5	-
Coefficient of earth pressure at rest ( $K_0$ )	-	0.5	0.5

Bottom face nodes were fixed in vertical displacement, and side face nodes were fixed in horizontal displacement. Coulomb criterion interface elements were applied in contacting faces between the bucket body and soil in order to model sliding and separation behaviour. Shear and normal stiffness values were set to 200 MPa/m which was larger than ten times the elastic modulus of surrounding soil (Itasca, 2005).

The analysis was run in three stages. The first stage simulated the initial  $K_0$  soil condition. The second stage simulated the installation of the bucket in the soil. The third stage was the loading stage where the top of the loading tower was horizontally moved in every step and unbalanced forces were calculated as the resistance of the foundation.

The ramping algorithm was used for the loading velocity control, in which the loading velocity was linearly increased with step to  $u_{d,max}$  per step ( $1 \times 10^{-6}$  m/step in this study) till prescribed steps were run and kept constant afterwards (Itasca, 2012).

### 3.2 Analyses and results

Cases considered in this study are summarized in Table 2 and a plot of displacement contour for C2 case is shown in Figure 6.

Table 2. Analysis cases

Items	Values
A1. Reference case	Parameters in Table 1
A2. Bucket weight and vertical load	Bucket weight 2220 kN Vertical load 5750 kN
B1. Horizontal boundary distance from model center (5D for reference case)	2D
C1, C2. Elastic modulus of SM layer (E, MPa)	20, 5.0
D1, D2. Internal friction angle ( $\phi$ )	38.7, 28.7
E1. Dilation angle ( $\psi$ )	3.7
F1. Cohesion (c, kPa)	0.1
G1. C2 + F1	

Figure 6. Contour of displacement for case C2

The prototype of the centrifuge test was modeled with larger thickness in the wall and the top plate than the preliminary design due to limitations in fabrication. The vertical rod and the connecting part between the bucket body and the rod were designed to have sufficient stiffness and strength for the centrifuge. These resulted in a heavier prototype and vertical load than the target structure in the preliminary design. Therefore, the effect of heavier structure weight was analyzed in the numerical analysis. The load – displacement curve is shown in Figure 7. Slight decrease in the resistance was observed for the reduced weight and vertical load, after around  $0.003 \sim 0.005D$ .

Figure 7. Load – displacement curves for different foundation weight and vertical load

The centrifuge model soil container had a radius of 447.5 mm, which was about two times the diameter of the model foundation. The results between 2D and 5D horizontal boundary distances are compared in Figure 8. The difference was negligible between the horizontal boundary distances considered.

Figure 8. Load – displacement curves for different horizontal boundary distances

Different elastic moduli resulted in a noticeable variation in the slopes of the curves (Figure 9). Therefore, proper estimation of the elastic modulus and application in the numerical model are thought to be important for the load – displacement behaviour in the conditions of this study.

Figure 9. Load – displacement curves for different elastic moduli of the silty sand layer

The effect of variations in the internal friction angle and dilation angle of the silty sand layer was considered (Figure 10). Slight changes in slopes were observed after around  $0.005 \sim 0.01D$ , but they were found to be relatively small in the displacement range considered in this study.

Figure 10. Load – displacement curves for different internal friction angles and dilation angles of the silty sand layer

The resistance was affected by the cohesion of the surrounding soil (Figure 11).

Figure 11. Load – displacement curves for different cohesions of the silty sand layer

Figure 12 shows the result when the elastic modulus and cohesion were decreased from the reference values. The curve is closer to the centrifuge test result than others. However, this does not mean that this set of parameters are the actual properties, but provides a guide on which parameters are more influential than others and how the numerical model can be improved. Further researches are needed to model the nonlinearity and the dependency on confining stress of elasticity of the silty sand layer.

Figure 12. Comparison of load – displacement curves for the centrifuge test result and numerical model

#### 4 CONCLUSIONS

The load – displacement behaviour of a monopod suction bucket foundation was studied by a centrifuge test and numerical modeling. The centrifuge model test was performed with a model soil which represented key soil characteristics of the target site. Horizontal load combined with overturning moment was applied according to the preliminary design of an offshore wind tower. In the centrifuge test, the foundation and

soil behaviour was observed for a wide load range from the initial to the post-yield load, so that the foundation design be verified and improved based on the test result. A series of numerical modeling were performed to validate the centrifuge test condition and study the effects of soil parameters on the load-displacement curves. It was found that the increased weight and vertical load provided slight increase in the resistance. The effect of the limited horizontal boundary distance in the tested centrifuge model was analysed to be minimal. Soil parameters such as elastic modulus and cohesion were found to have significant impacts than other factors in this study on the load – displacement behaviour of the monopod foundation in the silty sand layer. Refinement of the numerical model related to these parameters and elaborate estimation of them are important for realistic modeling of the foundation behaviour.

**ABSTRACT:** To capture the softening behaviour of dense sand, an extended Mohr-Coulomb model was developed using a critical state framework. The model extends Bolton's correlations to capture dilatancy and peak strength, and is compatible with the remeshing and remapping strategies used in large deformation finite element analysis. This model is initially being used to simulate the behaviour of sand layers during foundation and spudcan penetration into uniform and stratified soils, but is applicable to a variety of problems that cannot be accurately simulated using conventional M-C plasticity alone.

**RÉSUMÉ :** Pour attraper le comportement s'adoucissant de sable, un modèle de Mohr-Coulomb étendu a été développé en utilisant un cadre critique d'état. Le modèle étend les corrélations de Bolton pour capturer la dilatance et la résistance de pic, et est compatible avec les stratégies de remaillage et remappage. Ce modèle est initialement utilisé pour simuler le comportement des couches de sable lors de la pénétration du caisson vers les sols feuilletés. Donc, il sera applicable à une variété de problèmes qui ne sont pas bien capturés en utilisant la plasticité M-C conventionnel.

### 1 INTRODUCTION

Sand can display dilation and strain-softening during shearing under certain stress and relative density conditions. There are numerous constitutive models developed to capture these characteristics (Manzari and Dafalias 1997; Li et al. 1999). However, to be able to implement such a constitutive model into finite element software for large deformation analysis, a relatively simple model is essential with the minimum of control variables involved. This is to ensure that the large deformation analysis can be kept stable.

Large deformation of sand has not been analysed widely since large deformation doesn't occur in general when a conventional foundation is placed on sand. However, when foundations – such as the spudcan foundations beneath offshore drilling rigs – are placed on sand overlying clay in offshore design, it is more likely for the sand layer to experience large deformation (Yu et al. 2010). Although large deformation of layered soils has been studied extensively for stiff clay over soft clay soils using large deformation FE analysis (LDFE) and centrifuge tests, fewer LDFE studies for sand over clay conditions have been executed since to date no suitable modelling approach exists for efficient simulation of the large strain behaviour of sand.

This paper describes an investigation into the dependency of bearing capacity on the large strain shearing characteristics of sand. An extended Mohr-Coulomb (MC) model was developed, which features strain-dependent hardening and softening using a critical state framework. The model uses state dependent dilatancy and friction angles. The controlling relations have been calibrated for a number of well-characterised sands, demonstrating that the model is a practical approach that can capture the specific responses of particular soils. The model was implemented in LDFE analysis (Hu and Randolph 1998a, 1998b) using the remeshing and interpolation technique with small strain model (RITSS).

The results of LDFE/RITSS with the extended MC model show that the volumetric and softening behaviour of sand has a significant influence on the penetration resistance of foundations during large penetration. When a shear band forms in sand, its dilatancy angle reaches zero and the sand finds the critical state. For foundations on uniform sand, this model shows how the variation in the bearing capacity factors  $N_q$  and  $N_\gamma$  is linked to density and initial stress state, as well as the fundamental strength property, the critical state friction angle.

The extended CSMC model coupled with LDFE shows great potential to capture sand behaviour through large deformations in a simple and efficient computational framework.

### 2 CRITICAL STATE MOHR-COULOMB (CSMC) MODEL

#### 2.1 State dependent dilatancy angle and friction angle

Using the critical state concept, Been and Jefferies (1985) proposed a state parameter,  $\Psi$  to identify the current soil density state and to predict the subsequent shearing behaviour. The state parameter,  $\Psi$  is defined as:

$$\Psi = e - e_c \quad (1)$$

where  $e$  is the current void ratio;  $e_c$  is the critical state void ratio at current stress. The state parameter  $\Psi$  can be used to indicate the current volume change tendency of the sand and be linked to the dilation angle (Jefferies 1993; Manzari and Dafalias 1997; Li et al. 1999; Li 2002).

Been and Jefferies (1985) reported that both the peak friction angle  $\phi_p$  and dilatancy angle  $\psi$  decrease with increasing  $\Psi$ . This idea also can be extended to loose sand where negative dilatancy (or contraction) occurs. A simple single parameter relation can be written as:

$$\tan \psi = -A\Psi \quad (2)$$

where  $A$  is a constant and is suggested as 1.2 (Li et al. 2013). The parameter  $A$  serves as a scale factor to the dilatancy angle, and it influences dilatancy angle in both the negative and positive regions of the state parameter  $\Psi$ , i.e. both dense and loose sands.

For a better fit to experimental data, a three-parameter relation can be written as:

$$\tan \psi \approx A(1 - \exp^{\text{sign}(\Psi)m|\Psi|^n}) \quad (3)$$

where  $m$ ,  $n$  are constants;  $n$  is a parameter controlling the curve shape;  $m$  is a parameter majorly influenced the curve shape with positive state parameter, i.e. loose sand.

Bolton (1986) linked peak friction and dilation angles by:

$$\phi_p \approx \phi_c + a\psi \quad (4)$$

where  $\phi_c$  is critical friction angle;  $a$  is a constant. However, the value of  $a$  varies with soil stress condition and soil type (Li et al. 2003). Thus, the energy equation proposed by (Taylor 1948) is preferred here:

$$\tan \phi = \tan \phi_c + \tan \psi \quad (5)$$

Combining Eqs. 3 and 5, the relation between the mobilized friction angle and soil state parameter  $\Psi$  is illustrated in Fig. 1 with the variation of parameter  $A$ . The current state-dependent dilatancy angle and friction angle can be substituted into any modified Mohr-Coulomb (MC) model such as the hyperbolic MC model (Abbo and

Sloan 1995). This extension allows the MC model to capture soil hardening and softening behavior based on a critical state concept.

### 3 MODEL CALIBRATION

To implement state-dependent dilatancy and friction angles in the extended Mohr-Coulomb model developed here, the following parameters must be selected through the model calibration process (see Li et al. 2013 for further details):

(1) *Soil critical state line (CSL)*. A power relation (Li and Wang 1998) can be more accurate than the conventional log-linear CSL for sand under a confining pressure no more than 2MPa:

$$e_c = e_r - \lambda \left( \frac{p'}{p_a} \right)^\xi \quad (6)$$

where  $e_c$  is the critical void ratio at mean effective stress  $p'$ ;  $e_r$  is the critical void ratio as mean effective stress diminishes to zero;  $p_a$  is a reference pressure taken as,  $p_a = 101$  kPa (atmospheric pressure) for convenience;  $p'$  is the mean effective stress;  $\lambda$  is the slope of CSL in  $e$  versus  $(p'/p_a)^\xi$  plane, which is similar to the conventional compression index;  $\xi$  is a dimensionless constant. In this paper,  $\lambda$  is also termed as compression index and  $\xi$  is termed as compression power for convenience. For sand,  $\xi$  is typically 0.75 and the compression index can be estimated as  $0.01C_u$  where  $C_u$  is the coefficient of uniformity of sand;  $e_r$  is estimated as  $0.85 \times e_{\max} + 0.15 \times e_{\min}$  where  $e_{\max}$  and  $e_{\min}$  are the maximum and minimum void ratios of the sand.

(2) *Dilatancy parameter  $A$  for Eq. 2 or dilatancy parameters  $A$ ,  $m$ ,  $n$  for Eq. 3*. For Eq. 2,  $A = 1.2$  can be selected. For Eq. 3,  $m$ ,  $n$  can be estimated as 3.5, 0.75 respectively.  $A$  is to be calibrated by experimental data and is typically in the range of 0.3 to 1.0.

(3) *Young's modulus  $E$  and Poisson's ratio  $\nu$* . The stiffness of sand varies with void ratio and stress state. Good predictions can be made using the following equation (Hardin and Richart 1963; Wang et al. 1990; Li et al. 1999; De and Basudhar 2008):

$$E = E_0 \frac{(2.97 - e)^2}{1 + e} \sqrt{\frac{p'}{p_a}} \quad (7)$$

where  $E_0$  is suggested as 6~10 MPa (Carraro et al. 2009). The bulk and shear moduli,  $K$  and  $G$  can be calculated by the usual elastic relations from  $\nu$  and  $E$ .

## 4 IMPLEMENTATION OF CSMC IN LDFE

### 4.1 LDFE with RITSS technique

Large deformation FE (LDFE) analysis is conducted by remeshing and interpolation technique with small strain (RITSS) (Hu & Randolph 1998a, b). This approach is coupled with a finite element package named AFENA (Carter & Balaam, 1995). To avoid large mesh distortion and achieve large deformation simulation, a series of small strain analysis increments (using AFENA) are combined with fully automatic remeshing of the entire domain, followed by interpolation of all field variables (such as stresses and material properties) from the old mesh to the new mesh.

During the mapping of field variables, some mapping error is inevitable. The fewer number of variables that must be carried to describe the current material state, the less error will be introduced after each mapping, thus the more accurate and convergent the large deformation analysis. When CSMC constitutive model is implemented to the LDFE/RITSS, void ratio  $e$  is the only extra variable required to be interpolated in addition to the stress field. Thus, numerical stability can be kept.

In the mesh generation/remeshing algorithm, the angle in one triangle element is limited in the range of 26~111°. Two criteria are used to trigger mesh refinement: (1) the distortion ratio  $\rho$  (which is the shortest distance from the mid node to a straight line joining the corner nodes, divided by the length of that straight line) exceeding

0.02; (2) the ratio between the maximum and minimum element edge lengths exceeding 100.

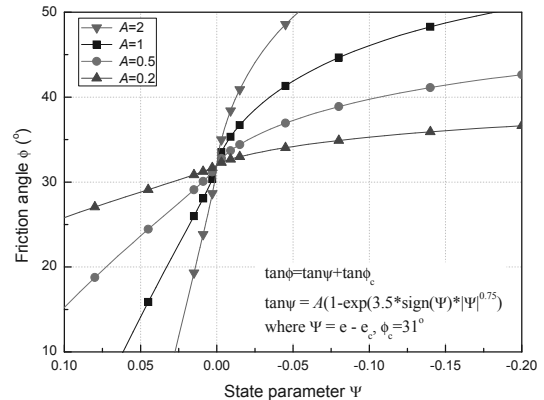

Fig. 1 Effect of parameter  $A$  on friction angle  $\phi$

### 4.2 Biaxial test

The calibration of the model parameters is illustrated using a single element simulation of a triaxial test and by a fully meshed simulation of a biaxial test, both in Ottawa sand (Alshibli et al. 2003). The close match of the prediction and the experimental data for a single element triaxial test provides the model parameters  $A = 0.36$ ,  $m = 8$ ,  $n = 0.75$  (Fig. 2).

When the calibrated parameters were applied to the bi-axial element test conditions, a much lower peak is observed (Fig. 3). However, if the dilatancy angle is increased, as the parameter  $A$  in equation 2 is raised from 0.36 to 0.6, the CSMC model shows a similar peak as the experimental data (Fig. 3). Bolton (1986) has also suggested that the dilatancy angle in plane strain test is about 1.6 times of that in triaxial test. This shows that different parameters might be needed for triaxial and biaxial test conditions. In the biaxial test, the softening behaviour is captured very well.

Fig. 2 Model calibration by single element triaxial test

Fig. 4 depicts the shear band formed in a biaxial test using the CSMC model. A single shear band is formed first at ~2% axial strain. Subsequently, a double shear band begins to form at ~3% axial strain and evolves gradually. This phenomenon is consistent with the observation in Alshibli et al. (2003).

The soil in the shear band yields and dilates gradually to the critical void ratio for this stress level, which is 0.61. The dilatancy angle decreases continuously until the soil reaches the critical state, mobilising  $\phi_c$ . However, the soil outside the shear band remains at the initial void ratio, i.e. 0.54. The local strain in the shear band exceeds the external strain. The single element simulation (Fig. 2) shows a much slower decrease in the principal stress ratio after the peak than the biaxial test (Fig. 3). This confirms that the measured axial strain in laboratory tests that undergo localisation is only an apparent value (Fig. 4).

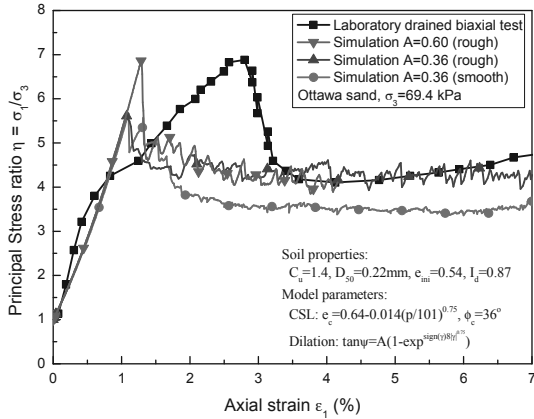

Fig. 3 Biaxial test result of Ottawa sand simulated by FEM

Fig. 4  $\epsilon_v$ - $\epsilon_1$  relation in biaxial test

Strain localization is critical in explaining some laboratory test results where after the peak, the deviatoric stress,  $q$ , often decreases to a stable value much earlier for axial strain than volume strain (Samieh and Wong 1997; Salgado et al. 2000; Alshibli et al. 2003). In Alshibli et al. (2003), the stress starts to oscillate around a stable value after 10% axial strain, whilst the volume strain continuously increases even over 25% axial strain. Once a “central” shear band of soil at the critical state is formed, the apparent shear strength of whole sample reaches the critical value. However the volume of whole sample still increases with yielding of soil at the margins of the shear band (Fig. 5).

Fig. 5 Void ratio field: (a)  $\epsilon_1=2\%$ ; (b)  $\epsilon_1=3\%$ ; (c)  $\epsilon_1=9\%$

The geometry of the specimen affects the shearing behavior. Biaxial simulation results with different sample aspect ratios are shown in Fig. 6. The  $\sigma_1$ - $\epsilon_1$  relation is nearly identical in all three cases. However, the  $\epsilon_v$ - $\epsilon_1$  relation is dependent on the aspect ratio of the soil specimen and the shape of shear band formed.

5 BEARING CAPACITY OF A FOUNDATION ON SAND

The bearing capacity of circular plate on sand is analyzed by both limit analysis (using the ABC program, Martin 2004) and LDFE. In soil with self-weight the bearing capacity factor  $N_\gamma$  is often coupled with  $N_q$  although the two parts are not simply superposable. An  $N_q$ - $N_\gamma$  bounding index  $\xi$  is defined as:

$$\xi = \frac{\gamma D}{q_{surf}} \tag{8}$$

where  $\gamma D$  is a representative self-weight stress beneath the footing and  $q_{surf}$  is the surface surcharge. The coupled  $N_q$  and  $N_\gamma$  bearing capacity can be characterized by an integrated bearing capacity  $N_{q\gamma}$  that varies with  $\xi$  and is defined as:

$$N_{q\gamma} = \frac{q_u}{q_{surf}} \tag{9}$$

Fig. 6 Effect of sample geometry on biaxial shearing behaviour

Limit analysis using ABC shows that the integrated  $N_{q\gamma}$  factor for a rough circular foundation can be approximated as (Fig. 7):

$$N_{q\gamma} = e^{2\pi \tan \phi} \left( 1 + 0.48 \tan \phi \frac{\xi}{1 + 0.0025 \xi} \right) \tag{10}$$

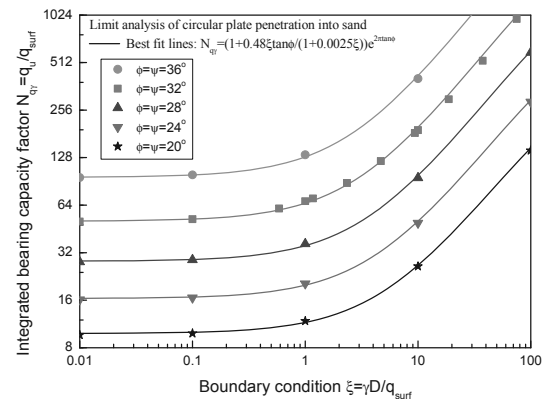

Fig. 7 Coupled bearing capacity factor  $N_{q\gamma}$  for a circular foundation

Referring to Fig. 7, the integrated  $N_{q\gamma}$  factor approaches a constant value with the decrease of the  $N_q$ - $N_\gamma$  bounding index  $\xi$ . That ultimate value,  $e^{2\pi \tan \phi}$ , can be regarded as  $N_q$ . Similarly, the integrated  $N_{q\gamma}$  of rough strip foundation can be calculated as,

$$N_{qY} = \exp^{5\pi \tan \phi} \left(1 + 0.91 \tan \phi \frac{\xi}{1 + 0.0025\xi}\right) \quad (11)$$

However, plasticity limit analysis involves certain assumptions: (1) an associated flow rule, i.e.  $\psi = \phi$ ; (2) rigid plastic strength. The FEM method can consider the effect of soil stiffness and soil dilatancy angle on bearing capacity factor and the CSMC model allows the progressive changes in strength and stiffness during bearing failure to be captured.

Calculations of the  $N_q$  bearing capacity factor for a circular plate on weightless sand have been performed using LDFE and the MC model. The results show that both stiffness and dilatancy angle have a significant influence on the soil bearing capacity. The bearing capacity factor  $N_q$  varies by up to 50% for a realistic range of stiffness. The variation of  $N_q$  induced by the variation of dilatancy angle is no more than 15%. An empirical relation can be drawn for the estimation of  $N_q$ , as:

$$N_q = (0.6 - 0.06 \ln \frac{q_{surf}}{E}) e^{2\pi \tan \phi} \quad (12)$$

For the plate on weighted sand, the integrated  $N_{qY}$  is found to vary with soil stiffness, soil weight, soil dilatancy angle and soil dimension (as shown in Fig. 8). The FEM results (Fig. 9) show that the integrated  $N_{qY}$  approaches its ultimate value  $N_q$  if  $\xi$  is smaller than 2, as follows:

$$N_q = \left(\text{atan} \frac{0.015E}{\gamma D} + 0.3\right) (0.65 + \sin \psi) \exp^{2\pi \tan \phi} \quad (13)$$

For all the cases, the integrated bearing capacity factor can be written as (seeing Fig. 8),

$$N_{qd} = \frac{0.45E}{q_{surf}} \frac{d}{D} e^{\tan \phi} \quad (14)$$

$$N_{qd} \leq N_q \left(0.95 + 0.009 \left(\frac{E}{\gamma D}\right)^{0.5} \tan \phi \frac{\xi}{1 + 0.02\xi}\right)$$

Fig. 8 Integrated bearing capacity factor  $N_{qY}$

Fig. 9 Ultimate value of integrated bearing capacity factor  $N_q$

## 6 CONCLUSION

In this paper, the classic Mohr-Coulomb (MC) model is extended to simulate soil hardening and softening behaviour based on critical state (CS) soil mechanics. Friction and dilation angles are linked with soil state parameter in an MC model. This new critical state Mohr-Coulomb (CSMC) model is verified by single element tests and large deformation finite element (LDFE) analysis using the RITSS method. The newly developed CSMC model can be easily applied to large deformation analysis and shows good stability.

# Plugging Effect of Open-Ended Displacement Piles

## Prise en compte de l'effet de bouchon pour les pieux battus ouverts

Lüking J.

HOCHTIEF Solutions AG, Civil Engineering Marine and Offshore, Hamburg, Germany

Kempfert H.-G.

Institute of Geotechnics and Geohydraulics, University of Kassel, Kassel, Germany

**ABSTRACT:** During jacking an open-ended displacement pile the soil is entering through the pile toe into the profile. This plug can close up the pile toe completely. Because of this the pile can be treated approximately as a fully closed-ended displacement pile and is able to mobilize an additional base resistance. Indeed the soil-mechanical processes and the different factors of influence on the plugging effect are mostly unknown. This report is based on research work and investigated the influence of different factors on the plugging effect and hence the change in the load-bearing behaviour mainly in non-cohesive soils using experimental, numerical and statistical methods. All investigations show that a fully plugged soil inside the pile could not be identified and disproved the classical model representation of a fully plugged pile toe. The load transfer in the plug takes place by compression arches, which are mainly influenced by the pile diameter and the soil density. Finally, based on these results a practical calculation method is suggested.

**RÉSUMÉ :** Lors de la mise en place d'un pieu battu ouvert, le terrain est susceptible de pénétrer dans le pieu par son pied de manière plus ou moins importante. Suivant le degré de pénétration du sol dans le pieu, celui-ci peut être considéré comme ouvert ou fermé et une résistance supplémentaire peut alors être mobilisée. Ce papier propose une étude des processus de pénétration du terrain dans les pieux battus ouverts pour des sols non cohésifs. La variation de capacité portante des pieux induite par ces processus est analysée selon des points de vue expérimentaux, numériques et statistiques. Toutes les investigations réalisées montrent que l'effet de bouchon complet n'existe pas et qu'un pieu battu ouvert ne peut pas être considéré comme véritablement fermé. L'effet de bouchon correspond à la formation de « voûtes » à l'intérieur du pieu. Enfin, une méthode de prévision de la capacité portante intégrant ces processus est proposée.

**KEYWORDS:** open-ended displacement pile, plugging effect, pile bearing capacity, pile foundation.

## 1 INTRODUCTION

Open-ended displacement piles are piles, which are open at the pile toe like pipe piles, H-profiles or composed of sheeting piles. During the piling process (jacking, impact driving, vibrating or pressing) the soil is entering into the pile tube. Between the opposite inner shaft areas a plug can occur, which is able to mobilize an additional toe resistance. This toe resistance depends on the soil parameters, the pile geometry and the stress distribution.

Open-ended displacement piles are often used in harbour constructions or as foundations for offshore wind plants (i.e. monopiles or jackets).

Technical standards like API or others assume a fully plugged open-ended displacement pile and treat this plug in a monolithic way. However the soil-mechanical process and the different factors of influence on the plugging effect are mostly unknown.

Starting with a short state of the art this paper summarizes laboratory tests, numerical and statistical calculations and recommends new experience values for the bearing capacity of open-ended displacement piles.

These research results are based on the works described in Lüking 2010 and also Lüking and Kempfert 2012.

## 2 STATE OF THE ART

The bearing capacity of the plug can be evaluated by the values IFR (Incremental Filling Ratio) after Bruzy et al. 1991 or the PLR (Plug Length Ratio) after Paik and Lee 1993, see Eq.1 and Eq.2.

$$IFR = \Delta h_p / \Delta d_e \quad (1)$$

$$PLR = h_p / d_e \quad (2)$$

These values describe the incremental and the absolute ratio of the height of the plug  $h_p$  to the pile embedded depth  $d_e$ .

An IFR = 1 means that the surface of the plug does not penetrate into the soil during driving in comparison to the last measurement. Only the pile penetrates into the soil. This means that no plugging effect takes place.

In contrast an IFR = 0 means that the surface of the plug penetrates into the soil with the same value as the pile. In this case the pile is fully plugged and all the soil has to be displaced sideways.

The IFR will be measured during driving by a sounding line. The PLR is only measured after finishing the driving and gives only an average value for the plug development. This is problematic in layered soils.

The highest radial displacement  $u_R$  and radial stresses  $\sigma'_R$  occur by an IFR = 0. In this case the soil is fully plugged which means that the soil resistance is the same like the toe resistance of the profile. Then the plug could be treated like a monolith and is comparable to a closed-ended pile. With an increasing IFR the radial displacement and the radial stresses are decreasing. If the IFR lies between 0 and 1 the soil is partially plugged. The changeover from a full plug to a partial plug and no plugging is steady and the statuses cannot easily be distinguished. Figure 1 gives an overview of the described context after White et al. 2005.

The maximum pile diameter in which a plugging effect could occur is about 1.5 m, see Jardine et al. 2005.

Figure 1. Distribution of the radial displacement  $u_R$  and the radial stress  $\sigma_R$  on the pile shaft depending on different IFR after White et al. 2005

### 3 EXPERIMENTAL INVESTIGATIONS

#### 3.1 General

Different experimental investigations were carried out. The next section gives a short overview of the laboratory test program before the results are discussed. A detailed description and a documentation of all test results is given in Lüking 2010.

#### 3.2 Model Tests and Particle Image Velocimetry Tests

In the first test series a test pile of two pipe piles was constructed. Both piles were only connected at the top. In all the test pile had the following geometry: outer pile diameter 19 cm and inner pile diameter 16 cm. The pile embedded depth after driving the test pile into a sand box was about 140 cm. After this a static pile test loading was carried out.

This test pile was equipped with different strain gauges. Based on the measured strain  $\epsilon$  the inner shaft friction  $q_{is}$ , the outer shaft friction  $q_s$  and the pile toe pressure  $q_b$  could be calculated. By means of a special constructed cone-penetration-test (lab-CPT) the change in density and the displacement effect of the pile installation could be examined.

In the second test series Particle Image Velocimetry (PIV) tests were carried out. The PIV method is a contact free measurement, in which displacement vectors can be identified. Basics to this method can be found in Raffel et al. 2007.

The test pile in the second test series had an outer pile diameter of 60 mm and a wall thickness of 2 mm. It was driven behind an acrylic glass to an embedded depth of 50 cm. Figure 2 gives a perspective view of both test series which were mainly carried out in non-cohesive soils.

Figure 2. Perspective view of a) test pile of the first test series and b) test pile of the second test series (PIV)

#### 3.3 Results of the experimental test series

In general the experience on the pile bearing behaviour regarding different influence factors could be confirmed. With

an increasing relative density and increasing stress level the pile bearing capacity is also increasing.

The change in density around the test pile was lower in dense sands than in loose sands, which could be identified by different tests with the lab-CPT. The base resistance of the lab-CPT inside the soil plug was up to 80 MPa. A higher density of the soil tends to a higher IFR. Nevertheless the IFR does not converge to a fixed value. It was increasing and also decreasing during driving which means that the soil inside was plugging and loosening again. This phenomenon was also identified during the static pile test loading. However during both test series the value never reached IFR = 0. The minimum was IFR = 0.2. This means that only a partially plugged soil could occur and based on this the concept of a monolithical soil plug should be analyzed critically.

Figure 3 shows the distribution of the inner and outer shaft friction at different load levels from the first test series. The outer shaft friction is increasing with higher pile length as expected. In contrary the inner shaft friction is very high on a length which approximate two pile diameters. Above this the inner shaft friction in section 1 and 2 is very low and it looks approximately independent of the load level. The increasing of the inner shaft friction in section 3 is an indication for a (partial) plugging effect of the soil.

Figure 3. Distribution of the inner and outer shaft friction  $q_{is}$  and  $q_s$  for different load levels in non-cohesive soils.

Figure 4 shows the vertical displacement of the soil on the lowest two pile diameters exemplary for the second test series.

Figure 4. Distribution of the vertical displacements in the soil at the pile toe in the second test series in non-cohesive soils.

There an inhomogeneous distribution could be identified. Near the inner pile shaft the vertical displacement is much higher than in the middle of the soil plug. This distribution occurs during driving independently of all investigated boundary conditions in the second test series. It is another indication that the load transfer takes place by the inner shaft friction and not by an additional base resistance underneath the soil plug. This assumption can also be supported by the comparable distribution of the inner and outer shaft frictions, see also in Figure 3. For a monolithical approach the vertical displacement had to be more constant which could not be observed. Furthermore the tests show that these results in non-cohesive soils cannot be transferred easily to cohesive soils. It

looks like that two different mechanisms are active which are not comparable.

## 4 NUMERICAL INVESTIGATIONS

### 4.1 General

The experimental works were further investigated by finite element calculations. The experimental test loadings as well as test loadings with bigger pile diameter were recalculated. The numerical calculation software PLAXIS 2D - Version 9.0 was used. A rotation-symmetric, 2-dimensional FE-model was built. The simulation of the soil displacement during jacking was considered by the method of Dijkstra et al. 2006. A detailed calculation description and the verification of the numerical model is given in Lükling 2010.

Finally the numerical results confirmed the results of the experimental tests quantitatively and qualitatively.

### 4.2 Results of the numerical calculations

Figure 5 shows the distribution of the inner skin friction for different inner pile diameters ( $D_i = 0.45$  m up to  $D_i = 3.95$  m) of a pile which is embedded in the soil of about  $d_c = 10$  m. The soil is non-cohesive and has a “dense” relative density (cone penetration resistance of about  $q_c \approx 20$  MPa). The settlement for the mobilization of the skin friction was about  $s = 4.2$  cm.

Figure 5. Distribution of the inner skin friction  $q_{is}$  under variation of the inner pile diameter  $D_i$  at a pile embedded length of  $d_c = 10$  m and a pile settlement of about  $s = 4.2$  cm

At low pile diameter ( $D_i = 0.45$  m) the results show a good agreement in the distribution to the experimental works, compare Figure 3 with Figure 5.

Furthermore the results show that the inner skin friction for lower pile diameters is significantly higher at a length of approximately two pile diameters. On the upper part of the pile length no skin friction was mobilized. With an increasing pile diameter the peak value of the skin friction is reduced and is transferred to the upper part of the pile. At pile diameters of about 3 m or 4 m the distribution of the inner skin friction is comparable to the outer skin friction. The changeover from a raised inner skin friction to a more constant inner skin friction is continuous. Calculations show that this changeover depends mainly on the pile diameter and the relative density of the soil, see Lükling 2010. The distribution of the inner skin friction is also valid at “loose” relative density ( $q_c \approx 10$  MPa).

Figure 6 shows the numerical results for the orientation of the stress trajectories and for the load transfer depending on the pile diameter in a “dense” relative density of a non-cohesive soil. The left part of each pile shows the derived load transfer based on the stress trajectories which are shown on the right part. In general all results show a rotation of the stress trajectories near the pile toe and also at the pile wall. With increasing distance from the pile wall to the middle of the soil plug the rotation is reducing. Also this depends mainly on the pile diameter.

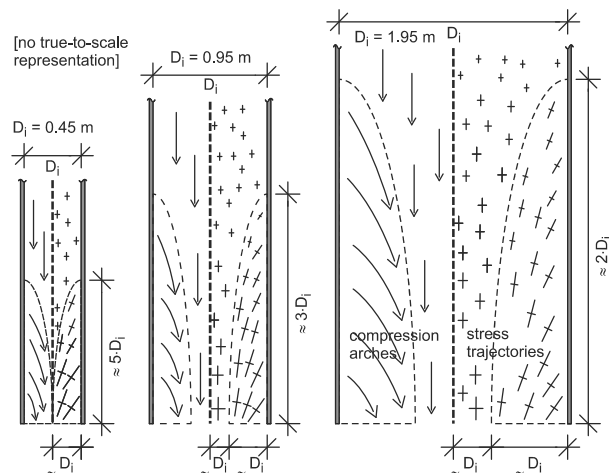

Figure 6. Numerical results for the orientation of the stress trajectories (right part of each pile) and the derived load transfer (left part of each pile) for different pile diameters in a “dense” relative density of a non-cohesive soil

The orientation of the stress trajectories suggests a compression arch, which is in analogy to the load transfer mechanism of the outer skin friction, see Kempfert 2009.

At low pile diameters these compression arches can be overlapped and results in another support. Because of this the inner skin friction can increase significantly which is also shown in the numerical and experimental results, compare Figure 5 and Figure 3. With increasing pile diameter the height of the compression arches is also increasing. This load transfer could also be identified in “loose” relative density.

Finally the results suggest that the load transfer takes place over an inner skin friction which is based on compression arches inside the soil. No fully plugged soil inside an open-ended displacement pile could be identified which would legitimate to treat the plug in a monolithic way.

## 5 CALCULATION METHODS

### 5.1 General

Based on the new knowledge two feasible methods for calculating the bearing capacity of open-ended displacement piles are suggested. The values were verified statistically to a large extend with calculation method 1 up to a pile diameter of  $D = 1.6$  m in cohesive and non cohesive soils and with calculation method 2 up to a pile diameter of  $D = 1.2$  m in non-cohesive soils. All histograms of the statistical verifications can be found in Lükling 2010.

### 5.2 Calculation Method 1

Calculation method 1 is based on an analysis of 28 static and 59 dynamic pile loading tests with pile diameters up to  $D = 1.6$  m. This method derived new adaptation factors which are linked to the values of experience of the EA-Pfähle 2012. The basic equation for calculating the pile resistance is given in Eq.3.

$$R_k = \eta_b \cdot q_{bk} \cdot A_b + \eta_s \cdot q_{s,k} \cdot A_s \quad (3)$$

- $R_k$ : characteristic pile resistance
- $\eta_b$ : adaptation factor for the pile toe, see Eq.4
- $q_{b,k}$ : characteristic pile toe pressure after EA-Pfähle 2012
- $A_b$ : pile base area (contact area of the pile and the bottom area of the soil plug)
- $\eta_s$ : adaptation factor for the pile skin, see Eq.5
- $q_{s,k}$ : characteristic pile skin friction after EA-Pfähle 2012
- $A_s$ : outer shaft area of the pile

The best compliance for the adaption factors was found by a hyperbolic correlation, see Eq.4 and 5.

$$\eta_b = 0.95 \cdot e^{-1.2 \cdot D_a} \quad (4)$$

$$\eta_g = 1.1 \cdot e^{-0.63 \cdot D_a} \quad (5)$$

$D_a$ : outer pile diameter

### 5.3 Calculation Method 2

Calculation method 2 is based on an analysis of 28 static pile loading tests with pile diameters up to  $D = 1.2$  m. In contrary to calculation method 1 this method derived new values of experience for each part of pile resistance for the 10 % and the 50 % quantile. Eq.6 gives the basic equation.

$$R_k = q_{is,k} \cdot A_{is} + q_{ak} \cdot A_a + q_{s,k} \cdot A_s \quad (6)$$

- $R_k$ : characteristic pile resistance
- $q_{is,k}$ : characteristic inner pile skin friction after Table 1
- $q_{a,k}$ : characteristic pile toe pressure of the pile contact area after Table 2
- $q_{s,k}$ : characteristic outer pile skin friction after Table 3
- $A_{is}$ : inner shaft area of the pile
- $A_a$ : contact area of the pile
- $A_s$ : outer shaft area of the pile

This method is valid for pile diameters from 0.3 m up to 1.2 m only in non-cohesive soils. The first values of the experiences in the following tables are the 10 % quantile and the second are the 50 % quantile.

Table 1. Values of experience for the characteristic inner shaft friction  $q_{is,k}$  depending on the pile settlement and the resistance of the CPT

Settlement $s$	Characteristic inner shaft friction $q_{is,k}$ [kN/m <sup>2</sup> ] at a cone penetration resistance $q_c$ [MN/m <sup>2</sup> ]		
	7.5	15	≥ 25
$s = 0.035 \cdot D_a$	15/κ ÷ 35/κ	35/κ ÷ 55/κ	50/κ ÷ 67.5/κ
$s = 0.1 \cdot D_a$	30/κ ÷ 50/κ	60/κ ÷ 80/κ	90/κ ÷ 100/κ

with  $\kappa = 2 \cdot \text{PLR}$ , see Eq. 2

Table 2. Values of experience for the characteristic pile toe pressure  $q_{a,k}$  depending on the pile settlement and the resistance of the CPT

Settlement $s$	Characteristic pile toe pressure $q_{a,k}$ [kN/m <sup>2</sup> ] at a cone penetration resistance $q_c$ [MN/m <sup>2</sup> ]		
	7.5	15	≥ 25
$s = 0.035 \cdot D_a$	650 ÷ 1.200	1.300 ÷ 1.750	1.750 ÷ 2.800
$s = 0.1 \cdot D_a$	1.100 ÷ 2.000	2.000 ÷ 3.000	2.800 ÷ 4.800

Table 3. Values of experience for the characteristic outer shaft friction  $q_{s,k}$  depending on the pile settlement and the resistance of the CPT

Settlement $s$	Characteristic outer shaft friction $q_{s,k}$ [kN/m <sup>2</sup> ] at a cone penetration resistance $q_c$ [MN/m <sup>2</sup> ]		
	7.5	15	≥ 25
$S_g^*$	15 ÷ 25	30 ÷ 50	50 ÷ 70
$s = 0.1 \cdot D_a$	20 ÷ 30	35 ÷ 60	55 ÷ 75

with  $S_g^* [\text{cm}] = 0.5 \cdot R_{s,k} [\text{MN}] \leq 1 [\text{cm}]$

### 5.4 Comparable Calculations

Figure 7 gives an overview of the calculation results of both methods compared with the results of the pile load tests.

Figure 7. Calculation results for the characteristic pile resistance  $R_{cal}$  of both calculation methods in comparison to results  $R_m$  of static pile load tests

Figure 7 shows that the requirements of the calculation methods for the 10 % and 50 % quantile are fully accomplished. Further calculations and variations of parameters are given in Lükling 2010.

### 6 SUMMARY

The load transfer inside a plug of an open-ended displacement pile was investigated by experimental, numerical and statistical methods. It was shown that the load transfer takes place by compression arches. A fully plugged soil could not be identified.

# A simplified procedure to assess the dynamic stability of a caisson breakwater

## Une procédure simplifiée pour évaluer la stabilité dynamique d'une digue en caissons

Madrid R., Gens A., Alonso E., Tarrago D.

Dep. of Geotechnical Engineering and Geosciences, Technical University of Catalonia, Barcelona, Spain

**ABSTRACT:** The paper describes a simplified method of analysis used to evaluate the stability of a caisson breakwater to sea wave actions. An intensive laboratory program was performed in order to evaluate the static and dynamic characteristics of the foundation soil. Anisotropic and isotropic consolidated cyclic triaxial tests and cyclic simple shear tests were used to define the cyclic interaction diagram for the foundation soil. The possibility of foundation cyclic mobility due to wave loading and their effect on the breakwater stability was examined combining the cyclic interaction diagram with the results of finite element analysis. The potential reduction in soil strength is then incorporated into a conventional stability analysis. The procedure is illustrated by a specific application to a caisson breakwater that is part of the extension works of the Barcelona Harbour.

**RÉSUMÉ :** L'article décrit une méthode simplifiée pour évaluer la stabilité d'une digue verticale sous l'action de la houle. Les caractéristiques statiques et dynamiques de la fondation ont été évaluées à l'aide d'un programme intensif de tests en laboratoire, qui inclut des essais triaxiaux cycliques isotrope et anisotrope et des essais de cisaillement simple cycliques dans le but d'établir le diagramme d'interaction cyclique du sol. La possibilité d'une mobilité cyclique de la fondation sous l'action de la houle et son effet sur la stabilité de la digue ont été examinés en combinant le diagramme d'interaction cyclique ainsi obtenu avec une analyse numérique par Éléments Finis. La réduction potentielle de la résistance du sol est ensuite incorporée dans une analyse de stabilité conventionnelle. La procédure est illustrée par une application spécifique à une digue en caissons qui fait partie des travaux d'extension du port de Barcelone.

**KEYWORDS:** cyclic tests, interaction diagrams, liquefaction, caisson breakwater, wave loading, stability.

## 1 INTRODUCTION

Two new breakwaters and a large container area, immediate to a new quay, are the main development works of the ongoing extension of Barcelona harbour. A plan view of the new breakwaters and quays is shown in Figure 1.

Breakwaters have a total length of 6.8 km. The East breakwater is of a rubble mound type whereas the South breakwater involves two different types: rubble mound and vertical caissons. This paper refers to the caissons section that has a total length of 1.7 km constructed in water depths that range from 20m to 25m. Most of the foundation soil immediately under the breakwaters consists of weak sediments of clayey silts and silty clays belonging to the pro-deltaic deposits of the Llobregat River.

The paper describes summarily the main geotechnical features of the foundation ground with special attention given to undrained strength parameters. The bases for the static design of the breakwater are then briefly presented. Finally, a description of the cyclic resistance of the foundation soil is described in terms of an interaction diagram; this information is then used in a simplified assessment of the stability of the breakwater under storm conditions incorporating the potential strength reduction due to cyclic loading.

## 2 SOIL PROFILE CHARACTERISTICS

A representative soil profile at the location of breakwaters is shown in Figure 2. It consists of: i) upper silts and clays, brown and grey in colour, although dark colours occasionally appear when organic matter content increases. The thickness of this deposit underneath the breakwaters is about 50 m. Sandy and silty sand inter-stratifications, were often found, specially in the

upper levels of the layer. ii) an intermediate layer of gravels and sands, whose thickness is about 7 m; some silt partings were also detected. iii) a lower level of clays whose identification properties are similar to the upper clay unit, although it is a denser soil. The maximum thickness of this layer is 14 m. iv) a lower layer of gravels and sands; it includes several clays and sands stratifications.

Figure 1. Plan view of the new breakwaters and new container areas of the Barcelona harbour. The location of the caisson breakwater is indicated.

Closer to the coast line, an upper deltaic sand deposit of increasing thickness, laid on top of the upper stratum of soft silty clays, appears. As it would be expected from a deltaic environment the transitions between this sand deposit and the upper clays are neither sharp nor regular. This sand deposit is 15 m thick at the shore line but it practically disappears at the breakwater location and it is not considered further in this paper.

Some of the geotechnical indices and properties obtained during the site investigations are shown in Figure 3. The fine grained materials classify mainly as CL (low plasticity clays) and ML (low plasticity silts). Water content commonly exceeds the liquid limit in the upper part of the soft silty clay unit, but at lower levels it is close to the plastic limit, an indication of the self weight consolidation of the sediments. Void ratios range between 0.8 and 1.0 in the upper clay stratum. Dry densities vary from 1.2 Mg/m<sup>3</sup> at the upper clay levels to 1.8 Mg/m<sup>3</sup> at deeper locations.

Figure 2. Soil profile under the caisson breakwater

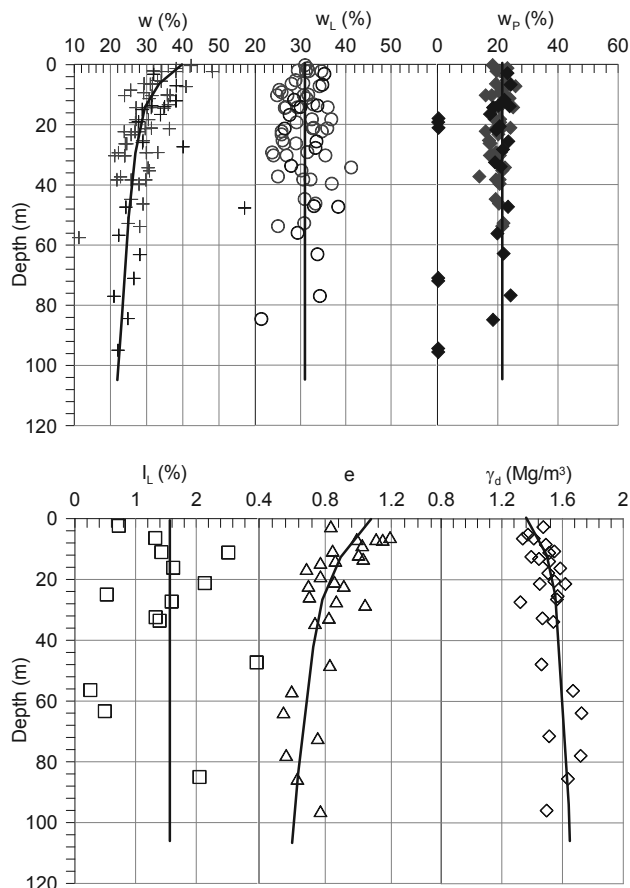

Figure 3. Basic soil properties

In the low permeability foundation soils, stability is controlled by the undrained shear strength ( $c_u$ ). In the normally

consolidated range, this parameter is largely proportional to the consolidation effective vertical stress. Undrained shear strength has been examined by means of laboratory and in situ tests.

Unconfined compression tests of clay samples provided a value of  $c_u=0.215\sigma'_v$ . However, sample disturbance and suction loss may lead to an underestimation of the real value (e.g. Tsuchida, 2000). Simple shear tests performed by NGI provided a value of  $c_u=0.25\sigma'_v$ , quite consistent with the results of CPTU tests. Anisotropically consolidated triaxial tests (compression and extension) yielded a range of  $c_u=0.21 - 0.33 \sigma'_v$ , the larger values associated with compression tests. A summary of results obtained is presented in Figure 4. The unusually large values of undrained strength obtained in some vane tests were probably due the occasional presence of sand lenses or laminations.

Figure 4. Undrained shear strength. Summary of results

It was also found that specimens sheared under normal effective stresses reproducing in situ stress conditions showed somewhat higher strength ratios than specimens consolidated to higher effective stress values. This is an indication of some modest overconsolidation/structure effects due to natural creep or aging phenomena. However, the additional stresses applied by the caissons and fills will take the soil in situ to a normally consolidated state. Therefore, a conservative attitude is favoured for the selection of the undrained stress ratio. The static design of the breakwater was eventually performed using a value of  $c_u=0.25\sigma'_v$ .

### 3 BREAKWATER DESIGN

The conventional breakwater design was performed using finite element analysis as the most efficient method to consider automatically the variation of undrained shear strength throughout all stages of construction. The following phases were considered: i) dredging and bench construction on the new soil surface, ii) caisson placement and filling, iii) construction of the superstructure, and iv) backfill behind the caissons to create a new quay zone. Although all potential limit states were considered, it should be pointed out that the use of finite element analysis readily identifies the most critical failure mechanism at every stage of the analysis. It should also be noted that the gain in undrained shear strength during each one of the construction phases was a critical feature with respect to the stability of the subsequent construction phase.

The wave and uplift forces due to storm loading in the different phases of construction are listed in Table 1. They were derived from physical model tests using the specific breakwater design. Wave forces depend on two factors: the height of the superstructure that provides the surface on which the wave impact acts and the wave height that in turn depends on the intensity of the storm. It can be observed that the wave height (and hence the storm intensity) is lower in Phase II. This is due to the temporary character of this Phase that makes it less likely

that an extremely large storm will occur during that limited period. Probability analysis based on available time series provides the design storm to be used in each particular stage.

For each construction stage, a variety of factors of safety were used to assess the degree of stability of the breakwater affecting either loads or soil strength parameters. In the former case, wave caisson weight and storm wave loads were considered both jointly and separately. The values of safety factors were assessed in relation with the perceived uncertainty of the parameters involved. Thus, a higher factor of safety was demanded when only the wave action was considered due to the much larger uncertainty of the load magnitude associated with the storm. In fact, uncertainty affects both storm intensity and the actual effect on the caisson. The final design of the breakwater is depicted in Figure 5. Note the wide rockfill bench required for stability. An example of the failure mechanism in a particular instance of the analysis is shown in Figure 6.

Table 1. Wave and uplift forces acting on the caissons breakwater at different phases of construction

Phase	Shoulder height (m)	Wave height (m)	Wave period (s)	Wave force (kN/m)	Force height (m)	Dynamic uplift (kN/m)
II	No	5	9	1036.3	9.48	525.1
III	+6	5.91	12.7	1436.1	10.36	878.2
IV	+11	8.04	12.7	748.9	6.10	766.2

Figure 5. Design of the caisson breakwater.

Figure 6. Failure mechanism for Phase III under storm loading.

#### 4 CYCLIC SHEAR STRENGTH

However, breakwaters are also subjected to cyclic wave loading. Storms are the primary source of energy that may cause cyclic mobility or, in extreme conditions, liquefaction of foundation soils. Even if such extreme events do not occur, undrained shear strength may be lower after a severe episode of cyclic loading. Consequently, clay behaviour under cyclic loading was also investigated in the laboratory by performing cyclic simple shear and triaxial tests (on isotropically and anisotropically consolidated specimens). Data from simple shear tests were favoured because they appear to correspond more closely to the actual breakwater foundation conditions during storm loading.

Results from these tests can be usefully summarized using interaction diagrams such as that shown in Figure 7. This diagram shows a relationship between the normalized average shear stress  $\tau_a/\sigma'_{vc}$ , normalized cyclic shear stress  $\tau_{cy}/\sigma'_{vc}$  and the number of cycles to reach the cyclic mobility criteria. Also, results obtained from simple shear testing on the plastic Drammen clay (Goulois et al, 1985) are shown for reference.

Failure occurs for a given combination of normalized cyclic and average shear stress. Figure 7 shows the approximate bounds of these combinations for two different loading conditions (40 impacts and 1000 impacts). The normalised cyclic shear stress  $\tau_{cy}/\sigma'_{vc}$ , for low values of the normalized average shear stress, is close to 0.17 for 40 cycles and to 0.10 for 1000 cycles. A second static bound is provided by the relationship  $\tau_{cy}/\sigma'_{vc} + \tau_a/\sigma'_{vc} = 0.25$ , which is based on the previous discussion on static undrained strength.

Figure 7. Interaction diagram from direct simple shear tests (NGI, 2002).

#### 5 SIMPLIFIED ANALYSIS USING THE INTERACTION DIAGRAM

An example of the simplified stability analysis concerning Phase III of construction is presented in this section. The design storm established for this Phase is summarised in Table 2 that contains the number of waves of different heights corresponding to a succession of storm intensities with different durations and different significant wave heights.

It is assumed that the design storm can be represented as the application of a number of wave impacts of a certain magnitude. Then, a static analysis can be used to identify areas in the foundation soil where the stress state exceeded the criteria of unstable stress defined by the interaction diagram. Naturally, to use the information contained in the interaction diagram, it is necessary to transform the variable wave loads of the storm into a series of cycles of uniform magnitude. This transformation always involves, to a certain extent, a degree of uncertainty and approximation. It is therefore advisable to adopt a measure of conservatism.

With this approach, two loads intensities were selected from the wave magnitudes shown in Table 2: a large load of 1011.5 kN/m and a smaller load of 341.6 kN/m. The former is assumed to act forty times and the latter five thousand times. The limit criteria corresponding to those two numbers of cycles have been indicated in Figure 7.

Now, it is possible to compute, using a conventional static finite element analysis and applying the corresponding wave loads, the points at which such criteria are exceeded, indicating the possibility that, in those zones, a degree of cyclic mobility occurs with a potential reduction of the undrained shear strength. A quite conservative assumption is that the operational undrained shear strength reduces to the residual value of  $c_u$ . The foundation zones affected are shown in Figures 8 and 9. They

are quite similar in the two cases and affect only a quite limited area of the foundation soil.

Table 2. Characteristics of the design storm

Wave height (m)	Number of waves				Wave force (kN/m)	Force height (m)
	H <sub>s</sub> = 3m (24 h.)	H <sub>s</sub> = 4m (24 h.)	H <sub>s</sub> = 5m (24 h.)	H <sub>s</sub> = 5.9m (24 h.)		
1-2	3124	1661	593	150	213.4	9.77
2-3	2203	1693	720	199	341.6	10.28
3-4	848	1133	626	198	475.0	10.62
4-5	195	545	427	161	685.0	10.65
5-6	28	194	236	111	825.4	10.74
6-7	2	52	108	66	870.5	10.80
7-8	0	11	41	34	920.0	10.00
8-9	0	2	13	16	1011.5	10.36
9-10	0	0	3	6	1410.1	11.46
10-11	0	0	1	2	1528.0	11.15
11-12	0	0	0	1	1559.3	11.38

Finally, a new stability analysis is performed with the new distribution of undrained shear strength of the foundation soil for the two cases considered. The analysis also considers the influence of the dynamic uplift caused by the storm loading, derived from the physical model tests carried out for this particular breakwater design. The results, in terms of factor of safety for strength reduction, are shown in Table 3. It can be seen that consideration of cyclic loading has a moderate but noticeable impact on the factor of safety. Given the exceptional character of the design storm and the conservative assumptions made in the analysis, the factor of safety obtained was considered adequate for accepting the design.

Figure 8. Foundation zones exceeding the interaction diagram criterion. Wave load = 341.6 kN/m and 1000 cycles.

Figure 9. Foundation zones exceeding the interaction diagram criterion. Wave load = 1011.5 kN/m and 40 cycles.

Table 3. Computed factors of safety (on strength parameters)

Consideration of cyclic loading	Factor of safety	
	Wave force = 341.6 kN/m 1000 impacts	Wave force = 1011.6 kN/m 40 impacts
Yes	1.48	1.18
No	1.55	1.40

## 6 CONCLUDING REMARKS

A key design feature of a breakwater is the assessment of the stability of the breakwater when subject to extreme storms. This is particularly the case for caisson breakwaters in which the effects of wave action are significantly stronger than for the classical rubble mound type. A proper consideration of the dynamic effects would require the performance of a full dynamic analysis. Here, a simplified stability analysis is proposed that takes into account the potential reduction of the shear strength of the soil due to cyclic loading. It is based on the experimental determination of the interaction diagrams that provide criteria to identify the conditions for which the soil can undergo cyclic mobility and strength degradation. The corresponding strength reduction is then taken into account in conventional stability analyses. The procedure has been illustrated by a specific application to a caisson breakwater that is part of the extension works of the Barcelona Harbour.

# The new remediation technique for buried pipelines under permanent ground deformation

Une nouvelle technique de pose des conduites enterrées soumises à des déformations permanentes du sol

Moradi M., Galandarzadeh A., Rojhani M.

Department of Soil Mechanics and Foundation Engineering of Collage of Civil Engineering, University of Tehran

**ABSTRACT:** One part of lifelines is buried pipelines such as gas, water and oil pipelines. Permanent ground deformation such as fault crossing and lateral spreads is one of the more important threats for pipelines. In this research, a new remediation technique for buried pipeline system subject to permanent ground deformation is proposed. Also this new technique has been evaluated by centrifuge modeling of buried pipelines subjected to concentrated PGD. In proposed technique, the high porosity gravels are used as low-density backfill to fill the trench around the pipe near the susceptible area to PGD, thereby reducing soil resistance and soil-pipe interaction forces and also pipeline strains. Previously, the expanded polystyrene (EPS) geofoam proposed to reduce density of pipelines backfill. However, the high porosity gravel is better than expanded polystyrene geofoam from many cases such as workability to construct, environmental effect, durability and cost. In this technical paper, described the proposed technique and also two centrifuge modeling have been done to evaluate its performance. The comparisons of responses of remediated pipeline with unremediated pipeline have been shown that the proposed technique is effective considerably.

**RÉSUMÉ :** Une partie des réseaux nécessaires au transport du gaz, de l'eau et du pétrole est constituée de conduites enterrées. Les déformations permanentes du sol dues à des tassements ou à des mouvements latéraux sont l'une des menaces les plus importantes pour les conduites enterrées. Dans cet article, une nouvelle technique de pose des conduites enterrées soumises à des déformations permanentes du sol est proposée. Cette nouvelle technique a été évaluée par des essais en centrifugeuse sur des canalisations enterrées soumises à des déformations permanentes du sol. Pour la technique proposée, des matériaux sableux dont la porosité est élevée sont utilisés pour le remplissage des tranchées. Ils réduisent les efforts induits par l'interaction sol-tuyau. Auparavant, c'est le polystyrène expansé geofoam qui était utilisé. Le matériau proposé est meilleur que le polystyrène expansé geofoam en ce qui concerne la mise en œuvre, l'effet sur l'environnement, la durabilité et le coût. Dans ce papier, la technique proposée est décrite ainsi que deux modèles en centrifugeuse réalisés pour évaluer sa performance. Les résultats obtenus montrent que la technique proposée est plus efficace que celle utilisée précédemment.

**KEYWORDS:** Centrifuge Modeling, Faulting, Lifelines, Pipeline, Earthquake

## 1 INTRODUCTION

Buried pipelines often serve as lifelines in that they may carry resources that are essential to the support of human life and this is the reason to retain them in serviceable condition in every situation. Among various kinds of natural hazards, earthquakes happen to be the most serious threats for lifelines serviceability. They can damage lifelines through faulting, permanent ground deformation (PGD) and deformations due to seismic wave's propagation. Faulting can affect pipelines in various ways (Fig. 1) and cause severe damages (Fig. 2) depending on faulting movement direction.

Considering mentioned hazards, lots of statistical, analytical and numerical studies have been conducted since 1970s in order to predict pipelines response and vulnerability level and also to investigate methods of damage mitigation; but it has been a difficult and somehow impossible way to evaluate theoretical and analytical research results due to loss of accurate and efficient records about pipelines response to faulting in actual case histories of earthquakes (Choo et al. 2007). In order to compensate such a gap, studies turned towards applying experimental and physical modeling of this phenomenon. Since 2003, significant researches have been started in U.S.A. and Japan with support of companies and institutes such as Tokyo Gas Company, US lifelines Agency, National Science Foundation in U.S.A, Earthquake Engineering Research Center and etc. Most of mentioned conducted studies have been focused on strike-slip faulting. So, still there is lack of studies

on normal and reverse faultings' effects and this puts them in prime importance of research priority.

Herein, the authors investigated the pipeline response due to reverse faulting and also investigated the use of high porosity gravel as low-density backfill in pipeline response. It is expected that low-density backfill for will reduce soil-pipe interaction and reduce the pipe strain.

Table 1. Centrifuge Facility Properties

Property	Unit	Quantity
Exerted acceleration	g	5 – 130
Acceleration accuracy	g	+ 0.2
Rotational velocity range	rpm	38 – 208
Rotation radius	m	3
Maximum model weight (up to 100 g)	kg	1500
Maximum model weight (up to 150 g)	kg	500

### 1.1 Faulting simulator split box

Experimental setup provision in order to use in centrifuge instrument has its own limitations; for instance, weight and dimensions of the box is thoroughly tied to the used centrifuge facility properties and it is of prime importance for the box to have the minimum weight and dimensions possible together with having enough strength for high magnitude forces caused due to high exerted accelerations. Regarding these limitations, the group-7000 aluminum alloy which has low density and high strength is used to build up the faulting simulator split box in

this study. Outer dimensions of the box are 102×76×68 cm (l×w×h) and the inner dimensions are 96×70×23 cm. The split line of the box which is the faulting line itself, makes the angle of 30° from the vertical direction. The box setup is assembled and fixed on a 4 cm thick aluminum block of 15 cm width that can bear the hydraulic jack caused 5 ton horizontal force and high magnitude vertical force which is exerted due to high accelerations. Holes have been cut in the two ending walls of the box as the backrests for studied structures such as pipelines. Regarding lack of space in the centrifuge basket, the motivating system and the other constituents of the simulator must occupy the minimum space possible.

Moving mechanism has been designed to be enough stable during the faulting movement and also can bear the high magnitude unbalanced forces derived from soil-structure friction.

A wedge-sliding mechanism has been applied for the box movement to direct the faulting through the 30° specified direction and prevent from any strike between fixed and moving parts of the split box. The wedge-sliding mechanism is consisted of two rails installed with the angle of 30° from the vertical direction and high level force tolerating ball bearings to guide the movement as desired. Sliding the wedge forward and backward, the moving part of the box would have an upward-downward movement (Fig. 4). Considering the high magnitude forces and weight increase in high order accelerations, the moving system has been chosen of hydraulic type to be strong enough and less space occupying. The velocity and displacement control can be done by means of electronic hydraulic valves with a satisfactory level of accuracy and reliability. The hydraulic pressure generator is installed out of the centrifuge basket to save a significant amount of space and is connected to the inside basket moving system by means of hydraulic pipe and rotary joints.

Figure 4. General View

### 1.2 Scaling laws

The scaling laws used for this modeling are indicated as below (Table 2).

Table 2. Scaling laws for centrifuge testing

Parameter	Model / Prototype	Dimensions
Length	1/N	L
Strain	1	1
Stress	1	ML-1T-2
Acceleration	N	LT-2
Axial Rigidity	1/N2	MLT-2
Flexural Rigidity	1/N4	ML3T-2

### 1.3 Soil properties

Soil material used in first test is chosen to be the granular soil of standard Firoozkough 161 sand. Soil material used in second test is high porosity gravel with low density. The density

of low-density soil is equal to 50% of Firoozkough soil density. (Table 3)

Table 3. Properties of Firoozkough and low-density Soil

Sand type	$G_s$	$e_{max}$	$e_{min}$	D50 (mm)	FC	$C_u$	$C_c$
Firoozkough 161	2.65	0.874	0.548	0.27	1 %	2.58	0.88
Low-Density	1.3	-	-	3	~0%	-	-

### 1.4 Instrumentation

Two types of instruments containing strain gauge and linear variable differential transformers (LVDTs) were installed in the model. The strain gauges are installed in axial and circumferential directions on the

pipelines with the number of 26 in 7 stations. Strain gauges are placed in a way that axial and bending strains could be measured separately. Strain gauges are of the high strain type and are connected in the quarter bridge form.

Three LVDTs of the whole 5 ones are installed on the surface of the pipeline to record the deformation profile and the 2 other ones measure the axial displacement of the two endings of the pipeline. Apart from above, colorful grids were being used on the surface and between the soil layers.

## 2 RESULTS

Two tests were conducted in this study. In the first one, a stainless steel pipe with diameter of 8.0 mm and wall thickness of 0.4 mm which buried in Firoozkough sand was subjected to a 70 mm reverse faulting with the acceleration of 40g. In the second experiment, the stainless steel pipe with 8.0 mm diameter and 0.4 mm wall thickness which buried in low-density gravel was subjected to the reverse faulting with 40g acceleration. The properties of model and prototype are indicated in Table 4.

Table 4. Properties of model/prototype for conducted tests

	1st Test		2nd Test	
	Model	Prototype	Model	Prototype
Pipeline Diameter (m)	0.008	0.320	0.008	0.32
Pipeline Wall Thickness (m)	0.0004	0.016	0.0004	0.016
Faulting Magnitude (m)	0.070	2.8	0.070	2.8
Backfill	Firoozkough 161		High Porosity Sand (Low Density)	
Faulting Type	Reverse (60%)		Reverse (60%)	

Following figures illustrate the deformations of pipeline and soil during the faulting process. In Figs. 9 and 10 bending and axial strains before pipe failure versus distance from the faulting in 2nd test are presented.

Figure 5. Surface Observation of 1st test

Figure 6. Surface Observation of 2nd test

Figure 10. Axial strain during faulting- (Top: 1<sup>st</sup> test, Down: 2<sup>nd</sup> test)

### 3 CONCLUSIONS

In this article the report of establishment of the first geotechnical centrifuge in Iran and its initial application in buried pipelines modeling subjected to faulting are presented. Also, a brief summary of the modeling details, related scaling laws and used facilities and instruments are described. Reported in this experimental study are the axial and bending strains diagrams of steel pipe versus distance from the normal faulting before pipe failure for the first time in the literature. Pipe failure happened almost at 3 cm in model or 1.2 m in prototype offset.

The use of light weight material to fill pipeline trench is an affective technique to improve pipeline response to PGD. This technique changes the pipeline response from wrinkling to beam buckling which is a better deformation mechanism. In this mechanism the deformation of pipeline is distributed along the pipeline, despite of wrinkling mechanism which the deformation concentrated on two points. Also in beam buckling mechanism, the axial strain of pipeline is very small and the maximum bending moment reduced and transferred to the middle of pipeline. Choo et al. (2007) also investigated the use of light weight material (polystyrene blocks) to remediate the behavior of buried pipeline under normal faulting. They found that this technique improved the performance of pipeline under PGD condition.

# Site investigation and geotechnical design strategy for offshore wind development

## Investigation géotechniques et stratégie de conception pour le développement d'éoliennes maritimes

Muir Wood A.  
DONG Energy

Knight P.  
Parsons Brinckerhoff

**ABSTRACT:** The development of multi billion euro Offshore Wind Farms presents geotechnical engineers with the opportunity to create comprehensive detailed ground models incorporating a large variety of geotechnical hazards. However the political structure of renewable energy projects often leads to a fragmented development team, with no one party appointed for the whole design process. Inexperienced clients are often commissioning surveys because they think that they want to do a survey rather than for an engineering reason. This leads to unclear specification, and a resulting survey that does not add the expected value to the project. The authors demonstrate in this paper how site investigation and ground modelling practices that are followed as routine in the design cycle of onshore projects can be adapted and applied to add significant value to offshore renewable projects. This paper seeks to set out a structure for development of the ground model for offshore wind projects, and demonstrates how clients can ensure their surveys are adding value to the design strategy for their projects.

**RÉSUMÉ :** Grâce au développement très coûteux de fermes éoliennes en mer, les ingénieurs géotechniciens, ont l'opportunité de concevoir des modèles de sol détaillés et exhaustifs qui peuvent rendre compte d'un large éventail de risques géotechniques. Cependant la structure politique conduit au fait que les projets concernant les énergies renouvelables se trouvent bien souvent menés par diverses équipes de conception sans véritable coordination. Des clients inexpérimentés ont souvent recours à des sondages dans le seul but de faire des sondages et non pour des raisons techniques. Cela conduit à avoir des cahiers des charges souvent imprécis qui n'apportent rien à la valeur attendue du projet. Les auteurs démontrent dans cet article comment les études de terrain et les pratiques de modélisation du terrain utilisées systématiquement dans les projets sur terre peuvent être adaptées et appliquées aux projets en mer et peuvent augmenter leur valeur considérablement. Cet article propose une structure de développement des modèles terrestres pour les champs d'éolienne en mer et démontre comment les clients peuvent s'assurer que leurs sondages valorisent les stratégies de conception de leurs projets.

**KEYWORDS:** geotechnical hazard management, site investigation strategy, ground model development, offshore wind farm

## 1 INTRODUCTION

The offshore wind industry in Northern Europe started with the development of small demonstration projects. In recent years these have significantly increased in size, and many of the current projects are now multi billion euro investments, with development times in excess of five years. The industry can demonstrate many examples of how lessons learnt and knowledge gained from the earlier projects have been incorporated into the recent larger projects, ultimately leading to lower capital and operational expenditure per MW of power generated.

Through this process the design methodology and codes (e.g. DNV 2011) which were originally predominately based on the experience of offshore oil and gas infrastructure have also continued to develop and there are many examples of good practice in current projects. However, for geotechnical site investigations this learning process has not been completely positive. It leads to a tendency to base the scope of the investigation on a specification for a previous projects, rather than on what is most appropriate for the site and specific development.

The authors have been involved in the design of over 15 projects, which when built will total more than 8GW of power. A review of these projects shows that they have all spent comparable money on site investigation - typically approximately 1% of the project capital costs (which on the current large projects leads to investigations costing in excess of €30M). However the success of the investigations in managing

the geotechnical risks and bringing value to the projects is extremely variable.

## 2 EXAMPLE PROJECTS

Typical problems that the authors have experienced are: investigations not planned to mitigate project specific geotechnical hazards; poor recording and interpretation of geological information; planning of surveys not based on the results of proceeding investigations/studies; and surveys not specified by the foundation designers.

Some specific examples of good and poor practice on projects are detailed in the following sections. The project names have not been stated however the approximate construction cost of each project is given.

### 2.1 *Poor practice*

#### 2.1.1 *Project 1 – value ~€2bn*

The site investigation comprised site wide sub-bottom geophysical survey with three rounds of geotechnical works: (1) met mast borehole; (2) site wide boreholes; (3) seabed CPTs on every foundation location. Extensive advanced lab testing and down hole geophysical methods and pressuremeter tests were undertaken.

Issues included: the detailed designer was appointed after the site investigation was completed; insufficient time was allowed for the interpretation of the geophysical and geotechnical

surveys; early CPT refusal and lack of boreholes on location meant that insufficient information was collected at many locations; and, the advanced cyclic testing undertaken was not optimised for the design load being applied to the soil.

The above issues meant that stratigraphy was not certain for the full foundation depth leading to very conservative design and uncertain driveability.

#### 2.1.2 *Project 2 – value ~€0.3bn*

The site investigation comprised a site wide sub-bottom geophysical survey with several rounds of geotechnical works comprising CPTs and boreholes.

The primary issue was the detailed designer being appointed after the site investigation was specified. The boreholes were not deep enough and insufficient information was gathered about the bedrock.

The developer had to commission another round of geotechnical investigation to gather further information for design and risk mitigation, which resulted in project delays and additional costs.

#### 2.1.3 *Project 3 – value ~€1.5bn*

The site investigation comprised a site wide sub-bottom geophysical survey with staged geotechnical works comprising CPTs and boreholes. Extensive advanced lab testing and down-hole geophysical methods and pressuremeter tests were undertaken.

Again, the detailed designer was appointed after site investigation had been undertaken, resulting in an insufficient number of boreholes to allow an efficient design.

#### 2.1.4 *Project 4 – value ~€0.1bn*

The site investigation comprised a site wide sub-bottom geophysical survey with staged geotechnical works comprising CPTs and boreholes.

The specification for the surveys was directly copied by the client from one of their previous projects in very different geology, and the detailed designer was appointed after the site investigations had been undertaken. This resulted in the geophysical techniques not being suitable for the geology and the developer had to repeat the geophysical survey to an enhanced specification.

### 2.2 *Mediocre practice*

#### 2.2.1 *Project 5 – value ~€1bn*

The site investigation comprised sub-bottom geophysical survey with one round of geotechnical investigation comprising full depth CPTs and boreholes.

The geophysics was incorrectly scoped, so when planning the geotechnical campaign, the detailed designer could not utilise the geophysics. The project programme was also compressed, meaning the geotechnical campaign was carried out in one stage.

More value, cost savings and mitigation of geotechnical risks could have been achieved with a collaborative geophysical and geotechnical interpretation and a staged geotechnical campaign with ground model development.

#### 2.2.2 *Project 6 – value ~€1bn*

The site investigation comprised sub-bottom geophysical survey with one round of geotechnical investigation comprising full depth CPTs and boreholes with geophysical borehole logging.

Again, the geotechnical campaign was carried out in one stage with the scope being developed whilst offshore. A more cost effective survey could have been achieved with a staged geotechnical campaign with ground model development.

### 2.3 *Good practice*

#### 2.3.1 *Project 7 – value ~€2bn*

The site investigation comprised sub-bottom geophysical survey with multi-stage geotechnical investigation comprising CPTs and boreholes. Extensive advanced laboratory testing was undertaken.

The foundation designer was involved in the specification of the surveys, and a ground model was developed based on collaborative geophysical and geotechnical interpretations. The geotechnical investigations were specified considering the confidence in the ground model and the foundation design.

#### 2.3.2 *Project 8 – value €1.5bn*

The site investigation comprised sub-bottom geophysical survey with multi-stage geotechnical investigation comprising CPTs and boreholes.

The early geophysics identified a considerable geological hazard which was successfully mitigated (Liingaard et al. 2012) through ground model development based on collaborative geophysical and geotechnical interpretations. A multi-stage geotechnical investigation allowed the detailed designer to develop a specific design method and scope the investigations to verify the variations from design codes.

## 3 SUGGESTED APPROACH

The above projects highlight the issues regarding quality and more importantly the effectiveness of the geotechnical investigations. There are common problems with scoping and management of site investigations. The offshore wind industry should look to the experience gained on projects in other fields of engineering, especially the lessons learnt by large onshore infrastructure projects. In particular they should: consider more formal approaches to the management of geotechnical risk; accept that a staged site investigation will deliver the most cost effective results; and, consider a contracting structure that brings the detailed designer onto the project from a very early stage.

### 3.1 *Management of geotechnical risk*

Managing ground risks solely through the traditional practice of thorough site investigation will not lead to the most cost effective project. Simply undertaking the most detailed site investigation that the budget will pay for leads to investigations being undertaken that are not specifically targeting the unknowns that are truly affecting the project, and also does not allow for the fact that the acceptable level of risk at construction is very different depending on the project developer and their attitude towards risk.

Developers should therefore seek to apply a more formal approach of managing geotechnical risk so that the site investigation specifically targets the unique project hazards. Clayton (Clayton, 2001) suggests formal processes for managing geotechnical risk, these have been adapted to form the recommended process detailed in Figure 1.

Figure 1 shows a design team led approach to planning, undertaking and reviewing effective site investigations. The design team identifies all hazards affecting the project (design, installation, operation and decommissioning). An assessment is made of the significance of those hazards in consultation with all project stakeholders. The site studies/investigations are planned to specifically target the hazards. The results are studied and the residual hazards reviewed. The consultation is repeated with the stakeholders and the need for further investigation evaluated.

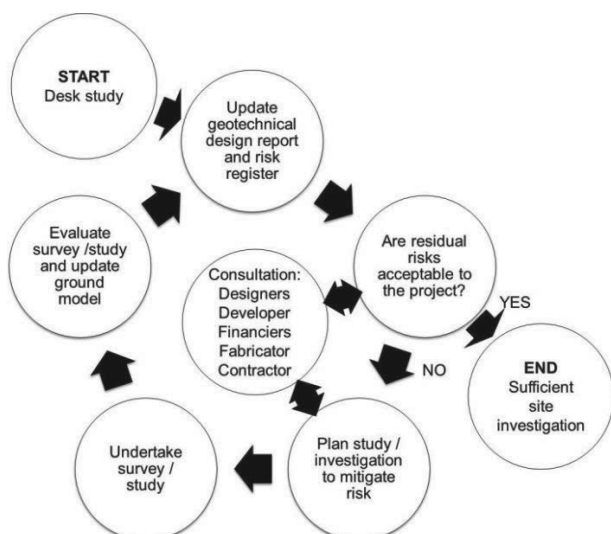

Figure 1. Risk based approach to managing geotechnical hazards

In managing this risk based approach it is essential that the designers appreciate that developers will have different acceptable levels of risk (Figure 2). This level of risk will depend on developers' sources of funding, project timescale and contracting/procurement strategy. The acceptable level of risk will also change as a project develops.

Figure 2. Acceptable level of geotechnical risk to a developer

### 3.2 Staged site investigations

All of the projects reviewed in Section 2 had separate stages of site investigation comprising a geophysical followed by a geotechnical campaign. However the good practice projects had a multistage geotechnical campaign. Eurocode 7 (EC7) (BS EN 1997-2:2007) states that “Ground investigations should normally be performed in phases depending on the questions raised during planning, design and construction”. The code goes on to define two distinct phases of investigation – preliminary investigation and design investigation.

The multistage geotechnical investigation allows for a comparatively cheap ground-truthing geotechnical campaign early in the design process. This campaign gives the designer sufficient information to confirm the expected ground model and develop a preliminary design solution. The design investigation will then be significantly more effective, since it can utilise the most effective methods of investigation for the ground conditions, and fit the foundation type and dimensions that are being designed.

The strategy outlined in Figure 1 will be most effective when repeated several times; designers should be wary of trying to understand all ground based hazards in one stage of geotechnical investigation. A simple preliminary investigation

combined with the existing understanding of the site will often provide the best value to the developer at an early stage.

### 3.3 Develop contracting structure that allows early appointment of the designer

Many of the example projects detailed in Section 2 had ineffective site investigations because the detailed designer for the foundations was not appointed until after all site investigations had been completed. These projects appointed engineers solely to organise and supervise a single phase of site investigation who were not otherwise engaged in planning or design of the project. “This practice inhibits continuity or integration of project development, with the prospect that the site investigation will not be coupled with other features of the project planning process and will, in consequence, not provide adequate answers to vital questions and will not allow consideration of innovative methods of working”. This quote from Muir Wood (Muir Wood 2000) is just as applicable to offshore wind farm developments as it is to the tunnelling projects it was originally written to describe.

Instead developers should seek to engage a designer at the start of the development phase, who has the competence and ability to provide the geotechnical engineering for the whole project. This allows the foundation design and the scope of the site investigation to develop with the project, which mitigates project risks and delivers cost effective site investigations.

This is the approach taken by most infrastructure projects of equal size and complexity to these offshore wind developments. As these projects have demonstrated, this does not prevent the use of different project procurement mechanisms, provided that mechanisms such as novation are available to the developer.

## 4 APPLIED EXAMPLE

The strategy detailed in Section 3 is being applied to the first project of the Hornsea Round 3 development area as follows.

### 4.1 Engineering contract setup

For this project, the developer – DONG Energy is using in-house engineers to undertake the geotechnical design and engineering. This capability is supplemented by the use of additional consultants appointed to the projects for long term positions. This setup gives an integrated approach to engineering and development. Different parts of the project will have different procurement strategies; where the developer chooses not to progress the detailed design in house the design for that element will be contracted to another party, with the original in-house design team maintained in a reviewing capacity.

### 4.2 Desk study

Prior to the desk study, no geotechnical design parameters were available. The principal geotechnical risks at this stage are shown in Table 1. At this point, the site investigations cannot be specified as the foundation type, ground conditions and design requirements are not understood.

Table 1. Design parameters and primary geotechnical risks prior to desk study

Design parameter	Geotechnical risks
None	Unknown site constraints
	Unknown design constraints
	Unknown construction constraints

Following completion of a desk study which includes a review of geological information, design requirements and possible foundation types and construction considerations,

geotechnical design information is available and project specific geotechnical risks can be identified, as shown in Table 2. At this point the design parameters have been selected based on geological memoirs and nearby site investigations. The undrained shear strength of the main clay unit has been used as an example to show how the design inputs change as more information is collected.

Table 2. Design undrained shear strength of main clay unit and primary geotechnical risks following desk study

Design parameter	Geotechnical risks
125 to 350 kPa	No wind farm specific ground information
	Presence of regional geohazards
	Several foundation types possible

The design information and project risks are reviewed at this stage. Referring to Figure 2, this level of design information and risk may be acceptable to some clients, in which case the design and construction risks will be managed with a conservative and uncertain design, or passed onto a third party with large financial consequences. However in this case, to confirm the ground conditions and add confidence to the design, site investigation works were specified.

#### 4.3 Geophysical survey

A site wide sub-bottom geophysical survey was carried out. The primary objectives were to: identify the geological units present; identify any unexpected geological features; and, collect information to allow preliminary geotechnical boreholes to be positioned.

#### 4.4 Preliminary geotechnical survey

A preliminary geotechnical survey consisting of seabed CPT and composite CPT and sampling boreholes was carried out. The primary objectives were to: validate the desk study and geophysical survey; collect information for ground model development including in situ testing and sampling in the primary units; and, identify unexpected ground conditions and risks.

Following completion of the preliminary geotechnical site investigation, the results were interpreted and a ground model produced.

#### 4.5 Ground model development

The ground model was developed using a collaborative geophysical and geotechnical approach. The engineering units were identified and geotechnical parameters selected using the CPT and laboratory testing results. Wind farm specific ground information is now known, and the regional geohazards understood, allowing preliminary design to commence. The design parameters and risks (Table 3) have been refined, resulting in a more efficient foundation.

Table 3. Design undrained shear strength of main clay unit and primary geotechnical risks following preliminary site investigation and ground model development

Design parameter	Geotechnical risks
Low: 145 kPa	Local variation in site geology
Mean: 240 kPa	Advanced design parameters unknown
High: 325 kPa	

#### 4.6 Design team and stakeholder review

The confidence and expected accuracy of the geotechnical interpretation and risks were reviewed by the design team and stakeholders. It was decided that there was sufficient knowledge

of the site to progress the design and construction planning and manage the geotechnical risks.

Some of the project infrastructure will be designed and developed by others. There is now sufficient knowledge of the site to be able to define a contract ground model baseline, and enable the risk to third parties of unknown ground conditions to be appropriately handled.

#### 4.7 Future geotechnical survey

The residual project risks are not acceptable for the finalisation of detailed design. To obtain this information, a small number of sampling boreholes (to obtain samples for advanced laboratory testing) complemented by one CPT to the expected foundation depth (to identify local variability and confirm the units present) will be carried out. Subsequent investigation may be required depending on the results of this investigation and the developer's acceptable risk.

## 5 CONCLUSIONS

Offshore wind projects in their early stages present considerable challenges to engineers managing the geotechnical hazards given the large complexity, cost and time scale of the projects.

A review of the site investigations undertaken for various projects highlights repeated mistakes leading to inefficient site investigations; namely the site investigations not being planned to mitigate project specific geotechnical hazards and surveys not being specified by the foundation designers.

Lessons must be learnt from the wider construction industry, including: the need for formal approaches to the management of geotechnical risk; acceptance that a staged site investigation will deliver the most cost effective results; and, considering a contracting structure that brings the detailed designer onto the project from a very early stage.

The authors have proposed an engineer led approach for managing geotechnical risks, where the design team and stakeholders are actively involved in assessing and mitigating the geotechnical risks, allowing the geotechnical foundation design and site investigation to develop with the project and ensuring that survey work is specified to directly control project risks.

These principles are being applied to the first project of the Hornsea Round 3 development area, where design and construction risks are being mitigated early with a relatively small amount of site investigation works.

# Diagrammes de stabilité cyclique de pieux dans les sables

## Cyclic stability diagrams for piles in sands

Puech A., Benzaria O.  
*Fugro GeoConsulting, Nanterre, France*

Thorel L., Garnier J.  
*IFSTTAR, Nantes, France*

Foray P., Silva M.  
*3S-R, Grenoble, France*

Jardine R.  
*Imperial College, London, UK*

**RÉSUMÉ:** Cette communication rassemble des diagrammes de stabilité cyclique obtenus dans des sables siliceux denses et par des moyens expérimentaux variés : essais in situ sur pieux réels, essais sur pieux modèles en grande chambre d'étalonnage et essais sur pieux modèles centrifugés. Elle couvre le cas des pieux battus en traction et celui des pieux forés en compression. Les diagrammes cycliques de stabilité sont des outils précieux pour une première estimation de l'effet des chargements cycliques sur le comportement axial des pieux.

**ABSTRACT:** This paper gathers cyclic stability diagrams obtained from various experimental sources: in situ tests on actual piles, laboratory tests on model piles in a large calibration chamber and model piles in a centrifuge. Driven piles in tension and bored piles in compression are addressed. Cyclic stability diagrams are useful tools for a preliminary assessment of the effects of cyclic loadings on the behaviour of piles.

**MOTS-CLÉS:** pieu battu, pieu foré, chargement cyclique axial, diagramme de stabilité cyclique

**KEYWORDS:** driven pile, bored pile, axial cyclic loading, cyclic stability diagrams

## 1 INTRODUCTION

Le concept de diagramme de stabilité cyclique pour représenter de manière synthétique la réponse des pieux soumis à des chargements cycliques axiaux a été introduit dans les années 80 par Karlsrud et al. (1986) pour les argiles et par Poulos (1988) pour les sables.

Ce concept se révèle particulièrement utile pour juger en première estimation de l'effet potentiel des chargements cycliques sur la réponse des pieux (Jardine et al., 2012)

On dispose en pratique de peu d'éléments dans les sables. La présente communication propose des diagrammes cycliques applicables aux pieux battus et aux pieux forés dans les sables denses.

## 2 ESSAIS EN TRACTION

### 2.1 Essais de Dunkerque (ICL)

Sept pieux tubulaires en acier à base ouverte non instrumentés ont été testés par l'Imperial College de Londres (ICL) sur un site de sable marin dans le secteur Industriel Ouest du port de Dunkerque, France (Jardine & Standing, 2000). Le profil du sol est caractérisé par 3 m de remblai hydraulique sur du sable des Flandres. Le sable est composé principalement de quartz (84%), d'albite et microcline (8%) et de débris de coquillages CaCO<sub>3</sub> (8%). Les profils pénétrométriques ( $q_c$ ) du site varient entre 10 et 35 MPa selon la profondeur et l'emplacement. La densité relative est en moyenne d'environ 75%. Des essais de cisaillement direct et triaxiaux indiquent un angle de frottement de pic  $\phi'$  de 35 à 40° et une valeur d'état critique  $\phi'_{cv} \sim 32^\circ$ . Des renseignements supplémentaires sur les caractéristiques du site et les essais de laboratoire réalisés sont présentés par Jardine et al. (2006).

Les essais cycliques ont utilisé les installations du projet GOPAL (Parker et al., 1999). Au total 21 essais statiques et 14 essais cycliques ont été effectués sur les six pieux de réaction du projet GOPAL. Ces pieux ont été battus jusqu'à une profondeur d'environ 19 m avec une relation espacement/diamètre du pieu d'environ 15. Leur diamètre est de 457 mm.

Plusieurs séries de chargements cycliques ont été appliquées, entrecoupées d'essais statiques référentiels en traction, la plupart d'entre eux avec des cycles uniquement en traction pour mieux individualiser la distribution des charges entre la pointe et le frottement latéral.

La réponse des pieux au chargement cyclique est décrite dans Jardine & Standing, 2012 ; Tsuchi et al., 2012; Rimoy et al., 2013.

### 2.2 Essais en chambre d'étalonnage (3SR-ICL-SOLCYP)

Dans le cadre d'une coopération entre l'Imperial College de Londres (ICL), le Laboratoire 3SR de l'Université de Grenoble et le Projet SOLCYP, plusieurs séries d'essais ont été réalisées sur un pieu modèle instrumenté dans la chambre d'étalonnage du laboratoire 3SR de Grenoble. L'objectif initial était de tenter de reproduire à une échelle de laboratoire et dans un environnement contrôlé les résultats obtenus par Jardine et Standing, 2000 sur les pieux battus dans le sable de Dunkerque.

La chambre de calibration a une hauteur de 1,5m et un diamètre de 1,2m. Dans sa paroi intérieure, une membrane en latex et une couche de graisse en silicone ont été mises comme système d'anti frottement pour avoir un meilleur contrôle des conditions  $K_0$  du sol. Un système d'isolation permet d'effectuer les essais à une température constante comprise entre 18 et 19°.

Le sable utilisé est le sable de Fontainebleau NE34, ( $d_{50} = 0,2$  mm,  $\gamma_{max} = 17,2$  kN/m<sup>3</sup> et  $\gamma_{min} = 14,2$  kN/m<sup>3</sup>). Pour l'ensemble des essais présentés, ce sable été mis en place par pluviation en obtenant un indice de densité relative compris entre 0,65 et 0,70. Le massif de sable est soumis à une pression

verticale appliquée sur la surface du massif de 150 kPa, correspondant à une résistance de pointe pénétrométrique  $q_c$  de 20 à 23 MPa.

Le pieu modèle instrumenté a été développé par ICL et est décrit en détail dans Jardine et al (2009). C'est un pieu à base fermée de 36 mm de diamètre, instrumenté en 3 niveaux le long du fût pour mesurer les contraintes tangentielles et radiales dans la surface du pieu. Chaque niveau d'instrumentation inclut aussi un capteur de force. Pour les derniers essais réalisés, il a été équipé d'un capteur de force en pointe.

L'installation initiale du pieu a été effectuée jusqu'à une profondeur d'environ 1 m par des cycles d'enfoncement successifs de 5 à 20 mm à une vitesse de 0,2 mm/s, suivis d'une décharge complète, de façon à simuler les effets d'un processus de battage.

Le programme expérimental a inclus quatorze essais cycliques autant sous contrôle de déplacement que sous contrôle en charge pour des cycles alternés et non-alternés (seulement en traction).

Une première partie des résultats concernant les essais de chargement cyclique a été présentée par Tsuha et al. (2012). On trouvera de plus amples informations dans Rimoy et al., 2013

### 2.3 Critères de rupture

L'application de cycles sur un pieu installé dans du sable provoque une succession de petits glissements relatifs sol-pieu dont le cumul détermine le déplacement global. La vitesse de déplacement initiale est fonction de l'amplitude  $Q_c$  et du niveau de chargement maximal  $Q_{max}$  mais ces mêmes paramètres conditionnent également l'évolution du frottement qui peut se détériorer pour des cycles de grande amplitude ou s'améliorer pour des cycles de faible amplitude (Tsuha et al., 2012). Sur un pieu sollicité en traction, la vitesse initiale se modifie pour :

- soit conduire vers la rupture : dans ce cas la vitesse s'accroît. La rupture peut être définie de manière conventionnelle (par exemple pour un déplacement de la tête du pieu de 0,1D) ou lorsque se produit une accélération brutale du taux de déplacement ;
- soit conduire vers la stabilisation : la vitesse décroît continuellement jusqu'à passer en dessous d'un seuil où on peut considérer que les déplacements cumulés deviennent non significatifs.

### 2.4 Diagrammes de stabilité cyclique

La caractérisation complète d'un essai de chargement cyclique suppose la définition des paramètres suivants :

- $Q_m$  : valeur moyenne de la charge sous chargement cyclique,
- $Q_c$  : demi-amplitude du chargement cyclique,
- $N_f$  : nombre de cycles conduisant à la rupture,
- $N$  : nombre de cycles appliqués en l'absence de rupture,
- $f$  : fréquence des cycles (en général 0,5Hz)

L'essai est dit répété (one-way) si  $Q_c < Q_m$  et alterné (two-way) si  $Q_c > Q_m$ . On définit de plus :

$Q_u$  : capacité statique ultime selon le mode considéré ( $Q_{ut}$  en traction et  $Q_{uc}$  en compression).

Il est pratique de présenter les résultats d'essais de chargements cycliques dans un diagramme où chaque série de chargement est identifiée par le couple de paramètres normalisés  $Q_m/Q_u$  et  $Q_c/Q_u$ . Ce type de représentation permet de bien visualiser les zones de fonctionnement sous chargements répétés et sous chargements alternés. Si on affecte chaque point du nombre de cycles  $N_f$  ayant provoqué la rupture ou du nombre de cycles  $N$  appliqué sans provoquer la rupture on peut définir des zones de « stabilité » ou d'« instabilité » du pieu. On voit que la taille de ces zones dépend du (des) critère(s) de rupture choisis.

On reproduit sur les Figures 1 et 2 les diagrammes cycliques obtenus pour les essais de Dunkerque (Jardine and Standing,

2012) et pour les essais en chambre de calibration (Tsuha et al., 2012).

Figure 1 : Diagramme de stabilité cyclique des pieux battus de Dunkerque (d'après Jardine and Standing, 2012)

Figure 2 : Diagramme de stabilité cyclique des pieux modèles en chambre de calibration (d'après Tsuha et al., 2012)

Pour ces deux diagrammes, la rupture est atteinte lorsque le déplacement de la tête du pieu atteint 0,1D. La zone *instable* caractérise les essais ayant atteint le critère de rupture avant 100 cycles. La zone *stable* correspond à une zone de faible amplitude de chargement cyclique dans laquelle les pieux ont été soumis à plus de 1000 cycles sans accumuler de déplacements significatifs (pour les deux types de pieux) ou pour lesquels la vitesse de déplacement était inférieure à 1mm pour 1000 cycles (pieux de Dunkerque). Entre ces deux zones se situe une zone qualifiée de *métastable* dans laquelle les pieux atteignent la rupture entre 100 et 1000 cycles ou développent des taux de déplacement pouvant faire craindre des ruptures au-delà de 1000 cycles.

Il est intéressant de mentionner que les trois zones de stabilité resteraient inchangées si on adoptait un critère de rupture à  $0,03 D$  comme pour les pieux en compression ci-après.

### 3 ESSAIS EN COMPRESSION

#### 3.1 Essais de Loon-Plage (SOLCYP)

Dans le cadre du projet national SOLCYP (Puech et al., 2012) des essais sur pieux réels ont été conduits sur le site de Loon-Plage constitué de sables denses. Cinq pieux forés et deux pieux métalliques battus ont été installés et soumis à des séries de chargements statiques et cycliques. Les résultats obtenus sur les pieux forés sont présentés dans Benzaria et al. (2013).

Le site expérimental se situe sur la commune de Loon-Plage (59) près de Dunkerque dans le Nord de la France. Il se caractérise par une couverture de remblais récents (0-0,6m) et d'argile sableuse (0,6-2,2m) sous laquelle on rencontre la formation de sable des Flandres.

Le sable est un sable siliceux très fin ( $D_{50}$  voisin de 0,15mm) et mal gradué (coefficient d'uniformité  $CU=0,98$ ) très proche de celui rencontré sur le site voisin des essais ICL (même origine). La formation est latéralement homogène et se caractérise par des valeurs de résistance au cône  $q_n$  croissant de 5 à 40 MPa vers 8 m de profondeur pour se stabiliser ensuite entre 30 et 50 MPa jusque vers 11,5m. L'interprétation des CPT conduit à un indice de densité  $I_D$  compris entre 0,7 et 0,9 (sable dense à très dense).

Une série d'essais triaxiaux monotones a donné un angle de frottement interne  $\phi'_{cv}$  voisin de  $31^\circ$  en bon accord avec les valeurs trouvées sur le sable de Dunkerque (Jardine et Standing, 2000).

Les deux pieux F4 et F5 sont géométriquement identiques ( $D=420\text{mm}$ , fiche 8m). Ils ont été exécutés à l'aide d'une tarière à axe creux vissée dans le sol sans extraction notable de matériau puis extraite sans dévissage tandis que le béton est déversé simultanément par l'axe creux. Les pieux sont équipés d'un train d'extensomètres amovibles de type LCPC introduits dans un tube de réservation positionné entre les armatures.

Les pieux ont été testés trois mois environ après leur mise en place. Les programmes de chargement comportaient des essais statiques de référence à paliers d'une heure selon la norme NF P 94-150, des essais de chargement rapides (réduction des paliers à 3mm) et des essais de chargement cycliques axiaux de type répété à la fréquence de 0,5Hz. Une description plus précise des modes de chargement est indiquée dans Benzaria et al. (2012).

#### 3.2 Essais sur modèles réduits centrifugés (SOLCYP)

Une campagne d'expérimentations sur modèles réduits centrifugés a été réalisée sur la centrifugeuse géotechnique de l'IFSTTAR à Nantes (Guefrech et al., 2012). Les pieux d'élanement 31 sont réalisés à l'échelle  $1/23^{\text{ème}}$ . Leur diamètre est de 18 mm. Leur surface est parfaitement rugueuse. Ils sont mis en place selon un procédé non refoulant consistant essentiellement à mettre le sable en place par pluviation alors que le pieu est déjà pré-positionné dans le conteneur. Cette technique simule un pieu moulé en place comme les pieux forés à la tarière creuse du site de Loon-Plage.

Le sable de Fontainebleau NE34 sec est en tout point identique à celui utilisé au laboratoire 3SR pour les essais en chambre d'étalonnage et présente des propriétés physiques et mécaniques très voisines de celle du sable des Flandres.

On s'intéresse dans ce qui suit à une série d'essais réalisés dans un massif à forte densité ( $I_D \approx 0,7$ ) à la fréquence de 1Hz. Seuls les essais de chargement cyclique en compression répétée sont analysés.

#### 3.3 Critère de rupture

La définition de critères de rupture en compression est plus délicate qu'en traction. En effet, quelle que soit la vitesse de déplacement initiale (sur les premiers cycles), les déplacements tendent globalement vers la stabilisation. Cette observation est commune aux pieux in situ (Benzaria et al., 2013) et aux pieux modèles (Guefrech et al., 2012). En effet, même s'il y a dégradation rapide du frottement, le déplacement du pieu provoque une mobilisation progressive de l'effort de pointe qui ralentit progressivement les tassements.

Le critère de rupture ne peut alors être défini de manière conventionnelle (e.g.  $0,1D$ ) mais doit s'exprimer en termes de déplacement cyclique acceptable. Ce critère pourra être franchi sur les tous premiers cycles en cas de chargement très sévère (avec une vitesse de déplacement forte voire croissante) mais plus généralement au bout d'un nombre de cycles plus ou moins important et avec une vitesse de déplacement décroissante.

Figure 3 : Vitesses de déplacements des pieux en compression pour les essais en centrifugeuse

L'analyse des vitesses de déplacement effectuée sur les pieux modèles centrifugés illustre les phénomènes en jeu (Figure 3). On distingue trois familles d'essai : a) les essais pour lesquels un tassement de  $0,1D$  est atteint en moins de 500 cycles et qui présentent une décroissance permanente de la vitesse de tassement ; b) ceux pour lesquels ce tassement est atteint entre 1000 et 5000 cycles avec une vitesse de tassement qui semble se stabiliser ; c) ceux pour lesquels la vitesse de tassement devient rapidement très faible ( $< 0,5$  mm pour 1000 cycles). L'évolution vers des déplacements importants est alors improbable.

Figure 4 : Vitesses de déplacement des pieux en compression pour les essais de Loon-Plage

La Figure 4 montre le même type d'évolution des vitesses de déplacement pour les pieux de Loon-Plage.

### 3.4 Diagrammes de stabilité cyclique

On présente sur les Figures 5 et 6 les diagrammes de stabilité cyclique obtenus pour les essais cycliques en compression sur pieux forés de Loon-Plage et les pieux moulés en centrifugeuse.

Pour ces deux diagrammes, la rupture est définie pour un déplacement du pieu de 0,03 D. La zone *instable* caractérise les essais ayant atteint le critère de rupture avant 100 cycles. La zone *stable* correspond à une zone de faible amplitude de chargement cyclique dans laquelle les pieux n'ont pas atteint le critère de rupture et les vitesses de déplacement sont faibles. Entre ces deux zones se situe la zone qualifiée de *métastable* dans laquelle les pieux atteignent la rupture entre 100 et 1000 cycles.

Figure 5 : Diagramme de stabilité cyclique pour les pieux forés de Loon-Plage

Figure 6 : Diagramme de stabilité cyclique pour les pieux moulés en centrifugeuse

On constate une bonne concordance entre les deux diagrammes. Il est recommandé de ne pas extrapoler les données dans le domaine des essais alternés. Les données disponibles (non montrées ici) indiquent en effet une forte réduction des zones métastable et stable dans le domaine alterné.

## 4 CONCLUSION

Cette communication rassemble des diagrammes de stabilité cyclique obtenus dans des sables siliceux denses et par des

moyens variés : essais in situ sur pieux réels, essais sur pieux modèles en chambre d'étalonnage et essais sur pieux modèles centrifugés. Elle couvre le cas des pieux battus en traction et celui des pieux forés en compression.

Les diagrammes cycliques de stabilité sont des outils précieux pour juger de la sévérité des chargements cycliques sur le comportement axial des pieux.

L'attention est attirée sur la difficulté de définir des critères de rupture significatifs, notamment en compression. L'interprétation des diagrammes ne peut être dissociée des critères choisis pour les élaborer.

## 5 REMERCIEMENTS

La rédaction de cette communication a été rendue possible par la collaboration de nombreux chercheurs et organismes. Les auteurs remercient tous leurs collègues impliqués dans ces recherches et les différents organismes ayant autorisé la publication des résultats.

**RÉSUMÉ :** Depuis trente ans, la réalisation d'essais d'expansion cycliques réalisés en trous préforés ou forés à l'avancement sur différents sites expérimentaux a permis de disposer d'une base assez importante de cas. La qualité de ces résultats permet de dériver des paramètres de déformabilité à des taux de déformation faibles. Ces essais cycliques ont été réalisés au pressiomètre Ménard et au pressiomètre autoforeur. Un peu moins d'une dizaine de sites ont été étudiés permettant d'observer le comportement de matériaux sableux et argileux normalement consolidés et surconsolidés. Cette communication présente le matériel utilisé ainsi que les procédures suivies. Le programme d'essai composé de plusieurs phases de cycles d'amplitude variable a été proposé dans les années quatre-vingt. On observe une évolution du module en fonction du nombre de cycles, de la nature du matériau et du rapport de l'amplitude et de la position moyenne avec la contrainte horizontale en place. Une synthèse des résultats des essais obtenus sur ces sites est présentée.

**ABSTRACT:** For thirty years, realization of cyclic expansion tests carried out in borehole pockets drilled using a separate tool or integrate in the probe, on different experimental sites allowed to have a rich database. The quality of these results allows to derive stress-strain parameters at low strain level. These cyclic tests were carried out using Menard and self-boring pressuremeters. A little less than ten sites were studied covering the behavior of sandy and clayey materials normally consolidated or overconsolidated. This paper will present the equipment used and procedures applied. Usually, the test program, which was proposed in the eighties, consists of several phases of cycles of variable amplitude. One can observe a shift of the module depending on the number of cycles, the nature of the material and the ratio of the amplitude and the mean position compared to the at rest horizontal stress. A summary of test results obtained on these sites is presented.

**MOTS-CLÉS :** comportement cyclique, essais d'expansion de cavité, pressiomètre autoforeur, pressiomètre Ménard

**KEYWORDS:** cyclic behavior, cavity expansion test, Self-boring pressuremeter, Ménard pressuremeter.

## 1 INTRODUCTION

Avec le matériel d'essai pressiométrique Ménard, il est possible de réaliser des essais d'expansion par palier (norme NF P94-110-1) et des essais cycliques (norme NF P94-110-2) (AFNOR, 1999 et 2000). Ces derniers essais comportent un cycle réalisé par paliers, dans les mêmes conditions que l'essai pressiométrique Ménard objet de la norme NF P 94-110-1. L'essai d'expansion classique, dans les conditions de forages préconisées par la norme NF P 94-110-1 et avec le protocole de chargement proposé, ne donne pas de résultats utilisables directement dans une étude de la déformabilité des ouvrages notamment lorsque la connaissance des modules en petite déformation est nécessaire (Combarieu et Canépa, 2001).

Les essais avec boucle de déchargement-rechargement permettent de déterminer un module cyclique de déformation. Les valeurs obtenues sont intermédiaires entre les modules en petites déformations obtenus au laboratoire, ou avec des essais de propagation d'ondes in situ, et les modules Ménard usuels (Les pressiomètres Louis Menard, 1960, Borel et Reiffsteck, 2006). Toutefois, un seul cycle est insuffisant pour cerner l'évolution des caractéristiques du sol sous chargement cyclique (Dupla et Canou, 2003). L'étude présentée, réalisée dans le cadre du projet national SOLCYP (projet de recherche sur le comportement des pieux soumis à des sollicitations cycliques, voir le site [www.pnsolcyp.org](http://www.pnsolcyp.org) pour plus d'information), comporte des essais multi-cycles réalisés avec la technique de la sonde mise en place dans un trou pré-foré ou foré à l'avancement.

## 2 DISPOSITIF EXPÉRIMENTAL

Le principe de l'essai consiste à mesurer l'évolution du volume injecté lors de l'application de cycles de pression.

### 2.1 Matériel

La mesure de la variation de volume en fonction des cycles se fait soit par mesure du volume d'eau injecté, soit par mesure du déplacement d'un palpeur (Figure 1a et b). L'idée étant de pouvoir réaliser des essais avec une sonde pressiométrique mise en œuvre par autoforage ou dans un pré-forage de type Ménard (AFNOR, 2000).

Le matériel utilisé développé par l'entreprise Jean Lutz SA est un contrôleur pression volume (CPV) (de type PREVO), capable de piloter des électrovannes par un ordinateur de type PC via une application spécifique.

Figure 1. Architecture de l'essai cyclique (a) au pressiomètre Ménard, (b) au pressiomètre autoforeur

Le principe de fonctionnement est le suivant. Les différentes opérations manuelles sont réalisées, soit directement sur le CPV, soit par le programme. Le pilotage en cyclique est réalisé sur la base d'un fichier d'essai acceptant tout type de signal, harmonique ou multifréquence. Le suivi se fait en temps réel sur un onglet graphique ou sur le tableau de valeur.

### 2.2 Méthode d'essai

Durant les années 70, l'Association pour la Recherche en Géotechnique Marine rassemblant différentes entreprises, bureaux d'étude et établissements de recherche dans le domaine a mené une campagne, sur plusieurs sites, d'essais cycliques au pressiomètre. Les détails des expérimentations sont rassemblés dans plusieurs rapports et articles du Symposium sur la pressiométrie et ses applications en mer tenu en 1982 à Paris (Jézéquel et le Méhauté, 1982 ; Puech et al., 1982). Trois types d'essais furent réalisés ; nous présentons les deux mis en œuvre dans la présente étude :

- essai de chargement cyclique entre deux bornes de pression  $p_M$  et  $p_m$  (Figure 2 a),
- essais de chargement entre deux bornes de pression variables, dont la moyenne est cependant constante, la borne inférieure restant supérieure à  $p_0$  la pression des terre au repos (Figure 2 b).

Figure 2. Différents types d'essais cycliques

Les paramètres retenus pour les essais cycliques découlent de la méthode proposée (cf. ci avant) : essai à pression contrôlée ; adaptation de la fréquence au type de sol pour tenter de rester drainé, niveau de sollicitation : 0,8 ( $R_c = \Delta p_{cyc} / p'_0$ ) ; fréquence : 0,01 à 0,05 Hz et nombre de cycles égal à 50.

La pression initiale  $p_m$  utilisée pour démarrer l'essai est définie comme la contrainte horizontale en place (pression des terres de repos) (effective de préférence) et la pression maximale  $p_M$  est égale à  $(1+0,8)p_m$  (Dupla et Canou, 2003). La pression  $p_m$ , qui a été prise égale à  $p_0$ , a été définie à partir des résultats d'essais d'expansion de type Ménard antérieurs par la méthode proposée par Briaud (1992).

### 2.3 Définition des modules

L'intérêt de réaliser des cycles avec le pressiomètre pour obtenir des modules en petites déformations est apparu très tôt (Les pressiomètres Louis Menard, 1960). Dès l'origine, plusieurs modules ont été définis à partir des courbes expérimentales.

Dans la première zone désignée comme « élastique », le module atteint une valeur quasi indépendante du niveau de déformation. Il est appelé module « initial »  $G_0$ .

Les courbes en partie monotone sont décrites par un module « sécant » ( $G_{s,1}$ ) défini par la pente de la droite reliant l'origine au point actuel et en partie cyclique, un autre module sécant ( $G_{p,N}$ ) déterminé par la pente de la droite reliant les deux points d'inversion du cycle N. Les modules maxima des cycles sont calculés avec la relation (avec les notations de la Figure 3) :

$$G_{p,N} = \frac{\Delta p}{\Delta V / V_m}$$

La boucle parcourue dans ces séquences de déchargement/remise en charge est de forme ellipsoïdale. Elle représente l'énergie dissipée en déformation plastique. L'évolution de l'inclinaison des cycles ou module au cours des cycles permettra d'évaluer le comportement du sol. On peut évaluer le durcissement ou l'adoucissement cyclique et l'accumulation de déformation, la stabilisation ou la relaxation ou l'effet rochet.

Figure 3. Calcul des modules des cycles

Le mode d'interprétation est basé sur l'évolution de l'aire caractéristique des boucles de chargement déchargement ainsi que du module sécant des boucles d'hystérésis (Figure 3).

## 3 ESSAIS CYCLIQUES

### 3.1 Essais du LRPC de Saint Brieuc

À la fin des années 70, le laboratoire des Ponts et Chaussée de Saint Brieuc a réalisé plusieurs campagnes d'essais d'expansion cyclique au pressiomètre autoforeur (modèle PAF76 de diamètre 132 mm). Ces essais comportaient une centaine de cycles voire plusieurs milliers de cycles (durée de 24 à 72 heures). Ils ont été réalisés sur deux sites principaux Cran et Plancoët (Le Méhauté et Jézéquel, 1980).

#### 3.1.1 Site de Plancoët

Le site est constitué d'une parcelle plane en bordure de la rivière Arguenon. Le sol est constitué de sols fins très lâches : silts en surface (0 à 4 m), sables fins ensuite (surtout de 6 à 9 m) puis des argiles (de 10 à 12 m) avec quelques inclusions de graviers et de sables. Le substratum est à 15 m. La nappe fluctue en fonction des saisons entre 0,30 et 1,50 m.

#### 3.1.2 Site de Cran

La plaine alluviale de la Vilaine en aval de Redon est une vallée sédimentaire de près de 2 km de large. On y rencontre un dépôt d'argile sur une épaisseur de 10 à 20 m, reposant sur une couche de sable et de galets qui recouvre le substratum rocheux. À Cran, la rive droite est constituée par un dépôt d'argile molle marine de 17 m d'épaisseur reposant sur un substratum rocheux (schiste et phanites).

### 3.2 Essais du projet Solcyp

Des tests de validation ont été effectués sur trois sites : Gosier, Cran et Merville. Les deux derniers sites ont fait l'objet de nombreuses études dans le cadre de recherches programmées par les Laboratoires des Ponts et Chaussées. Les caractéristiques qui ont présidé au choix, ont été une relative homogénéité d'ensemble sur une profondeur minimale de 5 à 10 m.

#### 3.2.1 Site de Gosier

Les premiers essais avec le nouveau matériel ont été entrepris sur le site de Gosier en Guadeloupe situé dans une zone potentiellement liquéfiable, instrumentée et étudiée dans le cadre du projet ANR Belle Plaine. Des essais pressiométriques Ménard (par paliers) ont été réalisés pour compléter les profils obtenus au pénétromètre statique à pointe électrique et définir les pressions  $p'_0$  à utiliser puis deux sondages pressiométriques cycliques ont été réalisés.

La figure 4a présente les courbes de la pression imposée corrigée en fonction de la variation volumique obtenue pour 4 essais de la série MC2. Après une première partie qui correspond à la montée à la charge moyenne en monotone, la phase cyclique entre  $p_M$  et  $p_m$  montre la tendance à la stabilisation de quasiment tous les essais, même si celle-ci n'a jamais été atteinte. Apparemment, l'essai à la profondeur 7 m montre une accumulation importante de déformation volumique (couche d'argile molle).

Figure 4. a et b Essais d'expansion cycliques pré-forés site de Gosier

#### 3.2.2 Site de Cran

Les essais réalisés en 2011 ont été placés à proximité des séries réalisées en 1979.

À la profondeur 2 m, la courbe d'essai présentée sur la Figure 5a montre une accumulation de volume élevée (de l'ordre de 900 cm<sup>3</sup>) conduisant à la conclusion que le test a été effectué dans la couche molle et que la pression initiale déduite des études précédentes a été surestimée. Le signal obtenu représenté sur la Figure 5a est assez bruité car l'amplitude de la plage de pression est faible, et une interaction entre l'asservissement de l'eau et l'air n'a pu être corrigée à temps dans le pilotage.

#### 3.2.3 Site de Merville

Sur le site expérimental de Merville (Nord), on rencontre à 1,5 m environ de la surface, une couverture de limons peu plastiques, affectée par le battement de la nappe et de 1,5 à 42 m de profondeur, l'argile (surconsolidée) des Flandres de l'Yprésien.

Figure 5. a et b Essais d'expansion cycliques autoforés site de Cran

Un sondage au pressiomètre autoforeur avec des essais cycliques à 6, 8 et 12 m, en alternance avec des essais d'expansion monotone croissante à 5, 7 et 11 m, a été réalisé (Figure 6 et Figure 7a). Les trois premiers essais cycliques ont été réalisés avec la même amplitude fixée à partir des essais d'expansion monotones. Le dernier essai a été réalisé avec une amplitude basée sur l'essai à 11 m.

Figure 6. Essais d'expansion cycliques autoforés multi-amplitude site de Merville

Les amplitudes de 60 kPa ont abouti à des résultats peu précis car d'une part la source de pression était réglée à une pression trop forte et de ce fait l'électrovanne de la chambre tampon avait du mal à réguler et d'autre part cette valeur est faible et de l'ordre de grandeur de la précision de l'asservissement. Il est donc nécessaire d'adapter les amplitudes aux profondeurs et de réévaluer la méthode de détermination de celle-ci.

Figure 7. a et b Essais d'expansion cycliques (a) autoforés et (b) pré-forés site de Merville

À proximité immédiate un sondage au pressiomètre Ménard avec un perforage d'un mètre à la tarière hélicoïdale avec des essais cycliques à 5, 7 et 11 m permet de disposer de résultats comparables (figure 7).

#### 4 DISCUSSIONS

Un premier constat est que le signal obtenu représenté sur les Figure 4 à 7 est plus bruité que celui donné dans les articles de Jézéquel et Le Méhauté (1982) car l'asservissement par contrôleur pression volume à vis à bille en vitesse de volume (2%/mn) est plus stable qu'un asservissement en pression par électrovanne. Les cycles obtenus présentent des points singuliers à méplats et non de rebroussement.

Les différentes expérimentations ont montré qu'il faut réaliser un minimum de 50 cycles pour obtenir une évolution claire du module sécant et qu'il n'est pas possible de se limiter à quelques cycles – 3 à 10 par exemple – pour obtenir des résultats représentatifs. A noter que l'évolution du module sécant de 50 à 500 cycles est de 10% en moyenne et de 500 à 5000 de 3%.

Même si les différences de protocole dues à la mise au point de ces matériels et essais ne permettent pas une comparaison détaillée, les accumulations volumiques constatées sont du même ordre de grandeur avec les différents modes de mise en œuvre. La qualité du pré-forage est essentielle pour permettre un essai avec un volume injecté initialement minimal. Sur deux sites (Gosier et Cran) indépendamment du mode de mise en œuvre, l'accumulation importante de déformation à certains niveaux a permis de localiser les couches susceptibles d'une chute de caractéristiques importante lors de l'application de sollicitations cycliques (figures 4 et 5).

Tableau 1. Caractéristiques des essais

Site	Forage	Sol	z (m)	$G_{p,1}$ ( $10^5$ Pa)	$a_{M0}$ (%)	$G_{p,50}/G_{p,1}$	
Plancoët	8-3	silt	2	5,19	0,5	1,6	
			16-1	3	3,46	1	1,8
			7-3	2	1,08	5	3
	8-3	sable	7	9,98	0,5	2,2	
			16-1	7	6,49	1	2
			7-3	7	2,69	5	3,3
			8-3	11	8,58	0,5	1,43
16-1	argile	11	6,47	1	1,9		
		7-3	11	3,75	5	2,1	
Cran 1	C1	argile	moy	29,9	1,67	1,15	
	C2	argile	moy	20	0,99	1,09	
Gosier	C2-PMT	sable	7	51,6	0,5	1,60	
			9	13,9	3,5	1,41	
Cran 2	A0-PAF	argile	1	60,8	10	2,71	
			2	25,6	12	1,59	
Merville	PAF	argile	6	426	0,8	2,01	
			12	294	3,5	1,93	
Merville	PMT	argile	5	145	0,6	1,37	
			11	255	0,9	1,21	

Lors de tous les essais, une stabilisation des déformations moyennes des cycles en fonction du nombre de cycle a pu être observée. Selon le type de sol, les cycles tendent à se redresser plus ou moins fortement, comme cela semble être le cas pour les sables de Plancoët et l'argile de Merville.

Les séries d'essais multi-amplitude permettent d'obtenir des courbes d'évolution du module cyclique en fonction de la profondeur et de l'amplitude des cycles pour différentes natures de sol (figure 6 et tableau 2).

Tableau 2. Évolution du module sur plusieurs amplitudes

Site	Outil	z (m)	$G_{p,50}/G_{p,1}$ de la phase			
			1	2	3	4
Plancoët	PAF	1	1.83	1.08	0.8	1.27
Merville	PAF	12	1,93	0,99	0,87	0,98
	PMT	11	1,21	0,94	1,42	1,06

On observe une évolution très similaire sur le site de sols lâches de Plancoët et sur le site d'argile raide de Merville : une évolution importante pour la première amplitude, puis une quasi stabilisation pour les autres amplitudes

#### 5 CONCLUSION

Les différentes campagnes de sondages avec essais cycliques mono ou multi amplitudes ont montré l'intérêt de cet essai pour cerner l'évolution du module de cisaillement en fonction du nombre de cycle et le potentiel de l'essai à localiser les horizons susceptibles de liquéfaction.

Il reste à mieux préciser les conditions d'essais pour avoir des jeux de données comparables et si possible disposer de la mesure de la pression interstitielle au niveau de la membrane pour estimer les accumulations potentielles de pression ou adapter la vitesse d'essais afin de rester drainé.

#### 6 REMERCIEMENT

Les auteurs désirent remercier le projet national SOLCYP ainsi que le ministère de l'Environnement de l'Énergie, du Développement Durable et de la Mer pour le financement de cette action de recherche ainsi que leurs collègues O. Malassingne et A. le Kouby.

# Displacement response to axial cyclic loading of driven piles in sand

## Réponse en déplacement au chargement cyclique axial de pieux battus dans le sable

Rimoy S., Jardine R., Standing J.  
Imperial College London

**ABSTRACT:** Interactive axial cyclic loading stability charts have been developed to guide the assessment of axial cyclic capacity degradation of piles driven in sands. Less guidance is available regarding displacement accumulation and cyclic stiffness response at full scale. This paper focuses on axial cycling experiments of six full-scale steel open-ended pipe-piles at a marine sand site in Dunkerque, France. Multiple suites of cyclic loading were applied, interspersed with reference static tension capacity tests. The piles' stable, meta-stable and unstable capacity responses are identified with reference to a site-specific normalised cyclic interaction stability diagram. The stiffness response and rates of accumulated displacement associated with each style of cycling are reported. It is shown that under stable loading, the piles' cyclic stiffnesses remain constant or decline marginally. Similar trends are observed with meta-stable tests up to onset of an eventual cyclic failure, after which stiffness degrades rapidly. Unstable tests displayed shorter periods of modest change before marked losses of cyclic stiffness. The patterns of accumulated displacement growth show more complex relationships with the cyclic loading parameters that can be expressed in multi-surface 3-D plots.

**RÉSUMÉ :** Des diagrammes interactifs de stabilité cyclique ont été développés afin d'évaluer la dégradation cyclique des pieux battus dans les sables. Peu de données sont disponibles à échelle réelle en ce qui concerne les déplacements. Cet article s'intéresse aux essais cycliques axiaux de six pieux tubulaires en acier à base ouverte dans un site de sable marin à Dunkerque. Plusieurs séries de chargement cyclique ont été appliquées, entrecoupées d'essais statiques référentiels en traction. Les réponses stable, méta-stable et instable de capacité des pieux sont identifiées en relation avec un diagramme normalisé de stabilité cyclique. La réponse en termes de rigidité et de taux de déplacement accumulé associée à chaque type de chargement cyclique est ensuite présentée. On montre que sous un chargement stable, la rigidité cyclique reste constante ou diminue légèrement. On observe des tendances similaires dans les essais méta-stables jusqu'à l'apparition d'une éventuelle rupture cyclique, après laquelle la rigidité se dégrade rapidement. Les essais instables ont montré de courtes périodes de léger changement avant de fortes pertes de rigidité cyclique. Les schémas de croissance des déplacements cumulés montrent des relations avec les paramètres de charge cyclique plus complexes qui peuvent être exprimées dans des représentations 3-D.

### 1 INTRODUCTION

The axial cyclic response of driven pile foundations can be critical in the design of offshore oil and gas platforms, and multi-piled wind turbines, towers and pylons. Lateral and moment loads imposed by wind or wave action can be large compared to self-weights, leading to multiple modes of axial and lateral cyclic loading on the foundation piles. Lateral loading model tests have been reported that tracked the gradual rotation and stiffness of monopiles (Leblanc et al. 2010); however less guidance is available on full-scale displacement accumulation and stiffness responses under axial cycling.

Jardine et al. (2012) reviewed the potential effects of cyclic loading on offshore pile foundations and considered how these may be addressed in practical design for a range of geomaterials. They note that loads vary with platform weight, water depth, metocean environment and structural form. Of the 15 field research studies they identified, only one concerned silica sands, that at Dunkerque, France reported by Jardine & Standing (2000, 2012). Merritt et al. (2012) describe how the most severe tens or hundreds of cycles imposed in storms are the most critical to pile performance. The Jardine & Standing (2000) field study investigated behaviour up to 1000 cycles.

Karlsrud et al. (1986), Poulos (1988) and Jardine & Standing (2000) have used cyclic stability diagrams to guide the assessment of pile axial cyclic behaviour. These consider the interaction effects of cyclic and mean loads (normalised by static capacity before cycling) and the number of cycles applied. Such interaction diagrams may be zoned to identify a cyclically stable (S) region where there is no reduction of load capacity after N cycles, a meta-stable (MS) region where some reduction of load capacity occurs after N cycles and an unstable (US) region where cyclic failure develops within a small specified number of cycles. Jardine & Standing (2012) used a similar

scheme in interpretation of their field tests at Dunkerque (Figure 1) where multiple cyclic loading tests performed that were interspersed with reference static tension capacity ( $Q_T$ ) tests. This paper focuses on further interpretation of the same axial cycling experiments. The axial static and cyclic stiffness responses are discussed and the accumulated cyclic displacement trends associated with each mode of cycling are examined, referring to the site specific normalised cyclic interaction stability diagram.

Figure 1. Axial cyclic interaction diagram for the full-scale pile tests in Dunkerque silica marine sands (Jardine & Standing 2012).

Figure 4. Illustration of the stiffness and displacement parameters used in the analyses

Figure 5. Pile stiffness from the first-time axial static monotonic tension loadings normalised by the reference stiffnesses against normalised load

Figure 6. Axial cyclic loading stiffness  $k_l$  responses normalised by  $k_{Ref}$  against number of cycles for the stable and meta-stable tests.

The loading stiffness  $k_l$  degradation trends for the unstable tests (Set 3 of Figure 1) are shown on Figure 7. By definition, these tests failed with sudden stiffness loss after relatively few cycles. However, even these piles retained most of their initial stiffnesses until within  $\sim 10$  cycles of final failure. Seemingly anomalous stiffness behaviour is observed towards failure in some one-way meta-stable and unstable loading tests when stiffnesses are defined from the unloading cycle phase  $k_u$ , Figure 8. This reversal in normalised stiffness results from an increased opening-up of the load-unload hysteresis loops as

cyclic failure approaches with more plastic displacements accumulating on the loading loops leading to the progressively decreasing secant loading stiffnesses and apparently stiffer behaviour on unloading as cyclic loading approaches failure.

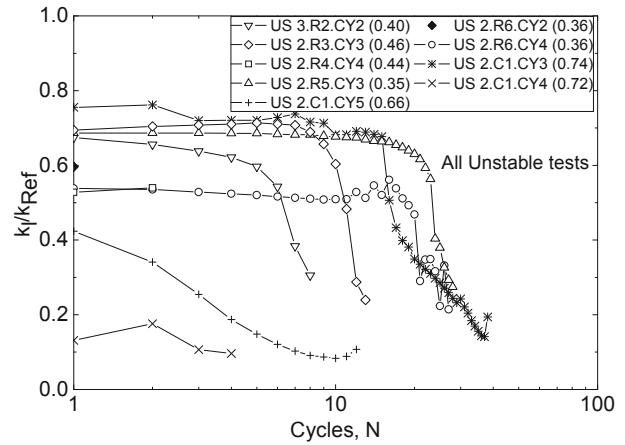

Figure 7. Axial cyclic loading stiffness  $k_l$  responses normalised by  $k_{Ref}$  against number of cycles for the unstable tests.

Figure 8. Axial cyclic unloading stiffness  $k_u$  responses normalised by  $k_{Ref}$  against number of cycles for selected metastable and unstable tests.

### 4.3 Accumulated cyclic displacements

The patterns of pile head displacement accumulation for the stable and meta-stable cyclic tests are shown on Figure 9. Also shown are the reference lines related to the predefined thresholds for stable, metastable and unstable accumulated displacements rates. An almost static accumulated displacement trend was observed in the single fully stable loading test 3.R4.CY6. The meta-stable tests 2.R3.CY2 and 2.R4.CY2 developed higher, but steady displacement rates  $> 1\text{mm}/100\text{cycles}$  while the other two meta-stable tests 2.R5.CY2 and 3.R6.CY6 displaced by  $> 1\text{mm}/10\text{cycles}$ . A range of responses is evident for the unstable loading tests summarised in Figure 10 which develop displacement rates  $> 1\text{mm}/10\text{cycles}$ .

While the cyclic stiffness patterns varied principally as a function of the applied cyclic amplitudes  $Q_{cyclic}$ , the accumulated cyclic displacement patterns depended on both the normalised mean ( $Q_{mean}/Q_T$ ) and cyclic ( $Q_{cyclic}/Q_T$ ) loads. Rimoy et al. (2013) demonstrate the interactive effects of the loading components  $Q_{cyclic}$  and  $Q_{mean}$  by considering the accumulated displacements developed after 3, 10, 30, 100, 200, and 300 cycles to produce tentative 3D surfaces equivalent to displacements of 2%, 0.2% or 0.02% pile diameter, Figure 11. The accumulated displacement trends flatten progressively as  $N$  increases. The zero cyclic effect boundary was set at  $Q_{cyclic}/Q_T =$

0.1 following centrifuge studies by Julio (2009). No displacements are expected to accrue due to cycling below this level; further full-scale specific investigation of this lower threshold is required.

Figure 9. Accumulated cyclic displacements for the stable and meta-stable loading tests

Figure 10. Permanent accumulated cyclic displacements response for the unstable tests

## 5 SUMMARY AND CONCLUSIONS

The analysis presented of the axial cyclic loading load–displacement, stiffness and accumulated displacements responses seen in tests on steel open-ended pipe piles driven in silica sand indicate the following.

- (1) Axial load–displacement behaviour is highly non-linear, even at relatively low levels of loading.
- (2) The piles' cyclic stiffnesses generally remained within 20% of those observed under initial static loading until cyclic failure was approached.
- (3) The patterns of accumulated displacements depended on both the mean and cyclic normalised loading levels.
- (4) While displacements accumulate rapidly over just a few cycles in the unstable zone, extended cycling in the stable zone led to minimal (and stabilising) accumulated displacements and axial capacity gains (Jardine et al (2006) meta–stable tests showed intermediate behaviour.

Figure 11. 3D plot for accumulated cyclic displacements equivalent to 0.02%D, 0.2%D and 2%D.

## 6 ACKNOWLEDGEMENTS

The above research was funded by the EU (through the GOPAL project) and Health and Safety Executive (HSE) of UK. We gratefully acknowledge the Port Autonome de Dunkerque for providing the test site. The field testing was conducted in conjunction with Precision Monitoring Control Ltd. of Teesside UK. The first author has been supported by the Commonwealth Scholarship Commission during the writing of this paper.

# Experimental Testing of Monopiles in Sand Subjected to One-Way Long-Term Cyclic Lateral Loading

Étude expérimentale de monopiles dans le sable soumis à un chargement cyclique transversal non alterné

Roesen H.R., Ibsen L.B., Andersen L.V.  
Aalborg University, Aalborg, Denmark

**ABSTRACT:** In the offshore wind turbine industry the most widely used foundation type is the monopile. Due to the wave and wind forces the monopile is subjected to a strong cyclic loading with varying amplitude, maximum loading level, and varying loading period. In this paper the soil-pile interaction of a monopile in sand subjected to a long-term cyclic lateral loading is investigated by means of small scale tests. The tests are conducted with a mechanical loading rig capable of applying the cyclic loading as a sine signal with varying amplitude, mean loading level, and loading period for more than 60 000 cycles. The tests are conducted in dense saturated sand. The maximum moment applied in the cyclic tests is varied from 18% to 36% of the ultimate lateral resistance found in a static loading test. The tests reveal that the accumulated rotation can be expressed by use of a power function. Further, static tests conducted post cyclic loading indicate that the static ultimate capacity increases with the magnitude of cyclic loading.

**RÉSUMÉ:** Dans l'industrie éolienne offshore, le type de fondation le plus largement utilisé est la monopile. En raison de la force des vagues et du vent, la monopile est soumise à une charge cyclique élevée dont l'amplitude, le niveau de charge maximale et la périodicité varient. Dans cet article, l'interaction sol-pieu d'une monopile implantées dans du sable et soumises à un chargement latéral cyclique est étudiée au moyen d'essais à échelle réduite. Les tests sont effectués avec une grue de chargement mécanique capable d'appliquer un chargement cyclique sinusoïdal avec amplitude, niveau moyen et période de chargement variable pendant plus de 60 000 cycles. Les tests sont effectués dans du sable dense saturé. Le moment maximum appliqué durant les essais cycliques varie de 18% à 36% de la résistance latérale ultime obtenue lors d'essais de chargement statique. Les essais montrent que la rotation accumulée peut être exprimée par l'utilisation d'une fonction de puissance. En outre, des essais statiques menés après le chargement cyclique indiquent que la capacité statique ultime augmente avec le niveau du chargement cyclique.

**KEYWORDS:** Experimental, wind turbine foundation, monopile, long-term cyclic loading, dense sand.

## 1 INTRODUCTION

In the offshore wind turbine industry, the most widely used foundation type is the monopile, i.e. a large diameter stiff pile. During the lifetime of a wind turbine, the monopile foundation is subjected to few load cycles with large amplitudes, caused by the strong storms, and also to millions of lateral load cycles with low or intermediate amplitudes due to the wave loading. This loading may cause failure in the fatigue or serviceability limit states, FLS and SLS respectively (Wichtmann et al. 2008). The cyclic loading might induce a change in the soil stiffness and a permanent accumulated rocking rotation (tilt) of the turbine. Due to the efficiency of the wind turbine, strict demands for the rotation and the stiffness of the entire structure are normally made and thus, the change in stiffness and rotation becomes key issues in the design. However, the current design guidance, DNV (2011), on this long-term loading is limited and a procedure for designing large diameter piles is yet to be fully expressed and confirmed. The development of a reliable design method requires verification and for that in-situ and large-scale testing is by far the best tool. However, this is also the most expensive and time-consuming tool. Therefore, the recent choice for evaluating the cyclic behaviour has been numerical modelling and small scale testing. Several authors has investigated this e.g. Niemunis et al. (2005), Achmus et al. (2005), Peng et al. (2006), LeBlanc et al. (2010) and Achmus et al. (2011). However, the research has mainly been based on cyclic triaxial tests, FEM-calculations and 1g experimental setups in dry sand.

In this paper, a 1g testing rig for modelling the environmental loading on a stiff monopile foundation in dense saturated sand is described and the results from four one-way

cyclic loading tests are presented. The purpose of the cyclic tests is to evaluate the influence of the number of load cycles,  $N$ , on the accumulated rocking rotation of the pile at seabed, under long-term cyclic loading with constant frequency but different loading amplitude and mean loading level.

The characteristic of the cyclic loading can be described by the ratios  $\zeta_b$  and  $\zeta_c$  as defined by LeBlanc et al (2010).  $\zeta_b$  expresses the magnitude of the loading as the ratio between the maximum load in a load cycle and the maximum static lateral capacity,  $\zeta_b = M_{max}/M_{static}$ .  $\zeta_b$  will take a value between 0 and 1. The cyclic load ratio  $\zeta_c$  defines the direction of the loading on the basis of the minimum and maximum load in a load cycle,  $\zeta_c = M_{min}/M_{max}$ .  $\zeta_c$  will take the value 1 for a static test, 0 for one-way loading, and -1 for two-way loading.

## 2 EXPERIMENTAL MODEL TESTS

The 1g small scale tests are carried out at the geotechnical laboratory at Aalborg University, Denmark. In the tests an open ended aluminium pipe pile is used. The pile is scaled approximately 1:50 in relation to a typical offshore monopile. In Table 1 the dimensions of the model pile are presented.

Table 1. Dimensions of the open ended aluminium pipe pile.

Diameter $D$ (mm)	Embedded length $L$ (mm)	Wall thickness $t$ (mm)	Load eccentricity $e$ (mm)
100	500	5	600

The bending stiffness of the model pile is similar to a scaled prototype steel pile, however, the behaviour of the pile during loading also depends on the stiffness of the surrounding soil. According to Poulos and Hull (1989) a pile behaves flexible if  $L > L_c$  and rigidly if  $L < L_c/3$ , where  $L_c$  is a critical length defined by Eq. 1.  $E_p I_p$  is the bending stiffness of the pile and  $E_s$  is Young's modulus of elasticity of the soil.

$$L_c = 4.44 \left( \frac{E_p I_p}{E_s} \right)^{0.25} \quad (1)$$

Due to the low stresses in the soil at 1g small scale testing, the stiffness is also low. From previous testing and numerical modelling an estimated soil stiffness of 4 MPa can be used for the sand in the test setup (Roesen et al. 2010). With use of Eq. 1 the model pile is thereby found to behave rigidly during lateral loading. In comparison a prototype steel monopile with  $D = 5$  m and  $t = 0.07$  m installed in sand with  $E_s = 70$  MPa is found to behave rigidly with a slenderness ratio  $L/D = 3$  and behave flexible with  $L/D = 9$ . Thus, for the examined slenderness ratio ( $L/D = 5$ ) the model pile experiences a more rigid behaviour than the prototype pile. Nevertheless, the results obtained in the small scale model tests can be used as underlying basis for understanding the monopile behaviour during lateral cyclic long-term loading.

The test setup consists of a cylindrical sand container with an inner radius of 2.00 m and a height of 1.20 m surrounded by a loading frame equipped for both static and cyclic loading. The setup is an improvement of the system presented in Roesen et al. (2012) which originally is based on the setup presented by LeBlanc et al. (2010). A cross-sectional sketch and a photo of the system are shown in Figure 1 and 2. The pile is installed in the middle of the container by use of a mechanical motor with installation velocity of 0.02 mm/s. The container holds up to 0.90 m dense saturated sand with 0.30 m highly permeable gravel underneath. In the bottom a drainage system with perforated pipes ensures homogeneous in- and outflow of water.

The cyclic loading system is a simple load controlled system based on a lever arm, weight hangers with applied masses,  $m_1$ ,  $m_2$ , and  $m_3$ , wires, and an electric motor controlling the rotation of weight  $m_1$ . The rotation causes an oscillating motion on the lever and thereby a cyclic loading on the pile. The system is thereby capable of providing sinusoidal loading to the pile for more than 60 000 load cycles. The rotational frequency of the motor is set to 0.1 Hz to be in agreement with environmental wave loading (Peng et al. 2006).

Initially, when the mass  $m_1 = m_2 = 0$ , the mass  $m_3$  is chosen to outbalance the system. Depending on the weights chosen for  $m_1$  and  $m_2$  the system is capable of providing both one- and two-way loading with varying  $\zeta_b$  and  $\zeta_c$ , i.e. different direction, amplitude, and mean loading level. The loading is applied through steel wires attached to the pile 600 mm above soil surface. Hence, the pile experiences both horizontal and moment loading. In both sides of the pile a HBM U2A 100 kg load cell is attached measuring the actual force applied to the pile throughout the whole test. The displacement of the pile is measured using three WS10-125-R1K-L10 displacement transducers from ASM GmbH. The transducers, D1, D2, and D3 are mounted 600 mm, 375 mm, and 155 mm above soil surface, respectively. The rocking rotation,  $\theta$ , and displacement of the pile at soil surface is found by use of linear regression of the three measurements assuming rigid pile behaviour. The data sampling rate is 2 Hz.

Before conducting any cyclic tests a static loading test is performed. The static test is conducted displacement controlled by use of a motor with a loading rate of 0.02 mm/s. The displacement is actuated 600 mm above soil surface, i.e. the same height as the loading in the cyclic loading tests. The pile is loaded to a rotation of 2°, unloaded, and reloaded to failure. The static test is used as a reference for the ultimate lateral

Figure 1. Sketch of the test setup. F1 and F2 refer to the two load cells, D1, D2, and D3 refer to the three displacement transducers and  $m_1$ ,  $m_2$ , and  $m_3$ , refer to the weights applied on the load hangers. All measurements are in meters.

Figure 2. Test setup for cyclically long-term loaded monopiles.

Table 2. Test programme with relative soil densities,  $D_r$ , loading characteristics, and number of cycles,  $N$ .

Test No.	Type	$D_r$ (%)	$\zeta_b$	$\zeta_c$	$N$	Static test after cyclic loading
1	Static	78.56	-	-	-	-
2	Cyclic	87.76	0.18	0.03	50 894	yes
3	Cyclic	85.38	0.24	0.10	51 732	no
4	Cyclic	87.87	0.25	-0.01	50 960	yes
5	Cyclic	91.70	0.36	0.03	60 224	yes

resistance and the maximum resistance obtained is interpreted as the ULS load on the pile.

In total four long-term cyclic loading tests are performed, each with more than 50 000 load cycles. The tests are conducted with  $m_1 = m_2$ , i.e. one-way loading with the target  $\zeta_c = 0$ . The magnitudes of the loading in the cyclic tests are chosen to reflect realistic loading conditions for FLS and SLS loading, which according to LeBlanc et al. (2010) is approximately 30% and 40% of the ultimate limit state loading (ULS), respectively. Thus, the target maximum moment applied in the cyclic loading tests are defined as 20%, 25%, 30% and 40% of the maximum static lateral resistance, i.e.  $\zeta_b$  is chosen in the interval 0.2 to 0.4. In Table 2 a summary of the testing programme with the obtained loading characteristics is presented.

In general the magnitude of the loading is seen to be a little less than expected. This result verifies the importance of measuring the actual force on the pile as some of the applied load is lost in the system due to friction. For three of the tests the cyclic load ratio,  $\zeta_c$ , is seen to be close to zero which is in agreement with the target loading.

In order to investigate the influence of cyclic loading on the ultimate lateral resistance static loading tests were performed after the cyclic loading.

### 2.1 Soil Conditions

The tests are conducted using saturated Aalborg University Sand No. 1 (Baskarp Sand No.15). In Table 3 the properties of the sand are summarised.

Table 3. Properties of Aalborg University Sand No. 1

Specific grain density	Maximum void ratio	Minimum void ratio	50%-quantile	Uniformity coefficient
$d_s$	$e_{max}$	$e_{min}$	$d_{50}$	$U = d_{60}/d_{10}$
(-)	(-)	(-)	(mm)	(-)
2.64	0.858	0.549	0.14	1.78

Prior to each test the sand is prepared by use of an initially upward gradient of 0.9 followed by mechanical vibration with a rod vibrator. The obtained homogeneity and compaction of the sand is verified by conducting three cone penetration tests (CPT) with a laboratory cone; one in the middle of the container and two in a distance 400 mm from the centre in the active and passive side of the pile, respectively. The relative densities of the sand,  $D_r$ , are derived in accordance to Ibsen et. al (2009) where the laboratory cone is correlated with in-house triaxial tests on the same sand type. The mean values of the relative densities found prior to each experiment are presented in Table 2 together with the characteristic of the tests themselves.

## 3 TEST RESULTS

Initially, the static loading test is used as a reference test for the ULS moment capacity and thus the choice of maximum moment loading in the cyclic tests. The moment-rotation relationships obtained in both the static and the cyclic tests are presented in Figure 3. The static test clearly defines a maximum moment capacity of 360 Nm which is interpreted as the ULS load. In all the cyclic tests the rotation obtained in the first loading cycle follows the static reference test cf. Figure 3. This verifies the use of the static test as a reference for the loading despite the difference in relative densities of the soil cf. Table 2. Even though the cyclic loading system is an improvement of the system presented in Roesen et al. (2012) the maximum moment loading in the cyclic tests are seen to decrease a little during the test. Therefore, the characteristics of the cyclic loading,  $\zeta_b$  and  $\zeta_c$  cf. Table 2, are calculated as mean values over the whole test and  $\zeta_b$  is seen to be lower than the target value.

In Figure 4 the rotation of the pile,  $\theta$ , at soil surface as a function of the number of cycles,  $N$ , for test no. 2 is presented. The figure shows the cyclic response during loading and the rotation is seen to accumulate throughout the entire test. Similar results are obtained in the three other tests. In the evaluation of the accumulated rotation the maximum values of the rotation are used, i.e. the rotation marked with dark grey in Figure 4. As seen in Figure 3 the rotation in the first loading cycle is equal to the rotation obtained in the static reference test. Thus, in order to evaluate the influence of the cyclic loading only the accumulated rotation,  $\Delta\theta(N) = \theta_N - \theta_1$ , is investigated.  $\theta_N$  is the rotation obtained at the  $N^{\text{th}}$  loading cycle and  $\theta_1$  is the rotation obtained in the first loading cycle.

Figure 3. Moment-rotation relationships of the static reference test and the four cyclic loading tests.

Figure 4. Rotation of the pile at soil surface as a function of the number of cycles in the test with  $\zeta_b = 0.25$ . Maximum and minimum values of the rotation are indicated by dark grey and black colouring.

Figure 5. Normalised accumulated rotation as a function of the number of cycles for the four cyclic tests.

In Figure 5 the accumulated rotation obtained in all four cyclic tests are presented. The rotations are normalised with respect to the rotation obtained in the first loading cycle. The accumulated rotations of the stiff pile are fitted with a power function as suggested by several authors, e.g. Long and Vanneste (1994), Peralta and Achmus (2010), and LeBlanc et al. (2010). The fitted expression is given by Eq. 2 and shown as the dotted black lines in Figure 5.

$$\frac{\Delta\theta}{\theta_1} = a N^b \quad (2)$$

$a$  and  $b$  are dimensionless constants determined empirically from the tests. The results from the long-term one-way loading cf. Figure 5 shows a general good agreement with the power function even though deviations in the first 1000 cycles are observed. The values for the power  $b$  are found to be similar for all the tests with values in the range of 0.11 to 0.18. These values are found to be smaller than the value of 0.31 as presented by LeBlanc et al. (2010). The results for the constant  $a$  cf. Figure 6 indicates that  $a$  depends linearly of the magnitude of the loading  $\zeta_b$  which is in agreement with the findings in LeBlanc et al. (2010).

Figure 6. Fitted empirical constant  $a$  as a function of the loading magnitude  $\zeta_b$  in the four cyclic tests.

The influence of the cyclic loading on the static lateral capacity is evaluated by means of the results from the three static tests performed post cyclic loading cf. Figure 7. The maximum moments obtained indicates that the lateral capacity depends on the cyclic loading and increases with increasing load magnitude.

Figure 7. Moment-rotation relationships obtained in the static tests post cyclic loading compared with the reference static test.

#### 4 CONCLUSION

This paper presents a description of a 1g laboratory small scale test setup for modelling laterally long-term cyclic loading of a stiff pile in saturated dense sand. A static loading test and four one-way cyclic loading tests with maximum moment loading equal to 18% to 36% of the maximum static capacity are presented. The purpose of the tests is to evaluate the influence of the number of load cycles on the accumulated rocking rotation of the pile at seabed during long-term cyclic loading. In addition the effect of the cyclic loading on the static lateral capacity is evaluated by means of static loading tests conducted post cyclic loading.

All the tests are carried out with an open ended aluminium pipe pile scaled approximately 1:50 in relation to a typical monopile foundation for an offshore wind turbine. In the four

cyclic tests more than 50 000 load cycles are applied to the pile. When evaluating the cyclic tests the accumulated rotation normalised with respect to the rotation obtained in the first loading cycles is used. The results reveal that the accumulation of rotation during long-term cyclic loading can be described by use of a power function. Further, the maximum moments obtained in the static tests conducted post cyclic loading indicates that the lateral capacity depends on the cyclic loading and increases with increasing load magnitude.

The entire test setup is still in the initial phase of testing and can be improved even more. Thus, the findings inhere must be evaluated further and supplemented with additional testing with varied loading characteristics, i.e. varied  $\zeta_b$  and  $\zeta_c$  for both one- and two-way loading.

#### 5 ACKNOWLEDGEMENTS

This research is associated with the EUDP programme “Monopile cost reduction and demonstration by joint applied research” funded by the Danish energy sector. The financial support is sincerely acknowledged.

# Pieu sous charge latérale : développement de lois de dégradation pour prendre en compte l'effet des cycles

Pile cyclic lateral loading: Development of degradation laws for describing the cyclic effect

Rosquoët F.

Laboratoire LTI (AE3899), Amiens, France

Thorel L., Garnier J., Chenaf N.

LUNAM Université, IFSTTAR, Nantes, France

**RÉSUMÉ :** A l'origine, le dimensionnement des pieux sous une charge latérale supposait que le sol est entièrement à l'état de rupture (calcul aux états limites). Les méthodes de calcul ont progressé et le dimensionnement est maintenant réalisé en déplacement mais sans possibilité de tenir compte de l'effet des cycles de chargement (sauf dans le cas des ouvrages offshore). Pour corriger cette lacune, nous proposons deux méthodes : une méthode globale basée sur le déplacement en tête de pieu et sur le moment maximum, et une méthode locale basée sur les courbes P-y. Pour la méthode globale, nous montrons que l'effet des cycles sur le déplacement est essentiellement lié au rapport entre l'amplitude de la charge cyclique et la charge maximale. Nous proposons une loi de type logarithme donnant le déplacement relatif en fonction du nombre de cycles. On notera que l'effet des cycles sur le moment maximum est faible. La méthode locale est basée sur l'interaction entre le sol et le pieu permettant de relier directement la réaction latérale du sol P et le déplacement du sol y. Nous introduisons un coefficient d'abattement qui permet de prendre en compte l'effet des cycles en modifiant la réaction des courbes P-y statiques.

**ABSTRACT:** Generally, the design of pile under lateral cyclic loads supposed that the soil is completely in the state of failure (limit states calculation). However, the calculation methods progressed and the design can be executed in displacement and at maximum bending moment. To analyse the cyclic effect we propose two methods: the global method is based on pile head displacement and maximum bending moments and local method is based on P-y curves. For the global method, we propose an empirical law to evaluate pile head displacements at application point. A simple power function of  $DF/F$  and a logarithm function of the number of cycles are proposed to calculate pile head displacements under cyclic loading from the displacement values under applied monotonic loads. We show that the effect of the cycles on the bending moments is weak. Local methods are based on the soil reaction profile, P and the pile lateral displacement, y called P-y curves. We propose a reduction coefficient then applied to the monotonic P-y curves to take the cyclic effect on the soil degradation into account.

## 1 INTRODUCTION

Le chargement latéral cyclique des pieux est généralement le résultat des sollicitations mécaniques engendrées par les vagues, le vent sur des structures offshore, l'amarrage de bateaux sur des quais, des surcharges variables ou des dilatations thermiques. Il est caractérisé par quatre paramètres qui sont la charge maximum appliquée F ; l'amplitude de la variation de la charge DF ; le nombre de cycles n et le type de chargement (non-alterné ou alterné).

L'utilisation des modèles réduits de pieux permet de réaliser des études paramétriques et ainsi améliorer notre compréhension de ces phénomènes à multiples variables. Une meilleure connaissance et quantification de la réponse des pieux sous charge latérale cyclique permettra d'optimiser leurs dimensionnement pour ce type de sollicitation mécanique.

La modélisation physique des structures géotechniques en centrifugeuse est une technique assez répandue (Garnier 2001) et a déjà été appliquée à l'étude de pieux sous charge latérale cyclique dans le sable (Rosquoët 2004, Rakotonindriana 2009) ou dans l'argile (Khemakhem 2012). La centrifugation des modèles réduits est indispensable pour assurer le respect des conditions de similitude qui imposent qu'un modèle à l'échelle 1/n soit testé sous une accélération centrifuge égale à n fois la gravité terrestre.

Un important programme de recherche est en cours en France sur les pieux sous charge cycliques (Projet national SOLCYP). Les travaux décrits ci-dessous s'intègrent dans ce programme et concernent les charges latérales cycliques. Le but final de ces études est de proposer une méthode rationnelle de

dimensionnement des pieux soumis à de telles sollicitations et d'évaluer l'influence du chargement latéral cyclique sur les éléments qui permettent de dimensionner le pieu, c'est-à-dire le déplacement horizontal en tête y, le moment maximum M ou encore les relations entre la réaction du sol P et le déplacement horizontal du pieu y, appelées « courbes P-y ».

L'étude se limite aux cas où les cycles dégradent la réaction du sol et aux charges cycliques de service. Le pieu modélisé peut être considéré comme un pieu souple. La partie du pieu située à une profondeur supérieure à 3 fois la longueur de transfert  $l_0$ , n'a théoriquement plus d'influence sur la réponse due à une charge en tête (Frank 1999). De fait, dans cette étude, on admettra que l'effet des cycles se manifeste essentiellement dans les couches de surface, à des profondeurs inférieures à 4 ou 5 fois le diamètre du pieu. A titre de comparaison, l'API (2002) fixe cette profondeur limite à  $z/B = 2,625$  pour des sables, soit 1,89 m dans notre cas.

## 2 DISPOSITIF ET MÉTHODE EXPÉRIMENTALE

Les essais ont été effectués dans des massifs secs homogènes de sable de Fontainebleau NE34 de poids volumique  $16 \text{ kN/m}^3$  (indice de densité  $I_D = 86 \%$ ) reconstitués par pluviation. Le pieu modèle au 1/40<sup>ème</sup> est mis en place à 1g par battage dans les massifs préalablement reconstitués. Ce pieu modèle est testé sous une accélération de 40 g. Il représente un pieu grandeur réelle de 0,72 m de diamètre, de 12 m de longueur de fiche ayant une rigidité à la flexion de  $476 \text{ MN.m}^2$  (Figure 1). Il est instrumenté par 20 paires de jauges de déformation collées sur

deux génératrices diamétralement opposées permettant de déterminer à tout moment le profil des moments fléchissants.

Figure 1. Pieu modèle instrumenté de 18mm de diamètre.

Un servo-vérin horizontal placé sur un bâti rigide fixé sur le conteneur d'essai permet d'appliquer le chargement à 40 mm au-dessus du sol. Deux capteurs de déplacement (d'une course de 100 mm) fixés par l'intermédiaire d'une rotule à 20 mm et de 65 mm au dessus du sol permettent de connaître le déplacement au point d'application de la charge (Figure 2). L'effort est mesuré à l'aide d'un capteur de force, d'une capacité maximale de 500 daN. Pour le chargement unidirectionnel non alterné (traction uniquement), un câble assure la liaison entre le capteur et le pieu modèle.

Figure 2. Détail du dispositif de chargement avec les capteurs de déplacement.

Dans le cas d'un chargement cyclique de type non alterné, l'effort est toujours appliqué dans le même sens, la charge variant entre  $F$  et  $F - DF$ .

### 3 MÉTHODE GLOBALE

#### 3.1 Déplacement en tête

L'effet des cycles sur l'évolution du déplacement en tête au point d'application de la charge (figure 3) est fortement dépendant de l'amplitude des cycles ( $DF$ ) et du chargement maximal ( $F$ ).

Figure 3. Evolution des déplacements relatifs sous la charge maximale ( $F = 960$  kN) en fonction du nombre de cycles pour différentes amplitudes  $DF$ .

Comme déjà observé par d'autres auteurs, une loi logarithmique représente très correctement la relation entre le déplacement relatif et le nombre de cycles (Eq. 1) :

$$\frac{y}{y_1} = 1 + b \ln(n) \tag{1}$$

où  $y_n$  est le déplacement au cycle  $n$ ,  $y_1$  le déplacement à la fin du chargement statique,  $b$  un coefficient positif adimensionnel et  $n$  le nombre de cycles (Figure 3).

L'interpolation des courbes est réalisée par la méthode des moindres carrés. Pour tous les cas étudiés, les valeurs expérimentales sont proches de la loi logarithmique choisie (coefficient de corrélation  $R^2 = 0,98$ ). Le coefficient «  $b$  » dépend de l'amplitude des cycles. Lorsque l'amplitude des cycles  $DF$  tend vers 0, nous sommes dans le cas d'un essai de fluage puisque la charge est constante et égale à  $F$ . Nous avons observé que le déplacement induit par le fluage peut être négligé, par conséquent, le coefficient «  $b$  », est dans ce cas proche de 0.

L'évolution du déplacement relatif en fonction du nombre de cycles, pour chaque essai réalisé, peut être caractérisée par ce coefficient «  $b$  ». On note  $\sigma_b$  l'incertitude liée à la mesure de ce déplacement. En supposant que les incertitudes sur le déplacement relatif soient toutes de même amplitude nous pouvons calculer les incertitudes sur la constante «  $b$  » de la fonction logarithmique (Rosquoët 2004).

Tableau 1. Estimation de  $b$  et de l'incertitude  $\sigma_b$  associée.

Essai	Nombre de cycles	$F$ (kN)	$DF$ (kN)	$b$ (.)	$\sigma_b$ (.)
P33	14	960	960	0,082	0,019
P344	14	960	960	0,081	0,017
P36	18	960	720	0,078	0,017
P347	40	960	720	0,075	0,01
P32	15	960	480	0,071	0,021
P318	25	960	240	0,044	0,017
P346	40	960	240	0,049	0,01

Il apparaît (Tableau 1), que le coefficient «  $b$  » est strictement croissant avec l'amplitude  $DF$ . Il est possible de représenter les variations de «  $b$  » par une fonction puissance. La figure 4 montre la courbe d'évolution du coefficient «  $b$  » en fonction du rapport entre l'amplitude et la charge maximale appliquée ( $DF/F$ ), permettant ainsi de rendre adimensionnelle l'amplitude des cycles.

Figure 4. Evolution du coefficient «  $b$  » en fonction de  $DF/F$ .

L'expression du coefficient «  $b$  » défini sur la figure 4 en fonction de  $DF/F$  permet de compléter l'équation (2) pour ainsi donner le déplacement en tête pour un cycle  $n$  donné.

$$\frac{y}{y_1} = 1 + 0,08 \times \ln(n) \times \left( \frac{DF}{F} \right)^{0,35} \tag{2}$$

Le tableau 2 présente les valeurs proposées dans la littérature pour le paramètre  $b$ , que l'on peut appeler paramètre de dégradation.

Tableau 2. Plages des valeurs de b proposées dans la littérature.

Auteurs	Sol	Pieux testés	Nombre de cycles	Paramètre de dégradation
Hettler (1981)	Sable sec	Rigides / 1g		0,2
Bouafia (1994)	Sable sec	Rigides Centrifugés	5	0,18 < b < 0,25
Lin et Liao (1999)	Divers sables	Pieux in situ	100	0,02 < b < 0,24
Verdure et al. (2003)	Sable sec dense	Flexibles Centrifugés	50	0,04 < b < 0,18
Rakotonindriana (2009)	Sable sec dense	Flexibles Centrifugés	500	0,12
Li et al. (2010)	Sable sec dense	Rigides Centrifugés	100 à 1000	0,17 < b < 0,25
Peralta (2010)	Sable sec	Flexibles 1-g	10000	0,21

Au regard des expressions de « b » proposées dans la littérature et des résultats des études réalisées par Rosquoët (2004) et Rakotonindriana (2009), nous retenons une valeur moyenne de b de 0,1. Finalement nous proposons pour l'expression de l'évolution du déplacement en tête en fonction du nombre de cycles et de l'amplitude (Eq. 3) :

$$\frac{y_n}{y_1} = 1 + 0,1 \times \ln(n) \times \left( \frac{DF}{F} \right)^{0,35} \quad (3)$$

### 3.2 Moment maximum

Le moment maximum est l'un des paramètres dimensionnant et il est important d'examiner son évolution lors de chargements cycliques (Figure 5).

Figure 5. Evolution des moments maximums relatifs en fonction du nombre de cycles pour différents rapports DF/F.

Comme pour les déplacements relatifs, il est possible d'interpoler l'évolution du moment maximum relatif en fonction du nombre de cycles par une fonction de type logarithmique (Eq. 4) :

$$\frac{M_n}{M_1} = 1 + a \ln(n) \quad (4)$$

L'effet des cycles sur le moment maximum s'avère faible, inférieur à 8 % pour 15 cycles (Rosquoët, 2004) et à 12 % pour 75000 cycles (Rakotonindriana, 2009). De plus, nous avons montré que les valeurs du coefficient représentant l'effet des cycles sur le moment maximum sont du même ordre de grandeur que l'incertitude sur ce coefficient (tableau 3). Par conséquent, dans le cas d'un sable sec et dense, nous proposons à ce stade d'appliquer une majoration forfaitaire de 10% au moment maximum observé sous la charge statique F (solution conservative).

 Tableau 3 : Estimation de a et de l'incertitude  $\sigma_a$  associée (F = 960 kN,  $I_D = 86\%$ ).

Essai	Nombre de cycles	DF/F (.)	a (.)	$\sigma_a$ (.)
P33	14	1	0	/
P344	14	1	0	/
P36	18	0,75	0,0047	0,0038
P347	40	0,75	0,0069	0,0052
P32	15	0,5	0,019	0,017
P318	25	0,25	0,026	0,014
P346	40	0,25	0,025	0,006

## 4 MÉTHODE LOCALE

Comme déjà proposé par plusieurs auteurs et adopté dans les règles API, nous admettons qu'il est possible de modéliser l'effet des cycles, sur les courbes P-y, par une diminution de la réaction P (pour un déplacement y donné) dans les couches de surface. Cette approche présente l'avantage de pouvoir être mise en œuvre avec tout logiciel de calcul de pieu sous charge latérale statique. Pour quantifier l'influence des cycles sur la « dégradation » du sol nous introduisons un coefficient d'abattement  $r_c$  qui dépend a priori de cinq paramètres : la profondeur z, le déplacement du pieu y, le nombre de cycles n, la charge appliquée F et l'amplitude des cycles DF.

### 4.1 Méthode itérative pour déterminer un coefficient d'abattement $r_c$

Le coefficient d'abattement  $r_c$  des courbes P-y statiques va être déterminé à l'aide d'un calcul itératif par calage progressif entre les données expérimentales (état du pieu au 15<sup>ème</sup> cycle) et les données calculées par le logiciel Pilate (courbe P-y statique abattues d'un coefficient r).

Figure 6. Evolution du déplacement en fonction de la profondeur.

Pour une profondeur comprise entre 0 et 3,6 m, si l'on note  $\delta$  le déplacement du pieu au niveau de la couche comprise entre 2,4 et 3,6 m, on constate que le déplacement est proche de  $2\delta$  entre 1,2 et 2,4 m et  $4\delta$  entre 0 et 1,2 m (Figure 6).

Figure 7. Evolution du déplacement en fonction de la profondeur.

Dans un premier temps, les coefficients d'abattement  $r_c$  sont déterminés par calage sur les données expérimentales obtenues sur le déplacement de la tête du pieu en fonction du nombre de cycles. Pour représenter l'effet des cycles, les courbes P-y

statiques de surface (jusqu'à 3,6 m) sont affectées d'un facteur  $r_c$  sur la réaction  $P$  inférieur à 1 et croissant avec la profondeur.

Compte tenu du constat tiré de la figure 6, on impose que le coefficient  $r$  soit égal à  $1 - 4\Delta$  entre 0 et 1,2 m ;  $1 - 2\Delta$  entre 1,2 et 2,4 m et  $1 - \Delta$  entre 2,4 et 3,6 m (avec  $\Delta$  un coefficient strictement positif tel que  $1 - \Delta$  soit inférieur ou égal à 1). Par itération, nous recherchons la valeur de  $\Delta$  qui conduit au rapport correct entre le déplacement au 15<sup>ème</sup> cycle  $y_{15}$  et le déplacement du pieu sous la charge maximum  $y_1$  (Figure 7).

La même procédure a été utilisée pour les autres cas, de charge maximum de 960 kN, d'amplitude des cycles variant entre 960 et 240 kN. Il est possible d'exprimer le coefficient  $r$  en fonction du rapport d'amplitude de la variation de la charge sur la charge  $DF / F$ , pour les couches de surfaces entre 0 et 5B (Figure 8).

Figure 8. Evolution du coefficient  $r_c$  en fonction de  $DF / F$  (pour 15 cycles).

L'extrapolation des courbes de la figure 8 permet de déterminer des expressions simples du coefficient  $r_c$  en fonction du rapport  $DF / F$  pour les trois couches de surfaces (Tableau 4).

Tableau 4 : Extrapolation par des droites de l'évolution du coefficient  $r_c$  en fonction de  $DF / F$  (pour 15 cycles).

Profondeur $z$	Expression de $r_c$ en fonction de $DF / F$
$0 < z < 1,5B$	$r = 0,87 - 0,12 \frac{DF}{F}$
$1,5B < z < 3B$	$r = 0,94 - 0,058 \frac{DF}{F}$
$3B < z < 5B$	$r = 0,97 - 0,029 \frac{DF}{F}$

## 5 COMPARAISON MÉTHODE GLOBALE / MÉTHODE LOCALE POUR LE DÉPLACEMENT EN TÊTE.

Un exemple de comparaison entre les deux méthodes est donné sur la figure 9 pour l'essai sur un pieu dans un sable dense ( $I_D = 86\%$ ) et des cycles caractérisés par  $F = 960$  kN et  $DF = 720$  kN.

Figure 9. Evolution du déplacement en fonction de la profondeur.

L'écart entre la méthode globale déduite de la relation présentée dans le tableau 4 et la courbe expérimentale est de 2% soit de l'ordre de grandeur de l'incertitude sur la mesure du

déplacement (l'incertitude sur le déplacement est de 0,104 mm, l'écart entre méthode locale et expérimentale est de 0,112 mm).

## 6 CONCLUSION

Une nouvelle analyse de l'étude paramétrique réalisée à l'IFSTTAR sur un pieu soumis à une charge latérale cyclique dans un sable sec et dense (Rosquoët 2004) et complétée par la suite (Rakotonindriana 2009, Khemakhem 2012) permet de proposer de nouvelles méthodes de dimensionnement des pieux sous chargement latéral cyclique. Une méthode globale, basée sur une loi logarithmique en fonction de  $DF/F$  permet de donner le déplacement en tête pour un nombre de cycles  $n$  donné. On notera que l'effet des cycles sur le moment maximum, dans le cas d'un sable sec et dense, est négligeable.

Une méthode locale basée sur l'abattement des courbes  $P-y$  statiques a été réalisée. Des calculs itératifs ont permis de valider la modélisation de l'effet des cycles sur le déplacement et sur les moments par une modification des courbes  $P-y$  d'un facteur  $r_c$  croissant entre 0 et 5B (soit entre 0 et 3,6 m). Des expressions simples ont été proposées permettant de déterminer ce facteur  $r_c$  à partir du rapport  $DF / F$ .

On note, pour finir une bonne concordance des résultats obtenus par les deux méthodes. Toutefois si la méthode globale est utilisable pour un très grand nombre de cycles ( $> 500$ ), la méthode locale n'est valide que pour une quinzaine de cycles et pour des chargements cycliques non alternés.

# Behavior of marine silty sand subjected to long term cyclic loading

Comportement du sable limoneux marin soumis à une charge cyclique de longue durée

Safdar M., Kim J.M.

*Pusan National University, Busan, South Korea*

**ABSTRACT:** The foundations for offshore wind turbines are demanding due to the dynamic nature of the offshore loading. A greater understanding of the behavior of wind turbine foundation soil, will certainly lead to the stable construction of foundations which in turn, will make offshore wind farms a more feasible part of the solution to the global energy problem. This paper presents the results of cyclic direct simple shear test (CDSS) to explain the long term cyclic behavior of marine silty sand. Cyclic behavior of marine sand are based on the number of loading cycles, cyclic shear strain amplitude, relative density, and cyclic stress ratio. These results are modeled and can be applied to design offshore wind turbine foundations.

**RÉSUMÉ :** Les fondations pour les éoliennes offshore sont principalement exigeante en raison de la nature dynamique du chargement offshore. Une meilleure compréhension du comportement de l'éolienne des sols de fondation, va certainement conduire à la construction des fondations stables qui à leur tour, feront de parcs éoliens en mer un rôle plus possible de la solution au problème mondial de l'énergie. Ce document présente les résultats d'essai de cisaillement cyclique directe simple (CDSS) pour expliquer le comportement cyclique à long terme de sable limoneux marin. Comportement cyclique de sable marin sont basés sur le nombre de cycles de charge, cyclique d'amplitude de contrainte au cisaillement, la densité relative et du taux de contrainte cyclique. Ces résultats sont modélisés et peut être appliquée à la conception fondations d'éoliennes off-shore.

**KEYWORDS:** *Cyclic Loading, Offshore Wind Turbine, CDSS, Cyclic Stress Ratio*

## 1 INTRODUCTION

Understanding the behavior of offshore marine sand subjected to long term cyclic loading is very vital in solving several offshore geotechnical problems. Several researchers have studied behavior of clay and sand subjected to cyclic loading.

(Vucetic et al. 1988) studied the degradation of marine clays under cyclic loading. (D. Wijewickreme et al. 2005) studied the cyclic loading response of loose air-pluviated Fraser river sand. (K.H. Andersen 2009) investigated in detail, the bearing capacity of the soil under cyclic loading, and stated that the cyclic shear strength and the failure mode under cyclic loading depend on the stress path and the combination of average and cyclic shear stresses. Safdar et al., 2013, studied the cyclic behavior of marine silty sand subjected to symmetrical cyclic loading. Different approaches have been made as an attempt to include cyclic loading in the design procedure of offshore wind turbine foundation (Soren et al. 2012).

### 1.1 Stress controlled CDSS test

Constant volume direct simple shear (DSS) test is a reliable method for measuring undrained shear strength of undisturbed or compacted soil samples. The DSS test is most similar to the CU triaxial test in that samples are consolidated prior to shearing. The simple shear is the test condition that only normal and shear stress acting on top face of a specimen is defined, whereas the displacement constraints exist for the other boundaries: The bottom face of specimen is theoretically fixed, and the radial strain on specimen is zero.

The CDSS test procedure is based on that of a constant-volume direct simple shear testing of soils, which has been studied extensively for half a century and is described in the standard ASTM D6528-07. The sample is consolidated under a

normal load within a wire-reinforced membrane (in this study) or a stack of thin rings that provide lateral confinement.

Once consolidation is complete, a horizontal shear force is applied to one end of the sample. The sample height is continuously maintained during shear to ensure constant volume. Rather than measuring pore pressures, which would require complete saturation of the sample, the pore pressure response is inferred from the change in vertical stress which is monitored throughout the test (Baxter et al 2010). In this way changes in applied vertical stress ( $\Delta\sigma_v$ ), which are required to keep the sample height constant, are assumed to be equal to the excess pore water pressure ( $\Delta u$ ) that would develop if the test were truly undrained with pore pressure measurements (Finn, 1985, Dyvik et al. 1987).

Figure 1 Simple Shear Condition, (Dyvik et al 1987)

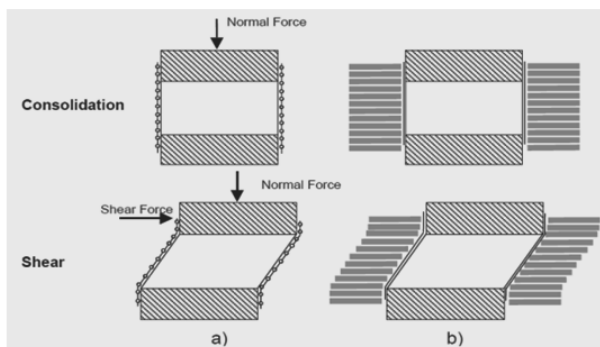

Figure 2 (a). Wire Reinforced Membrane (b). Stacked Rings (Baxter et al 2010)

The cyclic shear response of natural low-plastic Fraser River silt was investigated using constant-volume direct simple shear (DSS) testing (Wijewickreme 2010). Maria V. Sanin et al., (2011) studied the cyclic shear response of undisturbed and reconstituted Fraser River Silt. A soil can be subjected to many different stress conditions, being purely cyclic stress, static or average stress, or a combination of both. Andersen (2009) shows this clearly in a study on Drammen clays at the NGI. Drammen clays samples are tested in cyclic triaxial and cyclic simple shear conditions for different combinations of static and cyclic shear stresses. In this study cyclic simple shear tests have been performed with static or average shear stress,  $\alpha = 0$  or symmetrical cyclic loading.

### 1.2 Sample Preparation

Air Pluviation with dry compaction approach was developed to produce samples of the silty sand with consistent heights and initial relative densities. The equipment used consists of the shear box having bottom cap, two o-rings, wire-reinforced membrane, top cap, triaxial pressure panel, and compacting hammer. Sample diameter is 63.5mm and height is varied from 20 to 25 mm to maintain height to diameter ratio less than 0.4, in order to fulfill the ASTM D6528-07 criteria. In this study marine silty sand is obtained from the West coast of South Korea. Specific gravity of material tested is  $G_s = 2.65$ . Marine silty sand has minimum voids ratio of 0.74 and maximum voids ratio of 1.18. Details of properties of soil tested are given in Table 1.

Table 1 Properties of marine silty sand.

Properties of Soil Tested	
Min. Voids Ratio	0.74
Max. Voids Ratio	1.18
Coefficient of Uniformity	1.8 mm
$D_{10}$	0.08 mm
$D_{30}$	0.09 mm
$D_{60}$	0.14
USCS	Silty Sand (SM)
Specific Gravity ( $G_s$ )	2.652

Figure 3 Stress-path responses of NC Fraser River silt under constant volume cyclic DSS loading ( $\sigma'_v = 97$  kPa; CSR = 0.20;  $\alpha=0$ ; OCR = 1.0) (Maria V. Sanin et al., 2011).

Figure 5 Constant volume cyclic DSS test on undisturbed Fraser River Delta silt. ( $\sigma'_v = 100$  kPa, CSR = 0.14) (Maria V. Sanin et al., 2011).

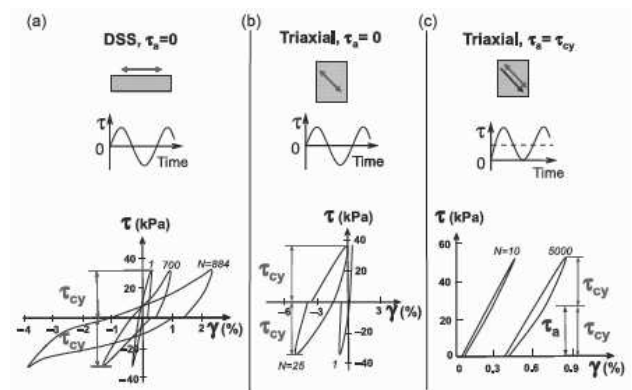

Figure 5 Stress-strain behavior under different loading conditions (Andersen, 2009)

### 1.3 Testing Program

The laboratory testing program for this study was designed to analyze the behavior of marine silty sand when subjected to cyclic loads for different combinations of parameters such as cyclic stress ratio, no. of loading cycles and relative density.

For marine silty sand, the tests were performed at a frequency of 0.1 Hz. Effect of Relative Density ( $D_r$  %) for 65, and 70 percent is studied for various CSR and no. of loading cycles. Marine silty sand has minimum voids ratio of 0.74 and maximum voids ratio of 1.18. Specific gravity of  $G_s=2.65$ .

To produce in-situ ( $K_0$ ) stress conditions, a vertical consolidation stress must be applied to the sample prior to shearing. Applied vertical stresses simulate the loads from overburden material located over the soil sample. For marine

silty sand, a normal consolidation stress of 100 kPa was applied in one step for all the specimens.

1.4 *Cyclic Direct Simple Shear test results*

Several researchers have used different shear strain failure criteria such as 3%, 4%, 5% and 7.5%. A shear strain failure condition was used for tests performed on marine silty sand and the failure criterion was established as 4% double amplitude shear strain. The results of a test are shown in Figure 6, 7 and 8. Figure 8 shows the applied cyclic shear stress of +/- 12 kPa (CSR = 0.12). Figure 6 shows the development of shear strain throughout the test, which reaches 4% double amplitude shear strain at nearly 205 cycles.

8 CDSS tests were conducted, 4 tests at voids ratio of 0.898 (Dr 65%) and CSR range of 0.10, 0.12, 0.14, and 0.16. 4 tests at voids ratio of 0.847 (Dr 70% and CSR range of 0.10, 0.12, 0.14, and 0.20. All the tests were conducted at nominal initial effective confining stress of 100 kPa to provide a basis for comparison between tests. In case of 70% relative density, Figure 6 shows the degradation curve and development of shear strain with increasing number of cycles. In a general sense, marine silty sand specimens seem to exhibit gradual increase in shear strain and degradation of shear stiffness with increasing number of load cycles. Typical stress paths and stress-strain curves of tests conducted on marine silty sand specimens are presented in Figures 7 and 8 respectively.

Figure 6 Peak-Peak Shear Strain vs No. of Loading cycles for ( $\sigma'_v = 100$  kPa, CSR=0.12 and Dr (%) = 70).

Figure 6 shows that samples having relative density of 70% reached 2% cyclic double amplitude cyclic shear strain after 42 cycles and 205 to reach failure.

Figure 7 Stress Path During constant volume cyclic DSS loading of silty sand for ( $\sigma'_v = 100$  kPa, CSR=0.12 and Dr (%) = 70).

Figure 8 Stress-strain response of marine silty sand under constant volume cyclic DSS loading ( $\sigma'_v = 100$  kPa; Dr (%) = 70, CSR = 0.12;  $\alpha = 0.0$ ; OCR = 1.0).

In case of 65% relative density, Figure 9 shows the degradation curve and development of shear strain with increasing number of cycles. Typical stress paths and stress-strain curves of tests conducted with 65% relative density on marine silty sand specimens are presented in Figures 10 and 11 respectively.

It was observed that specimens having higher relative densities require higher no. of loading cycles to reach 4% double amplitude cyclic shear strain and specimens having lower relative density reach to failure in smaller no. of loading cycles. In case of higher cyclic stress ratio (CSR) the soil samples reached the failure criterion in few no. of loading cycles.

Figure 9 Peak-Peak Shear Strain vs No. of Loading cycles for ( $\sigma'_v = 100$  kPa; Dr (%) = 65, CSR = 0.12;  $\alpha = 0.0$ ; OCR = 1.0).

Figure 9 shows that samples having relative density of 65% reached 2% cyclic double amplitude cyclic shear strain after 15 cycles and 57cycles to reach failure.

Figure 10 Stress Path During constant volume cyclic DSS loading of silty sand for ( $\sigma'_v = 100$  kPa; Dr (%) = 65, CSR = 0.12;  $\alpha = 0.0$ ; OCR = 1.0).

Figure 11 Stress-strain response of marine silty sand under constant volume cyclic DSS loading ( $\sigma'_v = 100$  kPa;  $Dr$  (%)= 65,  $CSR = 0.12$ ;  $\alpha = 0.0$ ;  $OCR = 1.0$ ).

Figure 12 CSR versus No. of Loading cycles to reach double amplitude shear strain of 4% for marine silty sand

Figure 12 shows the number of loading cycles versus cyclic stress ratio that reach shear strain of 4%. As expected, samples having higher value of cyclic stress ratio and/or low relative density fail at a small number of loading cycles. It is found in this particular study that the number of loading cycles required to reach the threshold strain is not much different for two relative densities after 300 loading cycles. The trends are little different from the previous study reported (Fig. 13) in which the curves are almost parallel even in high number of cycles.

Figure 13 Effect of stress densification on cyclic resistance of loose air-pluviated sand (Wijewickreme et al., 2005)

Samples having 70% relative density and subjected to CSR of 0.12 reached cyclic double amplitude of 4% shear strain at nearly 205 cycles. In case of samples having 65% relative density and subjected to CSR of 0.12 reached cyclic double amplitude of 4% at nearly 57 cycles.

## 2 SUMMARY AND CONCLUSIONS

The constant volume cyclic shear response of marine silty sand was examined using data from CDSS tests. The intent was to compare the shear response of the silty sand specimens under different relative densities. samples having higher value of cyclic stress ratio and/or low relative density fail at a small number of loading cycles. It is found in this particular study that the number of loading cycles required to reach the threshold strain is not much different for two relative densities after 300 loading cycles. The trends are little different from the previous study reported in which the curves are almost parallel even in high number of cycles.

**RÉSUMÉ:** Cet article présente un nouveau diagramme de stabilité cyclique pour le frottement latéral ainsi que l'effet sur la capacité en traction des pieux modèle instrumentés soumis à des chargements cycliques axiaux suite à une large série d'essais en chambre d'étalonnage dans du sable siliceux. Les mesures locales des contraintes dans le sol (verticales, radiales et orthoradiales) à différentes distances de l'axe du pieu, ainsi que les mesures tangentielles et radiales à l'interface sol-pieu, permettent une analyse détaillée de l'évolution des chemins de contraintes locaux autour du pieu et au sein du massif lors des chargements cycliques et post-cycliques.

**ABSTRACT:** This paper presents a new cyclic stability diagram for the lateral friction and the effect on the tensile capacity of instrumented model piles subjected to axial cyclic loading across a wide range of calibration chamber testing in silica sand. Local measurements of stresses in the soil mass (vertical, radial and orthoradial) at different distances from the axis of the pile, as well as shear and radial stresses at the soil-pile interface, provide a detailed analysis of the evolution of local stress paths around the pile and the soil mass during cyclic and post-cyclic loading.

**MOTS-CLÉS:** Chambre d'étalonnage, chargement cyclique axial, interaction sol-pieu, diagramme de stabilité cyclique.

## 1 INTRODUCTION

Des fondations sur pieux de plateformes de pétrole/gaz et des turbines éolienne/marémotrice peuvent être soumises à des chargements cycliques de très longue durée en raison des conditions environnementales. Les longs pieux battus, installés par des cycles de charge-décharge, subissent une dégradation sévère du frottement lors de leur installation (Lehane et al. 1993, Kolk et al. 2005). Celle-ci peut être compensée par un phénomène de « cicatrisation » avec le temps (« ageing »), observé dans des expériences in-situ (Chow et al 1998, Jardine et al. 2006). Selon leur finalité (fondation d'ouvrages offshore ou d'éoliennes), ces pieux sont ensuite souvent soumis à des sollicitations cycliques de service (houle, vibrations) qui affectent également leur frottement. La réponse cyclique de l'interface sol-pieu a été étudiée en laboratoire à l'aide de pieux modèle dans des chambres d'étalonnage pressurisées (Chan & Hanna 1980, Al-Douri & Poulos 1994, Chin and Poulos 1996, Le Kouby et al. 2004). Ces essais ont montré que la contrainte de cisaillement décroît d'autant plus que l'amplitude des déplacements tangentiels augmente. Jardine et al. (2006) ont montré à partir des essais in-situ réalisés à Dunkerque (Chow et al. 1998) qu'alors que des cycles de grande amplitude dégradent la capacité du pieu en frottement, des cycles non alternés de faible amplitude accélèrent les effets bénéfiques du phénomène de « cicatrisation » (augmentation de la capacité avec le temps). Le Kouby et al. (2004) donnent des résultats similaires sur un pieu modèle de 20 mm de diamètre.

L'étude présentée ici a pour but de donner une meilleure compréhension, à une échelle de laboratoire et dans un environnement contrôlé, des résultats obtenus sur des pieux réels à Dunkerque par Jardine & Standing (2000), en mesurant, grâce à une instrumentation exceptionnelle de la chambre d'étalonnage et du pieu, les chemins de contraintes locaux, le long du pieu et au sein du massif lors des différentes phases d'installation, de repos et de chargement statique et cyclique du pieu. Ce travail fait partie d'un programme de recherche

commun entre le laboratoire 3SR et Imperial College London, ainsi que du projet National SOLCYP.

## 2 DISPOSITIF EXPÉRIMENTAL

### 2.1 La chambre d'étalonnage

La grande chambre d'étalonnage du Laboratoire 3S-R a été adaptée de façon à maîtriser les conditions environnementales (température, pression, alimentation électrique) sur des périodes de longue durée (plusieurs mois), afin de pouvoir mesurer les phénomènes de « cicatrisation » du frottement après cyclage et après une longue période de repos. Une isolation complète de la cuve ainsi qu'un système de chauffage/refroidissement des parois ont été réalisés de façon à minimiser les variations de température dans la cuve. La pressurisation des membranes a été conçue pour fonctionner en cas de panne du réseau.

La chambre d'étalonnage de Grenoble est composée de trois éléments cylindriques de 50 cm de hauteur et d'un diamètre interne de 1.2 m. Le fond de la chambre et le couvercle supérieur sont constitués de plaques rigides d'une épaisseur de 100 mm. Une pression verticale d'environ 150 kPa est imposée par une membrane en caoutchouc remplie d'eau, qui est fixée sous le couvercle supérieur et contrôlée par un système d'interface eau/air. Une membrane en latex de 2 mm d'épaisseur a été installée sur la paroi interne de la chambre afin de mieux fournir des conditions  $K_0$  au bord de la cuve. Une couche de graisse de silicone entre cette membrane et la paroi de la chambre permet de réduire le frottement entre le mur et la masse de sable et d'assurer une meilleure homogénéité des contraintes à l'intérieur du sol.

Un système d'isolation thermique formé de serpentins en cuivre autour de la cuve permet de travailler avec une température presque uniforme entre 18 et 19 degrés.

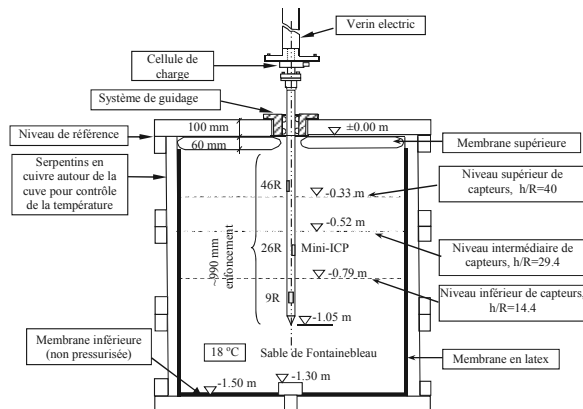

Figure 1: Modifications apportées à la chambre d'étalonnage du laboratoire 3S-R.

Pour les essais présentés ici, la chambre d'étalonnage a été remplie avec du sable siliceux de Fontainebleau NE34 commercialisé par l'entreprise Sibelco. En utilisant une technique de remplissage par pluviage, nous obtenons une densité du massif moyennement dense à dense,  $D_r=72\%$ . Le tableau 1 montre les propriétés mécaniques du sable.

Tableau 1: Propriétés mécaniques du sable NE34

$G_s$	$D_{10}$ (mm)	$D_{50}$ (mm)	$D_{60}$ (mm)	$e_{max}$	$e_{min}$	$\gamma_{max}$ ( $kN/m^3$ )	$\gamma_{min}$ ( $kN/m^3$ )
2.65	0.150	0.210	0.230	0.90	0.51	17.2	14.2

Plusieurs essais pénétrométriques ont été effectués sur des échantillons de sable NE34 sous 150 kPa avec une résistance en pointe quasi-constante de  $21 \pm 2$  MPa. Des détails supplémentaires sur les propriétés mécaniques du sable sont décrits dans Yang et al. (2010).

## 2.2 Le pieu d'essai Mini-ICP

Le pieu utilisé correspond au pieu modèle Mini-ICP développé par l'Imperial College London et décrit par Jardine et al. 2009. C'est un pieu tubulaire en acier à base fermée de 36mm de diamètre avec un cône solide de  $60^\circ$  à sa pointe. Il est composé de trois niveaux d'instrumentation (ou clusters) identifiés selon leur distance à la pointe en: A (9R), B (24) et C(44), R étant le diamètre du pieu. Chacun de ces clusters contient une cellule de charge axiale, qui peut être utilisée pour calculer la moyenne de frottement dans le fût du pieu; un capteur de contraintes en surface (SST: surface stress transducer) pour mesurer la contrainte totale radiale et la contrainte de cisaillement; un capteur de température MEMS et un inclinomètre. À partir de l'essai ICP03, une cellule de charge axiale a été ajoutée près de la pointe du pieu pour mieux séparer les contributions de la pointe et du frottement latéral dans la capacité totale du pieu.

Le pieu a été installé jusqu'à une profondeur finale de 0.98m par fonçage avec des cycles de charge-décharge en simulant la dégradation des efforts radiaux comme dans une installation par battage. La vitesse de pénétration varie entre 0.5 et 2 mm/s et l'amplitude des cycles d'enfoncement successifs est de 5, 10 ou 20 mm. La décharge de chaque cycle a été menée jusqu'à obtenir une charge en tête du pieu nulle.

## 2.3 Mesure des contraintes dans le massif

36 mini-capteurs Kyowa et TML de capacités variant de 500 kPa à 7 MPa selon leur distance au pieu, ont été mis en place sur trois niveaux comportant chacun douze capteurs, de façon à mesurer les contraintes verticales, radiales et orthoradiales sur des rayons concentriques à des distances de 2R à 16R. Leur étalonnage sous chargement cyclique a été effectué à Imperial College en suivant le protocole établi par Zhu et al 2009. La réponse de chaque capteur est représentée par une série de courbes d'hystérésis selon l'histoire de charge précédente.

## 3 PROGRAMME EXPÉRIMENTAL

Après une certaine période de cicatrisation post-installation, un premier essai en compression et un essai en traction ont été effectués pour définir la capacité du pieu avant les chargements cycliques. Plusieurs séries d'essais de faible et de haut niveau de chargement cyclique ont ensuite été effectuées, ainsi que des essais de traction pour évaluer l'effet des charges dans la réponse du pieu à l'arrachement.

Les essais cycliques ont été caractérisés selon deux paramètres de charge;  $Q_{cyclic}$  et  $Q_{mean}$  correspondant respectivement à la moitié de l'amplitude de chaque cycle et à la valeur moyenne de charge. Les essais de faible niveau en charge ont été effectués sous chargement contrôlé (FC), uniquement en traction (non alterné). Ces essais ont mobilisé jusqu'à 60% de la capacité totale du pieu en tension,  $Q_t$ . Les cycles de charge de haut niveau alternés (compression et traction) ont été conduits en déplacement contrôlé (DC). Les cycles ont été appliqués à une fréquence relativement basse, allant de moins de 0,5 cycles par minute pour les essais alternés, à presque 2,5 cycles par minute pour les essais de faible charge.

Des essais de traction statique post-cyclique ont été réalisés, avec un taux de déplacement de 0,01 mm/s, afin de vérifier les capacités à l'arrachement disponibles après chaque chargement cyclique. Comme indiqué par Jardine et al (2006), les essais préalables peuvent influencer sur les capacités développées lors des essais ultérieurs. Le tableau 2 résume les différentes séries d'essais cycliques réalisées.

Tableau 2: Programme d'essais de chargement cyclique

ID	N of cycles	Description	$Q_{cyclic} / Q_T$	$Q_{mean} / Q_T$

## 4 RÉSULTATS DES ESSAIS CYCLIQUES NON ALTERNÉS À FAIBLE AMPLITUDE

### 4.1 Evolution des contraintes le long du pieu et au sein du massif

Les mesures de contrainte effectuées au sein du massif et le long du pieu permettent de préciser les mécanismes conduisant à l'amélioration ou à la dégradation du frottement. La Figure 2 montre l'évolution des contraintes radiales dans le sol à différentes distances du pieu. On constate une décroissance de ces contraintes radiales avec le nombre de cycles, plus accentuée lors de cycles alternés. La même situation est vérifiée avec les contraintes radiales le long du pieu, accentuée lors des grands cycles mais avec des amplitudes plus grandes. On remarque également dans la Figure 2, que le chargement statique effectué entre les deux séries de cycles entraîne une nette augmentation des contraintes près du pieu après les petits cycles (effet de la dilatance).

La distribution des contraintes dans le massif du sol à différentes distances de l'axe du pieu a été interprétée par Jardine et al. 2012 en utilisant l'information des capteurs.

Figure 2: Evolution des contraintes radiales dans le sol : De 0 à 9,6h : 1000 cycles non alternés de faible amplitude (ICP1-OW1) ; de 10,4 à 14,7h : 100 cycles alternés de grande amplitude (ICP01-OW1).

La mesure simultanée des contraintes radiales et tangentielles permet de tracer les chemins de contraintes suivis par le sol au contact du pieu. Les petits cycles non alternés, tels que ceux représentés sur la Figure 3 pour les trois niveaux le long du pieu, provoquent un déplacement des chemins de contraintes vers la gauche, traduisant une tendance à la contractance de l'interface et donc sa densification. C'est cette densification qui produit ensuite une augmentation de la dilatance et l'amélioration de la capacité. Lorsque l'amplitude de ces cycles non alternés augmente, les cycles s'approchent de la droite de rupture en traction (Yang et al 2010).

Figure 3: Chemins de contraintes à la surface du pieu. Essai Mini-ICP2. Cycles non alternés de faible amplitude.

A l'inverse, les chemins de contraintes des grands cycles alternés traversent l'équivalent d'une « ligne de changement de phase » et produisent des alternances de dilatance/contractance et une désorganisation du sol autour de l'interface. On peut remarquer qu'on retrouve pour ces chemins de contraintes la forme en « ailes de papillon » qu'on observe lors d'essais de cisaillement cyclique à volume constant ou à rigidité normale contrôlée (Fakharian & Evgin 1997, Mortara et al. 2007).

Figure 4: Chemins de contraintes à la surface du pieu. Essai Mini-ICP4. Cycles alternés de forte amplitude.

#### 4.2 Capacité du pieu à l'arrachement avant et après chargement

Le tableau 3 montre les essais statiques effectués après chaque essai cyclique pour évaluer l'effet de ceux-ci sur la capacité à l'arrachement.

Tableau 3: Programme d'essais de chargement cyclique

Essai	Essai précédent (selon Tableau II)	$Q_r$ (kN)	Variation entre essais (%)
ICP1-T1	1ère compression	9,2	-
ICP1-T2	ICP1-OW1	10,8	17,4%
ICP1-T3	ICP1-TW1	4,9	-54,6%
ICP2-T1	1ère compression	12,1	-
ICP2-T2	ICP2-OW1	13,2	9,1%
ICP2-T3	ICP2-OW2	14	6,1%
ICP2-T4	ICP2-OW3	13,7	-2,1%
ICP2-T5	ICP2-TW1	8,7	-36,5%
ICP3-T1	1ère compression	12,5	-
ICP3-T2	ICP3-OW1	10,9	-12,8%
ICP3-T3	ICP3-TW1,2,3,4	4,8	-56,0%
ICP4-T1	1ère compression	11,5	-
ICP4-T2	ICP4-OW1	13,9	20,9%
ICP4-T3	ICP4-TW1	5,5	-60,4%
ICP4-T4	ICP4-OW2	6	9,1%

Comme indiqué, selon l'amplitude de la charge cyclique, il est possible d'obtenir une augmentation de la résistance, ce que proposent Jardine et al (2006) dans des essais sur le terrain.

Figure 5: Courbes force d'arrachement-déplacement du pieu avant et après application des cycles Essai ICP2.

Les essais d'arrachement avant et après l'application de cycles, présentés dans la Figure 5 pour les essais Mini-ICP2, montrent clairement que l'application des cycles non alternés de

faible amplitude améliore la capacité du pieu en raison de la densification de l'interface, alors que les cycles de grande amplitude avec passage de la traction à la compression produisent une nette dégradation de cette capacité due à la désorganisation de l'interface.

#### 4.3 Diagramme de stabilité cyclique

Une première partie des résultats concernant les essais de chargement cyclique a été résumée par Tsuha (2012). On a analysé l'évolution du frottement latéral du pieu et sa stabilité selon le nombre et le type de cycles appliqués (réversibles ou non réversibles), l'amplitude et la valeur moyenne de la charge. La Figure 6 montre le diagramme de stabilité cyclique établi à partir de la totalité des essais réalisés. Trois zones ont été identifiées pour le comportement du pieu.

- Stable, correspondant à une zone de faible amplitude au niveau de la charge et où le pieu peut être soumis à plus de 1000 cycles sans accumuler une déformation importante.
- Métastable, correspondant à une déformation importante ou une rupture entre 100 et 1000 cycles.
- Instable, correspondant à une rupture obtenue en moins de 100 cycles.

La rupture cyclique a été définie comme ; i) un déplacement permanent atteignant 10% du diamètre (i.e. 3.6 mm), ou ii) un taux de déplacement montrant une augmentation forte, en considérant comme « lent » un taux inférieur à 1 mm/10<sup>4</sup> cycle, et « rapide » un taux supérieur à 1 mm/100 cycle.

Figure 6: Diagramme de stabilité cyclique essais ICP1-4 (d'après Tsuha et al., 2012)

## 5 CONCLUSION

La mesure des chemins de contraintes le long de pieux instrumentés avec précision, ainsi que ceux au sein du massif de sol au voisinage du pieu, permet de mieux appréhender les mécanismes gouvernant la dégradation ou l'amélioration du frottement lors de sollicitations cycliques. Elle permet en particulier de faire le lien entre les états « stable », « métastable » et « instable » dans les diagrammes classiques de stabilité cycliques et le comportement élémentaire des interfaces par rapport à leur « ligne de transformation de phase » ou « droite caractéristique ».

L'ensemble des essais effectués jusqu'à présent montre que l'application d'un grand nombre de petits cycles non alternés produit une densification de l'interface sol-pieu, favorisant le développement d'une dilatance lors d'un chargement ultérieur et donc une amélioration de la capacité du pieu à l'arrachement.

A l'inverse les grands cycles alternés produisent une désorganisation de l'interface et une diminution de la dilatance

lors d'un chargement ultérieur et une dégradation de la capacité à l'arrachement. Ce phénomène est analogue à celui conduisant à une dégradation du frottement le long des pieux battus lors de leur installation.

**ABSTRACT:** Wind energy is a major source of renewable energy and is projected to capture 11% of the energy generation capacity for Ontario by 2018. A number of problems that the energy industry currently faces stem from a lack of understanding of cyclic loading of Ontario soils and a paucity of regional regulatory guidance for site investigation and design methods for wind turbine foundations. A multi-disciplinary research project is underway to integrate laboratory testing, field monitoring and numerical modeling of a commercial wind turbine on a shallow foundation. This paper describes an initial part of the study to characterize the geotechnical properties of the clayey silt till soils on the site. Emphasis has been placed on comparison of different *in situ* and laboratory methods, and correlations for determining key geotechnical parameters for wind turbine foundation design.

**RÉSUMÉ :** L'énergie éolienne est une source importante d'énergie renouvelable et doit permettre de satisfaire 11 % de la capacité de production d'énergie de l'Ontario d'ici 2018. Un certain nombre de problèmes auxquels l'industrie de l'énergie est actuellement confrontée provient d'un manque de connaissances des sols de l'Ontario sous charges cycliques et de directives réglementaires régionales pour les méthodes d'investigation et de conception des fondations d'éoliennes. Un projet de recherche multidisciplinaire est en cours pour intégrer les tests en laboratoire, l'instrumentation et la modélisation numérique d'une éolienne commerciale sur fondation superficielle. Cet article décrit la partie initiale de l'étude pour caractériser les propriétés géotechniques du silt argileux glaciaire du site. L'accent a été mis sur la comparaison de différentes méthodes *in situ* et en laboratoire ainsi que les corrélations pour déterminer les paramètres géotechniques clés pour la conception de fondation d'éoliennes.

**KEYWORDS:** wind turbine, clay, till, shallow foundation, soil-structure interaction, elastic, anisotropy, *in situ*, geophysical.

## 1 INTRODUCTION

### 1.1 Wind energy and turbine design in Canada

Wind is a major source of renewable energy and is projected to capture 11% of the energy generation capacity for Ontario by 2018 (CANWEA, 2011). However, to achieve this expansion some major technical and policy issues must be addressed by the Canadian wind sector. Some of these issues are associated with the construction and design of foundations for wind turbines. Foundations for onshore wind turbines usually consist of large gravity bases and monopiles (e.g. DNV/Risø, 2002). The geometry and foundation type depends on the wind climate, power regulation philosophy, physical characteristics of the machine, uplift criteria, required foundation stiffness and geotechnical characteristics of the site (Bonnett, 2005). The critical analyses for design include bearing capacity and overturning resistance, horizontal and rotational displacements, and dynamic soil-structure interaction (Harte et al., 2012).

Although there has been much recent research associated with foundations for offshore wind turbines (e.g. Byrne and Houlsby, 2003), the literature on onshore systems is still relatively sparse. Consequently, despite similar issues for wind turbine foundations across the industry, there is often diverse interpretation of design codes and understanding of the behavior of foundations (Morgan and Ntambakwa, 2008). This can lead to quite different foundation designs on different wind farms with the same turbines and comparable geotechnical profiles. This issue is exacerbated in Canada, since there is currently no regional regulatory guidance for site investigation and design methods for wind turbine foundations. Hence it is not surprising

that rather generic approaches have developed for site investigation and design, which are relatively crude and can lead to quite conservative designs. To capture more wind energy, the industry is continuing to develop larger turbines and is considering more marginal sites in terms of geotechnical characteristics, which will only complicate the current situation.

### 1.2 Project overview and objectives

A number of the above issues are being addressed as part of a multi-disciplinary research project that includes an integrated laboratory testing, field monitoring and numerical modeling program investigating the behaviour of a fully operational Canadian commercial wind turbine throughout its service life. The equipment installed on the turbine will enable an integrated, life cycle assessment of the wind turbine and its foundation. This paper describes the portion of the study that involves preliminary characterization of the geotechnical properties of the wind farm site. In particular, a comparison between the *in situ* testing, laboratory testing and commonly used correlations are presented. It is anticipated this process will guide future projects on clayey silt tills in Ontario and provide cost effective site investigation and design methods for turbine foundations.

## 2 SOIL PROFILES & MATERIAL CHARACTERISATION

### 2.1 Wind farm and geological environment

The wind farm is located in a simple geographical and environmental area in the Great Lakes region of Southern Ontario. The farm has horizontal axis 2.3 MW turbines with an

80 m hub height and triple bladed rotors with a 93 m diameter. The tower has a typical tapered tubular steel design and is founded on a 16 m diameter hexagonal reinforced concrete shallow foundation at 3.6 m depth. The site is underlain by carbonate-rich clayey silt tills that are a ubiquitous feature of the Great Lakes basins and is located at the confluence of four major geological deposits. These consist of the Port Stanley and Tavistock tills, glaciolacustrine sand and gravel, and glaciolacustrine clayey silt. These materials were laid down in the Port Bruce Stade (c. 14,800 years bp.) during the re-advance of the Laurentide Ice Sheet of the Late Wisconsin. These subglacial lodgement tills are calcareous and fine-grained, suggesting that the ice overrode and incorporated fine-grained glaciolacustrine sediments deposited during the previous Erie Interstade. This has created approximately 40-45 m thickness of clayey silt tills with interbedded glaciolacustrine sediments. The bedrock is shale with limestone-dolostone-shale interlayers.

## 2.2 Overview of site investigation

The site investigation was designed to establish detailed stratigraphic and geotechnical characteristics for the soils beneath the wind turbine foundation. Forty metre deep boreholes were drilled on the site to evaluate the soil profile, perform *in situ* tests and collect high-quality samples for laboratory testing. A track-mounted drill was used for the drilling activities. Three boreholes were drilled 10-16 m adjacent to the turbine foundation (to ensure minimal stress change from the foundation). The wash boring method was used for two of the holes and the PQ coring method for the other hole. The boreholes were drilled to depths of twice the foundation diameter and were spaced at 3 m to allow for later cross-hole geophysical testing. Thin-wall Shelby tube sampling was completed to obtain minimally disturbed samples for the laboratory testing. *In situ* testing adjacent/in to the boreholes consisted of SPT, field shear vane, cross-hole geophysics and seismic SCPTu, and was conducted to depths of 30 m. To complement the *in situ* test results, laboratory tests were conducted for soil classification and geotechnical properties.

## 2.3 Soil description and basic properties

This deposit can be separated into three zones: a heavily weathered oxidized upper crust from 0–1.5 m, a partially weathered lower crust that transitions from an oxidized to an unoxidized state from 1.5–4.5 m and an unweathered clay till below 4.5 m to greater than 40 m depth. The intensity of fissuring in the upper crust is very intense and the deposit becomes nearly unfissured below 4.5 m. The fissures are vertically dipping planar joints striking at right-angles. The fissure spacing at 1.5 m depth is 15 cm and this increases to 0.6-1.2 m at 4.5 m depth. The variation in moisture contents and the Atterberg limits with depth are shown in Figure 1.

The upper crust zone of this deposit is weathered, mottled brown-grey or brown-green with a stiff to very stiff consistency. This weathered zone generally has higher moisture contents (22-32%) due to the infiltration of surface water into the fissures of the clay. The underlying lower crust is prevalently brown in colour and has a very stiff consistency and relatively lower natural moisture content (16-20%). At several locations this layer has clayey silt, sandy clay and silt seams. A soil colour change occurs from brown to grey between 3 and 4 m below the ground surface. Below the crust, the unweathered till extends beyond the maximum depth of sampling. This zone is characterized by a uniform grey appearance, a stiff to very stiff consistency and relatively uniform moisture contents (16-24%).

Atterberg test results (Table 1) indicate that the material can be classified as CL-ML to CL (silty clay or low plasticity clay). There is an increase in liquid limit and plasticity towards the upper crust and the clay content is also found to increase near the surface, leading to little change in activity (0.5).

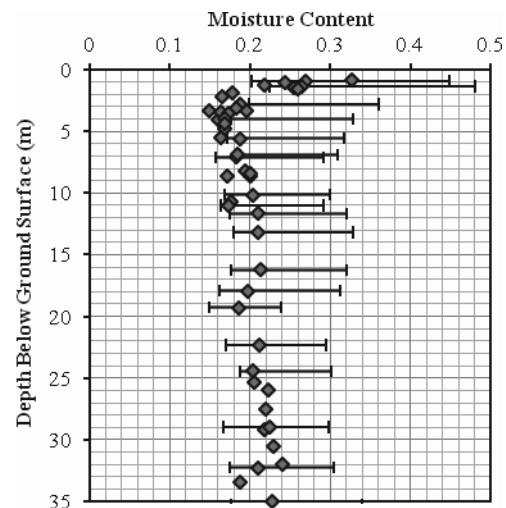

Figure 1. Moisture contents and Atterberg limits with depth.

The liquidity index ( $I_L$ ) is found to range from 0.2 to 0.4 in the virgin till, is below zero in the lower crust and ranges from 0.15 to 0.25 in the upper crust. The bulk unit weights of the profile are generally uniform and range from 20.3 to 21.6 kN/m<sup>3</sup>.

Table 1. Atterberg Limits and Particle Size Distributions.

Layer	Liquid Limit (%)	Plastic Limit (%)	Clay (%)	Silt (%)	Sand (%)
Upper Crust	46	21	40	45	15
Lower Crust	34	19	29	49	20
Unweathered Till	30	17	31	45	21

Semi-quantitative XRD shows that the unweathered till is predominantly composed of quartz/feldspar (39%), carbonate (25-35%), mica/illite (16%), chlorite/kaolinite (7%) and trace minerals. In the 2 micron range the minerals are dominated by illite, calcite and chlorite. The lower crust has a similar composition, with more quartz/feldspar (49%), lower carbonate (22%), mica/illite (18%), chlorite/kaolinite (7%) and swelling clay (2%) and other trace minerals. In similar deposits (Quigley and Obunbadejo, 1974) downwards leaching has removed carbonates from the near surface and redeposited lower in the crust. Table 2 shows the values of total carbonates, dolomite and calcite (from the gas evolution method) in the three zones, confirming the removal of carbonates from the near surface.

Table 2. Carbonate Contents in the Soil Profile.

Layer	Total Carbonates (%)	Dolomite (%)	Calcite (%)	C/D ratio
Upper Crust	0	0	0	-
Lower Crust	19.9	6.2	13.7	2.2
Unweathered Till	24.8	6.2	18.6	3.0

## 2.4 Compressibility and strength properties

In common with other tills around the world the compressibility, permeability and strength characteristics of this material are generally a function of the clay content. Estimates of undrained shear strength ( $s_u$ ) using various methods are

shown in Figure 2. All of the profiles show that the values of  $s_u$  are relatively constant with depth below 7 m and are in the range of 100-130 kPa. The lower crust material (2-4.5 m) increases in strength rapidly, in excess of 250 kPa and the upper crust material has a similar strength to the lower till. The usual hierarchy of strengths is seen for the different methods, due to the different modes of shearing. However, the field vane (FSV) shows higher values than the triaxial compression (CIU) test. This is likely due to partial drainage and problems rotating the vane slowly enough for an undrained state. Two estimates have also been determined from the CPT (Mayne, 2007):

$$s_u = (q_t - \sigma_{vo})/N_{kt} \quad (1)$$

$$s_u = \Delta u/B_q \cdot N_{kt} \quad (2)$$

where  $N_{kt}$  is a cone factor (taken as 15),  $\Delta u$  is the excess pore pressure and  $B_q$  is the ratio of excess pore pressure to the net cone resistance ( $q_t - \sigma_{vo}$ ). The approach based on excess pore pressures appears to give better estimates for the strengths, but the cone would be anticipated to provide lower values than CIU triaxial, since the shearing mode is a complex combination of triaxial compression/extension and plane strain. The depth of the foundation base and one base diameter (B) are also shown.

Figure 2. Undrained shear strength with depth.

From oedometer testing, average compression index ( $c_c$ ) for the three layers was found to be 0.072 and average recompression index ( $c_r$ ) was 0.008, giving a ratio of 0.12, which is in the usual range in the literature. The values of the two indices are quite low and are typical for sandy clays/silts, and the values from the crustal material are lower than those for the weathered till.

The pre-consolidation pressures ( $\sigma_{vp}'$ ) from oedometer tests have been estimated using the method of Boone (2011) and the corresponding overconsolidation ratio (OCR) is shown in Figure 3. This shows low OCRs in the weathered till, with a relatively small increase in the crustal material, up to an OCR of 4. Another estimate of OCR is shown using the relationship of Ladd et al. (1977), equation (3), with  $m = 0.8$  and the ratio of undrained shear strength (from CIU triaxial testing) to the *in situ* vertical effective stress [ $s_u/\sigma_{vo}'$ ] $_{nc} = 0.22$ :

$$\frac{[s_u/\sigma_{vo}']_{oc}}{[s_u/\sigma_{vo}']_{nc}} = OCR^m \quad (3)$$

This shows similar values of OCR at depths below 15 m, but much higher OCR values for shallower depths, up to an OCR of 15 at 4 m. Two further estimates of over-consolidation ratio have been made using the CPT data with expressions for the

preconsolidation pressure ( $\sigma_{vp}'$ ), after Mayne (2007):

$$\sigma_{vp}' = 0.33 \cdot (q_t - \sigma_{vo})^\mu \quad (4)$$

$$\sigma_{vp}' = 0.161 \cdot G_0^{0.478} \cdot \sigma_{vo}'^{0.42} \quad (5)$$

where  $G_0$  is the small-strain stiffness determined from the seismic cone data,  $\mu$  takes a value of 0.85 for silts and  $q_t$  is the cone tip pressure. These relationships show similar characteristics to the previous estimates, with the small-strain expression closely following the oedometer derived data and the CIU triaxial derived data following the CPT expression. Interestingly, the ratio of undrained shear strength to the *in situ* vertical effective stress in the upper crust [ $s_u/\sigma_{vo}'$ ] $_{oc}$  shows quite high values of 2.7-3.4, dropping to 0.3 at depth. This suggests values of  $K_0$  in excess of 1 and as high as 2.4 in the crust.

Figure 3. Overconsolidation ratio with depth.

## 2.5 Small-strain stiffness properties

Small-strain stiffness ( $G_0$ ) is presumed to be a function of the void ratio, stress history and ratio of horizontal (h) to vertical stresses (v). It is also thought to be related to the soil macro-fabric and can often display cross-anisotropic characteristics (where the vertical axis is an axis of radial symmetry). The characterization of cross-anisotropic elastic materials can be reduced to five independent elastic moduli ( $E_h$ ,  $E_v$ ,  $\nu_{vh}$ ,  $\nu_{hh}$  and  $G_{hh}$ ; Pennington et al., 1997). *In situ* and laboratory estimates of small-strain stiffness often use measurements of shear wave velocity ( $V_s$ ) travelling and polarized in different directions to determine shear modulus. Hence various methods of determining *in situ* elastic moduli provide often provide different components of the elastic stiffness tensor  $G_{o(ij)}$ .

Estimates of the small-strain stiffness ( $G_0$ ) from different *in situ* tests are shown in Figure 4. This includes cross-hole geophysics, seismic cone and two correlations; one using standard CPT output parameters (Long and Donohue, 2010) and one based on soil properties (Hardin and Black, 1969):

$$V_s = 1.961 \cdot q_t^{0.579} \cdot (1+B_q)^{1.202} \quad (6)$$

$$V_s = (159-53.5e_0) \cdot OCR^{0.18/2} \cdot \sigma_{vo}'^{0.25} \quad (7)$$

where  $V_s$  is the shear wave velocity,  $e_0$  the *in situ* void ratio, small-strain shear modulus  $G_0 = \rho \cdot V_s^2$  and  $\rho$  is density. The values of  $G_0$  appear to generally increase with depth and range from 50 to 350 MPa, with the majority of values being between 75 and 150 MPa. The cross-hole measurements were made with an axial hammer system and thus provide estimates of  $G_{ohv}$ ; these values are generally constant with depth and give the

highest *in situ* estimates of shear modulus. The seismic cone provides estimates of  $G_{ovh}$  and these values are lower than those of the cross-hole testing. The Long and Donohue (2010) CPT correlation (from equation 6) shows comparable variations in  $G_0$  with depth and falls between the two other *in situ* test datasets. However the Hardin and Black (1969) method based on OCR and overburden (equation 7) shows much higher estimates of  $G_0$  (despite using the lower values of OCR from Figure 3).

Figure 4. Small-strain shear modulus with depth.

Similar variations in the elastic shear moduli ( $G_{ovh}$  and  $G_{ohv}$ ) have been observed with *in situ* tests previously (Pennington et al. 1997). These would be expected to be equal for a perfectly cross-anisotropic material. However, the different travel times may result from the averaging of the shear wave velocity through layered strata (for vertical travel), compared to lateral wave velocity through the stiffest layers. This leads to cross-hole measurements tending to measure the stiffest layers, rather than the average stiffness for SCPT measurements.

### 3 DISCUSSION

The design of gravity base foundations for onshore wind turbines requires accurate estimates of strength parameters for bearing capacity and stiffness parameters for displacements, within at least 1B of the founding level. The adoption of the most appropriate methods for site investigation to determine these parameters is debated in the industry and various published correlations are commonly used. Unfortunately many of these correlations have been previously developed for geologically young and relatively simple materials, and their applicability beyond their original databases can be uncertain.

The different methods of determining the undrained shear strengths show the crustal materials are quite strong, particularly near the founding depth, with undrained shear strength of up to 300 kPa reducing to 100 kPa at the crust base. Given the relatively high  $c_v$  (and permeability) and field vane values, there is a possibility that the CPT and vane estimates may be artefacts due to partial drainage. The crustal zone also has fissuring related to drying/wetting and frost action, and field shearbox tests on similar materials have indicated that bulk strengths can reduce considerably, and therefore representative values may be closer to 60-80 kPa (Lo, 1970). However, whether crustal fissures and associated strength changes are significant for such large shallow foundations is questionable.

Since overconsolidation ratio is often used as a component of correlations to determine geotechnical parameters, accurate estimation is important. Overconsolidation in tills is often attributed to loads from the overlying ice, however if drainage is inhibited, then only a small degree of consolidation will occur.

The measurement of preconsolidation pressure in tills using laboratory testing has been found to be quite difficult due to the high pressures often required to fully define compression curves and the effects of sample disturbance (which lead to under-estimation of  $\sigma_{vp}'$ ). The difficulties with this process are evident in the wide range of estimates for OCR shown in Figure 3.

Stiffness anisotropy is often evident in soils from *in situ* and laboratory measurements. The data in Figure 4 shows the general difficulties in choosing appropriate estimates of the small-strain stiffness ( $G_0$ ). Indeed cross-anisotropy in till may be difficult to justify, since sub-glacial shear and consolidation could have effects on the anisotropy of the *in situ* stress and fabric. Rocking stiffness ( $k$ ) for circular surface loads (radius,  $R$ ) is estimated using equation 8, (DNV/Risø, 2002):

$$k = \frac{8R^3G}{3(1-\nu)} \quad (8)$$

where  $\nu$  is Poisson's ratio and  $G$  is the shear modulus determined from the shear modulus ratio  $G/G_0$  that corrects the stiffness for degradation due to strain level (this is typically 0.25 for the presumed strain levels of  $10^{-3}$  for wind turbines). Manufacturers recommend criteria for rocking stiffness to ensure the natural frequency of the turbine remains above the main excitation frequencies. The range of small-strain moduli in Figure 4 indicate rocking stiffnesses from 50 to 170 GNm/rad, which is in excess of typical requirements of 40 GNm/rad, but still represents quite a significant range of stiffness.

### 4 CONCLUSIONS

There is currently little guidance for choosing cost effective site investigation methods and interpreting the results for this type of geotechnical structure on glacial tills in Ontario. It is anticipated that the completion of this project will provide some of the missing knowledge and insight required in this area.

# Cyclic loading of caisson supported offshore wind structures in sand

## Chargement cyclique des éoliennes offshore soutenues par des caissons à succion en sable

**ABSTRACT:** With the number of offshore wind turbines in Europe growing rapidly, offshore wind farm developers are looking for support structures which are relatively light, easy to produce and install and are suited for water depths in excess of 30m. Suction caissons could offer a solution for these requirements. Since cyclic environmental loads form an important part of the loading conditions, the cyclic degradation of the caisson capacity needs to be evaluated in detail. During storm events, pore pressure build-up inside and around the caisson can lead to degradation of capacity and stiffness. To date, there are no generally accepted material models which combine generation and dissipation of pore pressure with the mechanical response of the sand. Existing methods for analyzing pore pressure build-up are reviewed. Subsequently, a numerical model is proposed which captures the phenomena of pore pressure generation and dissipation around the caisson. Pore pressure increases under storm load cycles are calculated from cyclic laboratory tests and are added to existing pore pressures in the numerical model. The influence of cyclic loading history and drainage effects on the caisson performance is assessed using the 3D FE model. Implications for suction caisson design in sand are outlined.

**RÉSUMÉ :** Vu la croissance rapide du nombre d'éoliennes offshore en Europe, les développeurs des parcs éoliens offshore sont intéressés par des structures combinant légèreté, facilité de fabrication et qui sont adaptées à des profondeurs d'eau supérieures à 30m. Les caissons à succion répondent à ces critères. Comme les charges environnementales cycliques constituent une partie importante du chargement total, la dégradation cyclique de la capacité portante du caisson doit être évaluée en détail. Lors de tempêtes, l'accumulation de pressions d'eau interstitielle à l'intérieur et autour du caisson peut induire une dégradation de la capacité et de la raideur. A ce jour, il n'existe pas de modèle de matériau unanimement accepté qui combine génération et dissipation de pression interstitielle et comportement mécanique du sable. Les méthodes existantes d'analyse de génération de pression interstitielle sont examinées dans un premier temps. Ensuite, un modèle numérique intégrant les principaux mécanismes de génération et dissipation de ces surpressions autour du caisson est introduit. L'augmentation de pressions interstitielles résultants des charges cycliques dues aux tempêtes est estimée de manière indirecte sur base des résultats d'essais cycliques en laboratoire; ces surpressions sont ensuite ajoutées aux pressions interstitielles existantes dans le modèle numérique. L'influence de l'historique de chargement cyclique et des conditions de drainage est évaluée à l'aide du modèle éléments finis 3D. Enfin, les implications de ces résultats pour la conception de caissons à succion sont exposées.

## 1 INTRODUCTION

### 1.1 Suction caisson as foundations for offshore wind turbines

The European Wind Energy Association expects that the installed offshore wind capacity within the EU will increase from 4GW to 40 GW by 2020 (EWEA 2011) requiring the installation of approximately 6000 6MW turbines located ever further offshore in consequently deeper waters. Due to the demanding working conditions at sea and the limited availability of offshore installation vessels, the foundation system typically accounts for up to 25-30 % of the total cost of an offshore wind farm. This makes the choice and design of the foundation an important factor in the overall cost effectiveness of offshore wind farms.

Offshore wind farm developers are thus looking for support structures which are relatively light, easy to produce and install and are suited for water depths in excess of 30m. Suction caissons could offer a solution for these requirements.

A suction caisson is a steel structure consisting of a circular top plate with peripheral vertical skirts (Figure 1). In operation it is similar to a skirted gravity foundation, but the skirt length is significant compared to the diameter.

Installation of the caisson is achieved in two phases. After initial penetration under the self-weight of the caisson, water is

pumped out. The induced pressure difference pushes the caisson into the soil, while the induced seepage forces and reduced effective stress near the skirt tips facilitate penetration.

Advantages of the caisson include a potentially lower cost than equivalent piled foundations (Senders 2008) and relatively easy installation and removal, not restricted by water-depth.

Figure 1: Cross-section sketch of a suction caisson and installation principle

### 1.2 Loads on offshore wind turbines

The foundation must resist loads caused by the weight of the structure, the operation of the turbine, currents, wind and wave action. Incoming waves exert a cyclic horizontal force (and moment) on the foundation, which in the case of offshore wind turbines may be a significant proportion of the weight of the structure. A vertical weight of 6MN and a horizontal wave loading of up to 3MN are realistic values for a 3.5MW turbine (Houlsby et al. 2005).

The offshore design standard DNV-OS-J101 (DNV 2011) specifies that the structure must be able to resist a 50-year design storm (a storm with a probability of occurrence of 1/50 during one year), where not only the peak loads, but the entire history of cyclic loading affects the stability of the structure. For the cyclic loading assessment, the irregular wave loading is usually converted into an idealized, equivalent design storm.

### 1.3 Structural configuration

Caissons could support offshore wind turbines in two ways, based on mode of load transfer to the soil (Figure 2). A monopod foundation consists of a single caisson and is suited for shallow waters. In deeper water, the increased moments acting on the caisson would require a very large caisson. In that case a tripod (three caissons) or quadripod (four caissons) structure could be economical, as moment loads are converted into a vertical push and pull action on the individual caissons.

Figure 2: The monopod and multipod concept and reaction forces on the caissons

### 1.4 Scope of work

The aim of this paper is to examine the effect of cyclic loading during a design storm on both the monopod and multipod and to produce a model which is suitable for engineering practice. The presented model is still under development, and is considered a starting point for more sophisticated approaches.

## 2 CYCLIC DEGRADATION OF SOILS AND FOUNDATIONS

### 2.1 Pore pressure build up in sand under cyclic loading

Cyclic shearing of sand degrades the soil structure and causes a tendency to densify. This is the case even for very dense sands that are dilative under monotonic loading conditions (Seed and Idriss 1980, Andersen and Berre 1999).

Under undrained conditions, volume changes are prevented by the low compressibility of water, so normal stresses carried by the soil will be transferred to the pore water, thus increasing the pore water pressure in the sample as illustrated in Figure 3. The decrease in effective stress furthermore causes a progressive increase in average shear strain. Failure occurs when the generated pore pressure reaches a critical value  $u_{max}$ .

Figure 3: Behaviour of sand under cyclic loading (after Andersen and Berre 1999)

The intensity of cyclic loading is expressed in terms of the cyclic shear stress ratio, the ratio of cyclic deviatoric stress amplitude over mean effective stress. This formulation is convenient for the interpretation of triaxial test results and for implementation in the finite element procedure.

$$CSR = q_{cy}/p'_o \quad \text{with } q = \sigma_1 - \sigma_3 \quad (1)$$

Based on several cyclic tests at different CSR, cyclic shear strength curves can be established, expressing the number of cycles required to induce failure  $N_f$  as a function of the CSR and Dr.

The cyclic shear strength depends on the relative density and the initial shear stress in the sample. The set of curves used in this study was presented by Lee and Focht (1975) in their investigation of the liquefaction potential at the Ekofisk site, North Sea. The curves for this typical dense North Sea sand are redrawn in Figure 4.

Figure 4: Cyclic shear strength curves for dense North Sea sand at the Ekofisk site (after Lee and Focht 1975)

The build-up of pore pressure in samples can be described by the empirically determined pore pressure generation function given in Eq. 2 and plotted in Figure 5. The empirical constant  $\alpha$  depends on the soil properties and is on average equal to 0.7 (Rahman et al. 1977). As it is cyclically loaded, the soil sample evolves from the initial, undisturbed state at  $N = 0$  to a state of liquefaction at  $N = N_f$  and  $u = u_{max}$ .

$$\frac{u}{u_{max}} = \frac{2}{\pi} \arcsin \left[ \left( \frac{N}{N_f} \right)^{1/2\alpha} \right] \quad (2)$$

### 2.2 Drainage conditions

In laboratory tests soil samples are brought to failure under undrained conditions. However, in situ loading conditions may be fully or partially drained, depending on the combination of soil permeability, frequency of the loading and drainage conditions.

For offshore turbines founded on sand, the high permeability and relatively slow wave loading results in the dissipation or redistribution of a significant part of the generated pore pressure

during the cyclic loading itself. This effect becomes more important as the soil permeability increases and the loading frequency diminishes. Not taking into account the simultaneous dissipation leads to overestimation of the generated pore pressure and potentially to overconservative design.

Figure 5: Pore pressure generation function.

### 2.3 Liquefaction of foundations

The definition of failure of a foundation due to liquefaction requires special attention. Not all parts of the soil under a foundation will fail at the same time or will fail at all. Some intensely loaded zones may liquefy completely or partially, while other zones may still be intact.

Taiebat (1999) discussed the problem and proposed the following definitions. *Total failure* of a foundation-soil system under cyclic loading is defined as the condition where the soil mass deforms continuously under the ambient and cyclic loads applied to the foundation, resulting in bearing capacity failure. *Partial failure* involves large permanent displacements during cyclic loading. Some elements of the soil liquefy and lose their strength, but overall, the soil mass remains stable.

Due to the complexity of the problem, numerical analysis is often the preferred method to assess to what extent the foundation capacity is degraded.

## 3 EXISTING NUMERICAL METHODS

There are at least two approaches to numerical modelling of offshore foundation liquefaction. In the first approach an appropriate constitutive model is used to capture cyclic stress-strain behaviour of the soil. Many such models exist and they can successfully reproduce soil behaviour in laboratory conditions (e.g. bounding surface plasticity, multi-surface plasticity). However, the number of required parameters and calculation time are two obstacles that up to now have limited application of these models to analysis of boundary value problems in engineering practice.

The second approach is simpler and consists of improving a conventional (possibly slightly modified) constitutive model by incorporating the effects of cyclic loading separately, based on a set of laboratory tests. A rigorous review of the work by researchers who followed this approach to analyze offshore foundations subjected to wave loading is given by Taiebat (1999).

## 4 IMPLEMENTED METHOD

The proposed method follows the second approach and is based on the work by Rahman et al. (1977), Taiebat (1999) and to a lesser extent Lee & Focht (1975) and Verruijt & Song (1991).

The calculation procedure is as follows: undrained pore pressure increases are calculated analytically, at regular time

intervals in the FE analysis. At each node, the pore pressure at the end of the previous interval (which includes effects of all previous loading) is converted into an equivalent number of cycles using Eq. 2. The increase in pore pressure during next interval (containing a number of load cycles) can then be calculated from Eq. 2, assuming the CSR is constant during this interval.

After the pore pressure and effective stress in the FE analysis are updated accordingly, the dissipation analysis continues over the length of the considered time interval. This is done in a coupled Biot-type consolidation analysis in the FE package Abaqus.

The total design storm consists of a number of load parcels, during which the cyclic load (and thus the CSR) is assumed to have a constant average and amplitude. The load parcels are subdivided in a number of steps and the process of updating the pore pressure and subsequent consolidation is repeated for every subdivision, tracing the average pore pressure response (excluding oscillations within each load cycle) over the entire load history of the design storm.

## 5 APPLICATION TO SUCTION CAISSONS

In two case studies the influence of cyclic loading history and drainage effects on the caisson performance is assessed using the proposed model. Realistic forces acting on the foundation are estimated from the loads outlined in section 1.2 and a simplified load histogram is adopted. Corresponding realistic caisson dimensions are found by applying the bearing capacity equation (DNV 1992) for the tripod caisson and the formula proposed by Byrne and Houlsby (2003) for the monopod caisson. In both cases the sand is represented by an isotropic elastic material model with Mohr-Coulomb plasticity.

### 5.1 Leeward caisson of a tripod

#### 5.1.1 Model

Initially the horizontal load, divided over three caissons, is neglected. The resulting axisymmetric problem only considers vertical cyclic loading on the individual caisson due to weight of the structure and overturning moments as this is the most important load component. The histogram consists of 3 load parcels of 2000 seconds each, applying 200 load cycles at 60% of the maximum load in the first and last parcel and 200 cycles at maximum loading in the middle parcel.

#### 5.1.2 Results

An example of calculated pore pressure response within and around a 8x8m caisson is shown in Figure 6. First of all it is clear that the abrupt increases (generation) and gradual decreases (dissipation) are an approximation for the real behaviour.

Figure 6: Example of excess pore pressure history, tripod caisson

The analysis predicts liquefaction of the soil near the skirt tips and build-up of pore pressure inside the caisson during the second load parcel. Stress redistribution towards the baseplate will cause an additional increase in pore pressure inside the caisson. The abrupt increase at  $t = 2000$ s is due to the nonlinear dependency of generated pore pressure on the CSR, which increases at the start of the second load parcel. Much of the pore pressure is dissipated by the end of the last load parcel, even though cyclic loading continues (at 60% of the second parcel). As the pore pressure dissipates, settlements due to the cyclic loading are expected.

The discretization of cyclic loading in load parcels and subsequently in subdivisions affects the accuracy of the analysis, but the results seem to converge as the number of subdivisions is increased. Where short drainage paths or high CSR values are involved, sufficiently short steps are required. The rate of pore pressure dissipation is affected by the length of the skirts. Longer skirts result in slower dissipation and higher potential for pore pressure accumulation inside the caisson.

## 5.2 Monopod

### 5.2.1 Model

The monopod caisson (20x10m) is subjected to three degree of freedom loading, including a horizontal and moment load. A 3D FE model of half the caisson is sufficient, taking advantage of the plane of symmetry formed by the vertical and the direction of aligned wind and wave loading. A six hour design storm, consisting of 2160 waves in five load parcels, was adopted.

### 5.2.2 Results

The five load parcels are distinguishable in the pore pressure response plotted in Figure 7 and peak pore pressure occurs right after the peak of the storm. The permanent horizontal load due to wind and/or current causes an asymmetric cyclic shearing in the example, so the observed peak pore pressure (4 kPa) does not occur on the center line. The consequences, such as potential differential settlements and tilting of the turbine, should be examined in a more advanced analysis.

Figure 7: Example of excess pore pressure history, monopod caisson

## 6 CONCLUSIONS AND FURTHER DEVELOPMENTS

A pore-pressure generation and dissipation model has been developed to study the effect of cyclic loading on suction caissons in sand. Example analyses have shown that the proposed model can be successfully applied to the study of suction caissons, both in 2D and in 3D. However, the model needs further improvement to allow prediction of the complete liquefaction behaviour, including settlements, of a caisson.

The model can be used to predict which areas are prone to pore pressure build-up, estimate the rate of pore pressure build-up and to some extent how fast this pore pressure is dissipated.

Analysis of the type presented here may be useful to assess the geotechnical and structural risks related to cyclic loading of caissons in sand such as:

- reduction in caisson bearing capacity due to generated pore pressures;
- caisson foundation stiffness reductions;
- pore pressure induced total and differential settlements for offshore wind turbine structures;
- analysis of the effect of scour on pore pressure gradients.

The model can be improved to reflect more realistic soil behaviour. As some zones underneath the suction caisson liquefy, the load is transferred to other parts of the foundation. This leads to secondary pore pressure increases which are not yet considered in the presented model.

If sufficient soil data are available, the cyclic shear strength curves could include dependency on the relative density and initial shear stresses in the soil.

Finally, a large part of the vertical load on suction caissons is taken by friction between the caisson skirts and the soil. A systematic study of the influence on the liquefaction potential would be interesting.

## 7 ACKNOWLEDGEMENTS

The work described in this paper was performed as a part of the author's master thesis (Versteede 2012), supervised by professor Charlier (Université de Liège), whose guidance is gratefully acknowledged. Development of the model and calculations were performed at, and with support of Cathie Associates SA/NV.

# General Report of TC 211 Ground Improvement

Rapport général du TC 211  
Amélioration des sols

Huybrechts N.

*Belgian Building Research Institute, BBRI & KU Leuven, Belgium*

Denies N.

*Belgian Building Research Institute, BBRI, Belgium*

**ABSTRACT:** The present General Report highlights the significant contributions of the papers of the Session of the XVIII ICSMGE dedicated to Ground Improvement. All papers that have been reviewed are referred (in bold) in the General Report in order to provide a balanced overview of the entire Technical Session.

This General Report discusses the latest developments and current researches in the field of Ground Improvement (GI) works. The various GI techniques are classified considering the recent classification proposed by Chu et al. (2009). The papers are then tackled according to the described GI technique and with regard to the topics that are assessed: execution process, mechanical characterization of the treated material (in laboratory or in situ), case history, Quality Assurance/Quality Control (QA/QC) activities and design aspects. Conceptual works and numerical modeling are supported by laboratory and field investigations - with in situ monitoring and large scale tests. Finally, other references on the topics discussed are also given in the report.

**RESUME :** Le présent rapport général met en évidence les contributions significatives des articles de la session « amélioration des sols » de la 18<sup>ème</sup> CIMSG. Tous les articles revus ont été référencés (en gras) dans le rapport général de manière à fournir une vue d'ensemble équilibrée du contenu de cette session.

Ce rapport discute des derniers développements et des recherches actuelles dans le domaine des travaux d'amélioration des sols. Les différentes techniques sont classées selon la récente classification proposée par Chu et al. (2009). Les articles sont ensuite abordés en tenant compte de la technique d'exécution décrite et du sujet choisi par les auteurs : procédé d'exécution, caractérisation mécanique du matériau traité (en laboratoire ou in situ), cas pratique, activités de contrôle et d'assurance du point de vue de la qualité et aspects liés au dimensionnement. Les approches de conception et la modélisation numérique sont supportées par des recherches en laboratoire et par l'expérience de chantier – apportée par le monitoring in situ et par les essais en grandeur réelle. Finalement, d'autres références concernant le domaine de l'amélioration des sols sont aussi indiquées.

**KEYWORDS:** ground improvement/reinforcement, deep mixing, drainage, geosynthetics, grouting, inclusions, vacuum consolidation

## 1 INTRODUCTION

Ground improvement (GI) is one of the major topics in geotechnical engineering. With regard to the world population growth and in response to the expansion needs of our society, it has become a fast growing discipline in civil engineering as an alternative allowing construction on soft/weak/compressible soils. Various specialized ground improvement conferences have been frequently held in the past and recent years such as the International Symposium on Ground Improvement organized by the Technical Committee 211 of the ISSMGE and recently held in Brussels (Denies and Huybrechts, 2012) especially with more than 140 papers and 7 General Reports focusing on GI works. A number of books covering various topics on ground improvement have been also published in the past. Most of them are referred in Chu et al. (2009). During the last decades the importance of the ground improvement market has enormously increased. New methods, tools and procedures have been developed and applied in practice. In order to support this evolution in a scientific way, research programs have been and are being carried out worldwide, leading to more and better insights and delivering the basis for the establishment of design methods, quality control procedures and standards. As a result, many technical papers on GI works were published in journals and conference proceedings. It is not possible to mention all. Separate lists are given on the TC211 website ([www.bbri.be/go/tc211](http://www.bbri.be/go/tc211)). Major GI techniques have been

documented by the Working Groups of TC211 and are currently available on this website.

TC211 adopts a classification system as shown in Table 1 in Chu et al. (2009) with the following categories (and methods):

- A. GI without admixtures in non-cohesive soils or fill materials (dynamic compaction, vibrocompaction,...)
- B. GI without admixtures in cohesive soils (Replacement, preloading, vertical drains, vacuum consolidation,...)
- C. GI with admixtures or inclusions (Vibro replacement, stone columns, sand compaction piles, rigid inclusions,...)
- D. GI with grouting type admixtures (Particulate and chemical grouting, Deep mixing, jet grouting,...)
- E. Earth reinforcement (geosynthetics or MSE, ground anchors, soil nails,...)

This classification is based on the broad trend of behaviors of the ground to be improved and whether admixture is used or not. In the following sections, the papers of the Session of the XVIII ICSMGE dedicated to GI works will be reviewed according to this classification and with regard to the topics that are assessed: execution process, mechanical characterization of the treated material, case history, QA/QC activities and design aspects. It can already be noted that there is no paper considering GI without admixtures in non-cohesive soils (category A) in the present Technical Session.

## 2 GI WITHOUT ADMIXTURES IN COHESIVE SOILS

In the present Technical Session, six papers can be put in the category B: GI without admixtures in cohesive soils. They are mainly related to the subject of consolidation acceleration by vertical drains combined with surcharge or Vacuum. The interest seems to be oriented to the approach of “smear”. **Parsa-Pajouh et al. (2013)** address this delicate topic so difficult to model due to the lack of field parameters. According to the authors, the smear zone varies between 1.6 and 7 times the drain radius or 1 to 6 times the mandrel equivalent diameter. Numerical models are used within the framework of case studies. Parameters studies confirm their validity. As a result of their researches, it is recommended to assess the smear zone on the basis of trial construction with the help of back calculation process.

**Chai and Carter (2013)** present a theoretical approach of Prefabricated Vertical Drains (PVD) and consolidation combining vacuum pressure and surcharge loading. Using Hansbo's (1981) solution, consolidation parameters of the smear zone and the undisturbed zone were derived using a simple equation. Adopting an average well resistance and with some approximation, the dimensionless parameter  $\mu$  quantifying the effects of PVD spacing, smear zone and well resistance can be expressed. The study was performed in uniaxial consolidation condition, which is not in agreement with the real isotropic character of deformation under Vacuum. Moreover, the classical assumption of uniform smear zone cannot be measured. However the pore pressure measurements of the tested samples are in extreme close concordance with the prediction confirming the validity of the approach and the selected parameters.

**Indraratna et al. (2013)** treat similar subject in conjunction with a real construction site in the Port of Brisbane where the consolidation of thick Holocene clays was performed with PVD's under surcharge and/or Vacuum loading. Variable drain spacing was selected and analytical solutions were proposed. For the excess pore pressure dissipation, the same equation as in Chai and Carter (2013) was adopted. The results demonstrate that Vacuum combined with preloading would speed up consolidation compared to preloading alone. Moreover, Vacuum results in isotropic consolidation increasing the stability of the surcharge fill (decreasing lateral displacements).

In a similar way, **Lee et al. (2013)** have also studied the effect of the smear zone for a consolidation case history in Busan (South Korea). Modification of Hansbo's analysis is proposed to study the degree of consolidation considering the properties of the soil within the smear zone.

As another case history, **Islam and Yasin (2013)** present an application of PVD's coupled with preloading used for the construction of a large container yard in Bangladesh. The soil profile consists of 4 to 6 m thick silty clay, 8 to 10 m of sand and silt and 16 m of clayey silt. On the basis of design requirements, GI of the upper soft clay layer was considered essential. Five alternatives were assessed and compared. A solution combining PVD and preloading was adopted for this site. The settlement under preloading was monitored during the consolidation phase. Pre and post consolidation SPT tests are presented to illustrate the efficiency of the technique. It is believed that dynamic compaction although economical would not have been technically feasible due to the clayey nature of the upper fill. However, dynamic replacement in the upper 4 m with densification of the lower silty sand might have been technically and financially optimal.

For their part, **Jebali et al. (2013)** have assessed the theory of Carillo using three different oedometer tests carried on Tunis soft soil. Oedometer tests were conducted, conventionally (NF P94-90-1) for the first test, with a vertical drain allowing only radial drainage for the second one and finally with a drain

allowing vertical and radial drainage for the last one. Defining  $C_r$  and  $C_v$  as the radial and vertical coefficients of consolidation and  $K_r$  and  $K_v$  as the coefficients of radial and vertical permeability, they observed that the often-made assumption of the equality between the ratio's  $C_r/C_v$  and  $K_r/K_v$  is only valid at high levels of stress conditions. Moreover, on the basis of experimental results, the authors demonstrated that the global degree of consolidation computed with respect of the Carillo's theory can lead to underestimated consolidation times.

The paper of **Weihrauch et al. (2013)** describes a combination of GI methods for the improvement of roads in the Hafencity area in Hamburg. Indeed, in the Hamburg Harbour area, many roads are lifted with almost 3 m to ensure safety in case of flooding. Special measures are necessary when the subsoil contains compressible layers. At the Hongkongstrasse, three different construction methods have been applied, namely:

- installation of PVD and preloading with sand (settlements of more than 30 cm have been measured);
- filling with lightweight aggregate: expanded clay (almost no settlement was observed);
- pile supported embankment including geogrid-reinforced sand layer (measurements are discussed in another paper).

The different aspects of each method are described. The conclusion is that when comparing different methods, not only the absolute costs must be ascertained, but also the project specific reconstruction, protection and follow-on measures, as well as the time and flexibility for individual measures, and their technical feasibility under local conditions.

## 3 GI WITH ADMIXTURES OR INCLUSIONS

### 3.1 Rigid inclusions

Moving towards category C, GI with admixtures or inclusions, the paper presented by **Kirstein and Wittorf (2013)** is an interesting transition between categories B and C. Indeed, the authors describe the improvement of soft fat clay using rigid inclusions combined with vertical drains, preloading and the use of geotextile. The aim of the project was the construction of a bridge for a new road in Germany including 1.5 to 7 m high embankments. Vertical drains were first used to accelerate the consolidation under the embankments (preloading condition). Even using 600 kN/m woven geotextiles, vertical settlement of around 1.5 m and horizontal displacement up to 27 cm were measured throughout one year of monitoring. Because the bridge could not tolerate residual settlements, Controlled Modulus Columns (CMC) were designed and executed. The design of the transition interface between the bridge and the embankment, referred as the Load Transfer Platform (LTP), was confirmed by the monitoring.

**Ciri3n et al. (2013)** set the constructive procedures and bases of design of rigid inclusions including the LTP. The ASIRI guidelines (IREX, 2012) were not yet published at the time of preparation of this paper. The paper highlights the difference with pile foundation. In rigid inclusion solutions, there is no mechanical link between the pile and the structure. A LTP is usually placed between the inclusions and the structure. This distribution layer spreads the acting loads from the structure towards the underlying soil-inclusions setup. As indicated by the authors, isolated or continuous footings can possibly be used to directly transmit the loads to the soil-inclusions setup. This GI technique can also be applied for embankments and landfills.

The following paper constitutes a good transition with the next topic concerning stone columns. According to **Carvajal et al. (2013)**, dealing with the design of Column Supported Embankments (CSE), a clear distinction has to be made between rigid inclusions (e.g. concrete type columns) characterized by a brittle behavior in its Ultimate Limit State

(ULS) and stone columns (made of gravel and sand) which demonstrate a ductile behavior in its Serviceability Limit State (SLS) due to its compressibility and drainage characteristics (influence of the consolidation process on the design). Due to the brittle behavior of concrete type columns, larger safety factors have to be introduced, certainly for very slender elements. The General Reporters fully agree that similar approaches cannot be applied for very slender concrete type columns and for stone columns. However it has to be remarked that it is not common to consider stone columns as drainage elements.

### 3.2 Stone columns

In the present Technical Session, **Vlavianos et al. (2013)** propose technical solutions for the design of a road project in the Region of Western Greece. The geology of the site consists of soft silty clays and silty sands with high liquefaction susceptibility. The high ground water table and the seismicity of the area result in a design solution including GI. The installation of stone columns followed by preloading was selected. For the design of the bridge embankments and the pile foundations for bridge piers, a comparative parametric study was performed with or without stone columns. As discussed by the authors, the main aim of the preloading was the increase of the undrained shear strength of the superficial fine-grained soil layer. With the installation of the stone columns, the following requirements were met:

- increase of the general stability of the embankments;
- increase of the bearing capacity;
- reduction of the internal forces in the classical pile foundations;
- acceleration of the consolidation process;
- mitigation of the liquefaction susceptibility.

Although “stone columns” is nowadays a well-known GI method, installation effects arising during the execution still remains poorly understood. In order to investigate this question, **Klimis and Sarigiannis (2013)** describe the numerical analysis of the installation of stone columns with a diameter of 0.8 m and a depth of 23 m by means of the FLAC 3D Finite Difference code. The excavation stage has been modeled in one unique step and the realization of the stone column as follows:

- a) vibration and compaction, modeled by the application of an equivalent radial pressure against the internal wall of the cylindrical excavation;
- b) filling with a linear elastic geomaterial.

This numerical sequence was necessary to correctly determine the area in the surrounding soil influenced by the installation of the stone column and hence to assess with more accuracy the effective diameter of this latter.

**Poon and Chan (2013)** present another methodology to design stone columns. In this analysis, stone columns are replaced by equivalent strips, as illustrated in Fig. 1. The equivalent friction angle of the strips is dependent of the stress concentration ratio which is defined as the ratio of the average applied vertical stress within stone column to the average vertical stress of the surrounding soil at the same level. A method is proposed to compute this ratio by means of an axisymmetric Finite Element Model (FEM) containing one column and the surrounding soil. Numerical results obtained with this methodology (2D FEM with strips) have been compared with the results of a 3D FEM and with the results of a conventional 2D FEM analysis in which the entire soil is represented by a single block with equivalent properties. The authors conclude that the strip model is preferable to the block model for the assessment of the horizontal displacements. Further research is still necessary to investigate the question of the equivalent strength of the interface in the 2D strip method.

Figure 1. 2D stone column strips, from Poon and Chan (2013)

### 3.3 Geotextile confined columns

Rigid inclusions are a common GI technique for foundations of embankments in soft soils. Nevertheless, when the soft soil does not provide enough lateral support, the columns can be encased with a geotextile. The following papers mainly focus on the geotextile confined columns, also defined as geocased granular columns (GEC's).

**Castro et al. (2013)** describe and compare analytical and numerical analyses considering the behavior and the performances of geotextile confined columns (GEC's). Parametric studies of the settlement reduction and stress concentration show the efficiency of GEC's for GI purposes. This efficiency is mainly related to the contrast of stiffness between the encasement and the soil. As another conclusion, it is found that the settlement reduction is nearly the same for different replacement ratios but decreases with the applied load. Finally, columns with smaller diameter are better confined.

If GEC's are often used to reduce settlements induced by the construction of large embankments on soft soils, up to now no rational displacement based design approach has been introduced. For the purpose of investigating this question, **Galli and di Prisco (2013)** first review the most common design standards and then focus on the interaction between the embankment and the geocased columns. The main contribution of the paper resides in the consideration of the deformable base of the embankment. Indeed, real embankments are characterized by a deformable base, as illustrated in Fig. 2. As a consequence, different values of settlement are expected for the top of the column ( $u_c$ ) and for the soil ( $u_s$ ) at the base of the embankment. As explained by the authors, vertical stresses are redistributed at the base of the embankment between the internal zone of the cell (above the column characterized by an average stress  $\sigma_i$ ) and the external one (a circular crown above the soil, characterized by an average stress  $\sigma_e$ ) due to the arch effect. Shear stresses are then activated at the GEC-soil interface, and differential settlements are expected even at the top of the embankment.

Figure 2. Mechanical response of the system in case of (a) rigid and (b) deformable embankment, from Galli and di Prisco (2013)

**Hataf and Nabipour (2013)** have designed a reduced-scale model in such a way to identify the parameters governing the behavior of the GEC's installed in clayey soils. As a result, they propose to encapsulate only the upper half of the column.

### 3.4 Geosynthetic reinforced column or pile supported embankment – the use of geogrids

Another way to use geosynthetic material for GI application is the design of geogrids for the support of embankment, land levees, yards and structure foundations (slabs and superficial isolated or continuous footings).

Investigating the use of geosynthetics for reinforcement under ground mass collapse, **Ponomaryov and Zolotozubov (2013)** compare the method outlined in British Standard BS 8006 and several design approaches with numerical calculations. On the basis of experimental elongation results, they introduce the ratio of actual tensile force to deformation. Computational assumptions are proposed for the description of the mechanisms of stress-strain development in the reinforced ground mass. The authors finally present a comparison between experimental measurements and the results of seven different methods used for the calculation of the tensile force in the geosynthetic, its deflection and the surface settlement.

**Mihova and Kolev (2013)** analyze the benefit of a geosynthetic reinforced pad of crushed stone used for the foundation of a hall in Sofia over soft saturated soil. Field tests were performed to estimate the E-moduli before and after improvement. The authors also conducted Finite Element analysis to model the consolidation process and to confirm the design stability under static and seismic conditions.

**Dimitrievski et al. (2013)** present a history case of soil reinforcement with geosynthetics for the construction of a six-storey structure in Ohrid (Republic of Macedonia). Multi layers geogrids were designed and the effects of the geostatic, hydrostatic and dynamic loading conditions were studied with the help of FEM calculations. The validity of the analysis was demonstrated with the help of in situ measurements obtained for a close similar structure.

### 3.5 Sand compaction piles (SCP's)

In the sand compaction pile (SCP) method, sand is fed into the ground through a casing pipe and is compacted by vibration, dynamic or static compaction to form columns. In practice, SCP's are mainly used to prevent liquefaction and reduce settlement with similar success in sandy and clayey soils. With the help of laboratory and field tests, **Burlacu et al. (2013)** investigate the potential of columns made of loess-sand-bentonite mixture for the reinforcement of collapsible loess deposits in Romania. Indeed, as explained in the paper of **Alupoae et al. (2013)**, these collapsible soils require GI works. They are characterized by high water sensitivity: when its water content increases, important deformations in the soil can be observed. In such a way to illustrate this phenomenon, the authors present a case study of differential settlement of buildings founded on loess sensitive to wetting. In spite of the good realization and control of the foundation, important differential settlements were measured thereafter as a result of the defective rainwater recovery system.

### 3.6 Microbial methods

The use of microbially induced carbonate precipitation (MICP) to cement cohesionless soils has recently received substantial attention from geotechnical researchers. The most common MICP mechanism is hydrolysis of urea. MICP via ureolytic hydrolysis relies on microbes to generate urease enzyme, which then serves as a catalyst for the calcium carbonate ( $\text{CaCO}_3$ ) precipitation reaction. If it is to date well known that the mechanical properties of the treated soils are directly correlated to the amount of ( $\text{CaCO}_3$ ) precipitation, a gray area still remains concerning the influence of the original nature of the granular material on the resulting properties of the treated soil. Within the framework of a laboratory campaign, **Tsukamoto et al.**

**(2013)** investigate the influence of the relative density of sand samples on the MICP. As a result of their study, the MICP tends to increase as the relative density of the soil decreases. Nevertheless, considering the results of triaxial tests, maximum principal stress differences were obtained for the samples with the highest relative density. In light of these results, this technique seems to be very promising for the future but due to the bioplugging (permeability reduction) of the granular material and to the generation of toxic product (ammonium salt); soil stabilization using ureolytic MICP remains currently unusual. According to **Hamdan et al. (2013)**, the use of plant derived urease to induce the carbonate cementation could be the solution to avoid these drawbacks.

## 4 GI WITH GROUTING TYPE ADMIXTURES

### 4.1 Deep Mixing Method (DMM) and soil stabilization

The deep mixing method (DMM) is nowadays a worldwide accepted GI technology. In this method, the ground is in situ mechanically (and possibly hydraulically or pneumatically) mixed while a binder, based on cement or lime, is injected with the help of a specially made machine. Numerous reviews and recent progresses of the DMM are referred in Denies and Van Lysebetten (2012). In the recent years, the DMM is undergoing rapid development, particularly with regard to its range of applicability, cost effectiveness and environmental advantages, as illustrated by the papers of this paragraph.

In the deep mixing projects, the design can be based on laboratory mixing tests. Soil-cement samples are then prepared and tested to study the mechanical properties of the stabilized soil. But, up to now, many laboratories prepared these samples without standardized procedure. Actually, molding techniques have a great influence on the mechanical characteristics of the stabilized material. According to **Grisolia et al. (2013)**, this influence is strictly correlated to the workability of the soil-cement mixture and this latter can be quantified with the measurement of the torque required to turn an impeller in the mixture. Five molding techniques have been studied and the authors propose the abacus illustrated in Fig. 3 to define the range of applicability of these techniques in function of this torque.

Figure 3. Ranges of applicability of the different molding techniques, from Grisolia et al. (2013)

The applicability of each molding technique was evaluated by an “Applicability index”, related to “densest specimens with the highest strength” and “results repetitiveness”.

Since several decades, DMM has been used for GI works. But in recent years, this technique has been increasingly used

for structural applications. Standardized guidelines for the design of this kind of applications are not currently available. If the previous work allows the construction of standardized and international test procedures for laboratory mix samples, the Quality Control (QC) of the execution process is generally based on the results of Unconfined Compressive Strength (UCS) tests performed on cored material. As part of the semi-probabilistic design approach presented in Eurocode 7, it is thus essential to define the UCS characteristic value that can be taken into account in the design. **Denies et al. (2013)** discuss the definition of this value. In the first category of approaches, the characteristic strength is defined as an X% lower limit value computed either on the basis of a statistical distribution function or based on the cumulative frequency curve of the original experimental dataset of UCS values obtained from tests on cored samples. A second approach to determine the UCS characteristic value is the use of the average value of the dataset in combination with a safety factor. For the first category of approaches, a value for the X% has to be defined. Actually, one major issue is the representativeness of the core samples with regard to the in situ executed material. For the purpose of investigating this question, the authors present the results of a study on the influence of soil inclusions and then they discuss the topic of the scale effect with regard to large scale UCS tests.

The following papers concern the investigation of the mechanical properties of the soil mix material under the field of laboratory or in situ experiments and with the help of numerical modeling.

In such a way to investigate the properties of the soil mix material, **Szymkiewicz et al. (2013)** have carried out a parametric study on lab soil-cement mixtures. The influences of the particle size, the clay content and the water content on the strength of the material were considered. They propose an abacus relating the UCS of the specimens to the cement content. Six zones are identified in the abacus depending on the nature of the soil. In addition, the authors also propose a formula valid for granular soils for the estimation of the UCS at 28 curing days. This formula takes into account the water, the cement and the fine contents.

In a similar way, **Correia et al. (2013)** have performed laboratory tests to study the improvement of soft clayey silt with high organic content by mixing it with a binder made up of 75% Portland cement (PC) and 25% blast furnace slag. They first give a formula for the assessment of the UCS at 28 days in function of the binder content and the liquidity index (LI) of the soil. A normalized UCS is then introduced as follows:  $UCS_{LI} = UCS \times LI$ . In a second step, the applicability of the normalized UCS approach is analyzed for seven other cement-stabilized soft soils with successful result.

If the water/cement (w/c) ratio is often used in attempt to understand soil-mix properties, it can be found limited since in practice execution is mostly performed in soils in the presence of water (unsaturated or saturated conditions). A well-adapted governing parameter could be then the porosity/cement index defined as the ratio of porosity to the volumetric cement content ( $n/C_{iv}$ ). **Rios et al. (2013)** highlight the influence of this index on the mechanical properties of cemented Porto silty sand. Unique trend was obtained between the UCS and an adjusted porosity/cement ratio ( $n/C_{iv}^{0.21}$ ), proposed by the authors. Similar observation was also made with indirect tensile strength. Triaxial tests resulted in two peak strength envelopes for each predetermined ( $n/C_{iv}^{0.21}$ ) and finally, oedometer tests establish this ratio as the governing parameter of the behavior of the soil-cement specimen in one-dimensional compression in lieu of the cement content or the initial void ratio.

A major advance in DMM could be found in the contribution of **Yi et al. (2013)** with the investigation of the carbonation of reactive magnesia (MgO) for soil stabilization. Nowadays, Portland cement (PC) is the most common binder used in the

deep mixing applications. However, there are significant environmental impacts associated with its production in terms of high energy consumption and CO<sub>2</sub> emissions. In their laboratory study, reactive MgO was used as a binder and the MgO-soil samples were carbonated by CO<sub>2</sub> to improve the mechanical properties of the soil and reduce the CO<sub>2</sub> emission. As an evident result, the UCS values of the uncarbonated MgO-stabilised soils were much lower than those of the PC-stabilised soils; both mixes took ~28 days to finish most of their strength development. Nevertheless, the carbonation process significantly increased the UCS of MgO-stabilised soils in a very short time, this latter fast reaching the UCS value of the 28-day PC-stabilised soils, indicating that it could be used to support a structure just after the completion of the carbonation procedure.

Another type of binder largely used for soil stabilization is lime. **Mesri and Moridzadeh (2013)** discuss the results of a laboratory study focusing on the improvement of the Brenna clay (high plastic lacustrine clay of North Dakota) by adding lime. Lime contents varying between 3 and 10 % of the dry weight of the clay have been considered. The authors observed a decrease of the measured pH with time and an increase of the Liquid Limit and the Plasticity Index with time when 5 % of lime was added. Adding 3 to 8 % of lime, the residual friction angle (in drained conditions) increases between 3 to 6 %. Unfortunately the laboratory test results were not compared with full scale test results.

Extensive laboratory tests have been performed by **Szendefy (2013)** for the purpose of determining the effect of lime stabilization on 21 Hungarian clayey soils. In addition, some in situ stabilized soils have also been analyzed. According to his study, the improvement of the clayey soil with the lime is mainly related to the coagulation of the clay particles related to the cation exchange. Indeed, during the stabilization with lime, Ca<sup>2+</sup> ions attach to the surface of clay particles. As a result of this high charging, the clay particles coagulate resulting in a material characterized by an increased internal friction angle. The pozzolanic reaction would play then a secondary role in the stabilization.

Soil stabilization can also be performed with fiber reinforcement, such as discussed in **Madhusudhan and Baudet (2013)**. In their study, laboratory tests have been performed to determine the influence of adding polypropylene fibers on the shear strength characteristics of completely decomposed granite (CDG). In Hong Kong, CDG is regularly used for landscaping and as green cover of existing shotcrete slopes. The test results clearly indicate an important increase of the UCS when adding 0.5% of fibers and compacting the CDG at the water content close to the optimum Proctor value. In triaxial drained tests, the addition of fibers seems to increase the shear strength of the CDG and its stiffness. Dilation is also reduced.

In Singapore, laboratory tests have been performed by **Xiao et al. (2013)** in order to determine the characteristics of the Singapore upper marine clay when mixed with 20 to 50% Portland cement (PC) and up to 0.32% fibers of different types. As a result of their study, strength and ductility of cement-treated clay were improved by fiber reinforcement. There is an optimum fiber content with regard to performance and workability of the material. Polyvinyl alcohol (PVA) fibers are generally more efficient than polypropylene (PP) fibers except for low cement and water contents. The length of the fibers has a significant effect on the ductility of the cement-treated clay for both fiber types. Concerning the strength, the influence of the fiber length is more significant for PVA reinforcement than for PP reinforcement.

**Cuira et al. (2013)** present the results of numerical models simulating an axial Static Load Test (SLT) on a soil-cement column. Numerical and experimental results are compared with the help of three Finite Element models and one simplified

semi-analytical model. Numerical results are in agreement with the experimental observations all along the SLT but especially regarding to the fracture pattern: structural failure localized in the upper part of the column. This numerical study highlights the nonlinear behavior of the soil-mix material. In comparison with classical “rigid” piles, the contrast of strength (and stiffness) between the column and the soil is lower and has a huge influence on the global behavior.

Originally, DMM was developed for GI applications in soft clays and organic soils. But more recently, it was also dedicated to various structural and environmental applications such as illustrated by the following case histories.

Recently, the DMM has been chosen for several Hungarian railway projects involving soft soils, such as the restoration of the “Sárrét” railway line crossing an area where the subsoil consists of soft chalky silt. For the foundation of a 4m high embankment, two DMM were taken into account: the mass stabilization and the soil-cement columns. **Koch and Szepesházi (2013)** firstly describe results of laboratory tests on chalky silt samples mixed with cement for different w/c contents. Both DMM are then assessed using 3D-FEM considering the site requirements in term of stability and settlement.

In a similar way, DMM have been widely used in Japan for the improvement of soft clays and organic soils. **Matsui et al. (2013)** introduce the concepts of an hybrid application of soil-cement columns combined with soil mix walls (SMW) designed for the foundation of an embankment. The concept is illustrated in Fig. 4. The authors propose a conceptual method allowing the control of ground deformation and ensuring an optimization of the volume of treated soil. The method is supported by 2D-FEM and in situ monitoring is performed for the validation of the concept.

Figure 4. GI with soil-cement columns and SMW, from Matsui et al. (2013)

In Lund (southern Sweden) a new generation synchrotron radiation facility, called MAX IV, is under construction. According to **Lindh and Rydén (2013)**, it should be 100 times more efficient than any existing comparable synchrotron radiation facility in the world. For this kind of facility, the vibration requirements are very stringent. Various alternatives were discussed and simulated during the conception. The optimum solution was achieved with a four meter thick layer of stabilized soil below the concrete foundation. A combination of quicklime and ground granulated blast furnace slag (GGBFS) was found to be in agreement with both design and construction requirements.

**Jeanty et al. (2013)** describe the use of the CSM and the Trenchmix methods for the realization of SMW. Both techniques are explained in details and different applications are

presented, namely: settlement reduction, improvement of slope stability, reduction of active pressure on retaining walls and decrease of liquefaction susceptibility. The two last topics are then illustrated with case histories.

Other case history tackles the topic of liquefaction susceptibility restrained with the DMM. **Yamashita et al. (2013)** deal with the measurements performed underneath a piled raft completed with SMW to reduce the risks of liquefaction. It concerns a 12-storey office building. The load distribution between piles, SMW and the surrounding soil has been monitored during a period of three years. After the end of the construction, settlements of 20 mm have been recorded, as illustrated in Fig. 5. As another result, 70 % of the load was taken by the piles, 14 % by the SMW and 15% by the soil, as shown in Fig. 6. The measurements also learned that the Tohoku earthquake of March 2011 had almost no influence on the settlements and on the load distribution.

Figure 5. Measured vertical ground displacements below raft, from Yamashita et al. (2013)

Figure 6. Time-dependent load sharing between raft and piles, from Yamashita et al. (2013)

If the foundation of embankments and buildings are become both common applications of the DMM, underpinning with soil mix material constitutes an interesting emerging technique, such as illustrated in the following paper.

Traditional DMM are commonly restricted for underpinning, limitations being mainly related to the capacity of the machine to pass existing foundation structures as reinforced slabs or footings, the reduced working spaces and the possible low headroom conditions. **Melentijevic et al. (2013)** present a case history of underpinning of an existing floor slab in an industrial building using DMM. The soil-cement columns were installed with the new Springsol® tool. After the realization of a contact grouting between the slab and the soil, the slab and the contact grouting layer are cored. The spreadable Springsol® tool is then introduced into the gap. Finally, its blades are opened and the soil-cement column is executed until the predetermined depth. The conception is supported by numerical modeling and QA/QC aspects of the project are related to the testing of core and wet grab samples.

#### 4.2 Use of stabilized dredged material for construction

As previously discussed in Chu et al. (2009), dredging and land reclamation have increasingly become important parts of construction activities that involve heavily geotechnical knowledge. If dredging provides low cost construction material,

it is sometimes necessary to resort to additional GI methods in order to obtain a product meeting the design requirements. The following paper illustrates how GI and dredging are complementary construction processes.

**Loh et al. (2013)** present considerations in the design and construction of a containment bund made of modified geotextile tubes (M-GT) filled with cement-mixed soil. In the port of Singapore, dredged soil mixed with cement was used as in-fill material in the M-GT's and as the core of a large geotextile containment bund, as illustrated in Fig. 7. Field instrumentation and monitoring were carried out with the help of strain measurements, hydrographic survey, inclinometers and extensometers during and after the construction to verify the design and the performance of the system.

Figure 7. Geotextile containment bund, from Loh et al. (2013)

#### 4.3 Recent advances in the jet grouting applications

If special devices have been developed in the past to measure the diameter of the jet grout columns executed in situ, considerable effort should be made in the understanding of the physical processes governing this parameter. **Bzówka et al. (2013)** analyze excavated jet grout columns. The experimental results are used to model the bearing capacity of the columns by means of the Z-soil software. Indeed, although the jet grout columns have been realized in compacted medium sand underlain by stiff clay, almost all columns had an irregular shape influencing its bearing capacity.

In the grouting applications, the bleed capacity is another indicator of grout effectiveness, since it is representative of the volume of voids filled by cement. The grout's water-to-cement ratio (W/C) and the maximum cement grain size ( $d_{max}$ ) are two important parameters controlling the cement grout bleed capacity. **Pantazopoulos et al. (2013)** provide some insights on the effect of grout bleed capacity on the mechanical properties of ordinary and microfine cement grouted sands, in conjunction with the effect of the W/C ratio. They demonstrate that the distinction between stable and unstable grouts (see EN 12715) may not be an indicator of grout effectiveness since similar effects may be produced by both stable and unstable grouts: e.g. same coefficients of permeability were obtained for a bleed capacity ranging from 5 (stable) to 30 % (unstable suspension). Bleed capacity correlates very well with some grouted sand properties (i.e. unconfined compression strength and cohesion) and not at all with other properties (i.e. internal friction angle and damping ratio).

## 5 EARTH REINFORCEMENT

### 5.1 Geosynthetics

Centrifuge tests have been performed by **Bo et al. (2013)** in order to study the reinforcement of low plastic brown weathered shale with polypropylene fibers for the construction of an embankment. Vertical and horizontal displacements deduced from the centrifuge tests have been compared with those obtained from FEM analyses. Both approaches demonstrate the contribution of the fibers on the stability.

In a similar way, **Tabarsa and Hajiesmaeilian (2013)** have studied the influence of sand encapsulated non-woven geotextile (sandwich technique) on the stability of clay embankment. Using FLAC 2D Finite Difference model, the authors highlight the efficiency of the method with regard to the geotextile-reinforced and the unreinforced embankments.

### 5.2 Vegetation methods

A significant element in the reclamation of landfills is the reinforcement and biological stabilization of the slopes which can be very sensitive to surface erosion. According to **Koda and Osinski (2013)**, landfill stability improvement activities can be divided in two phases: the first one consists in the technical reclamation of the landfill and the second one is the biological restoration of the vegetation cover. For both phases, the authors argue it is possible to use recyclable materials such as fly ash or sewerage sludge. They discuss the improvement of slope stability of a solid waste disposal with the help of this approach. On the one side, fly ashes can be considered as impermeable and present good compaction properties. Mixed with cohesive soil, it could be therefore used for the capping of the waste disposal. On the other side, the sewerage sludge protects the seeds from erosion and excessive drying. Moreover the sewerage sludge presents a high nutrition content supporting the development of the vegetation cover. Unfortunately, no information is given in the paper concerning the installation procedures of the fly ashes and sewerage sludge and how the influence of vegetation can be introduced in the stability calculations.

## 6 CONCLUSIONS

In the present General Report, 47 papers of the Technical Session on GI of the XVIII ICSMGE are reviewed. It can be noted that 40% of these papers deal with Deep Mixing and soil stabilization, proving the huge interest in these techniques. Similar percentage was already observed in the Proceedings of the TC211 IS-GI 2012 (Denies and Huybrechts, 2012) but this is not surprising, as these methods constitute outstanding and cost-effective sustainable construction processes.

Finally, beyond the choice of the GI solution, the necessity of monitoring was also highlighted by several authors of this Technical Session. For example, **van der Stoel et al. (2013)** discuss a well-documented case history concerning the realization of two deep excavations in the courtyards of a historical building in Amsterdam. Based on 2D FEM calculations, an extensive monitoring program has been proposed and performed (including levelling point measurements, inclinometers and the use of a permanent webcam). Thanks to this monitoring process the consequences of two important accidents during the execution of the excavations could be limited as much as possible. Most important was that the time delay remained very small. The authors conclude that the costs of the meticulous and proactive monitoring were minor in comparison with the potential costs of a delayed opening of the hotel.

If ground improvement is really become an efficient and controllable cost-effective alternative to classical foundation technique, measure still remains treasure.

## 7 ACKNOWLEDGEMENTS

The authors wish to thank the chairmen of the TC211 Jan Maertens and Serge Varaksin for their contribution to the review of the papers of the Technical Session on GI works.

# Time-dependent behaviour of foundations lying on an improved ground

## Temps-comportement dépendant de fondations reposant sur un sol amélioré

Alupoae D., Aşucei V., Răileanu P.

"Gheorghe Asachi" Technical University of Iasi, Faculty of Civil Engineering and Building Services, Department of Roads and Foundations, 43 Dimitrie Mangeron Bd, 700050, Iasi, Romania

**ABSTRACT:** The paper presents some aspects concerning time-dependent behaviour of the improved foundation soils. The foundation soils can develop favourable or inappropriate resistance properties under the loads submitted by constructions. Engineers and investors encounter more and more difficult foundation soils, in their desire to efficiently use the construction sites. In this case, physical and mechanical properties of the soil have to be improved, in order to sustain the infrastructure and structure of a building. The paper reviews some improvement methods, after presenting difficult foundation soils from Iaşi area. The paper presents a case study regarding problems caused by difficult foundation soils that are present in the region, during the operating period of structures. The presence of water in the foundation soil created a negative impact in its behaviour, which led to differential settlements and, consequently, the buildings were switching from their initial vertical position. The study also analyzes time-dependent settlements of a construction. Finally the paper presents some conclusions resulting from studies both bibliographic and practical.

**RÉSUMÉ :** Le document présente quelques aspects concernant le comportement en temps des sols améliorés pour les fondations. Le terrain de fondation peut avoir un comportement favorable ou par contre défavorable sous l'action des charges donner par les constructions. Pour utiliser efficacement les terrains des constructions, les ingénieurs et les investisseurs rencontrent souvent des sols de fondation de plus en plus difficile. Dans ce cas, les propriétés physiques et mécaniques du sol doivent être améliorées, afin d'assurer des bonnes conditions d'appuis pour l'infrastructure et la structure d'un bâtiment. Le document passe en revue les sols de fondation difficiles de la zone de Iaşi et des méthodes de les améliorées. Il est aussi présenté une étude de cas concernant les problèmes qui peuvent apparaitre au cours de la période d'exploitation de structures, a cause des ces sols de fondation difficiles. La présence de l'eau dans le terrain de fondation a eu un impact négatif sur son comportement, ce qui a produit des tassements différentiels, ca veut dire que les bâtiments furent commutés de leur position initiale, verticale. Pour conclure, le document présente des conclusions issues de l'étude bibliographique et pratique à la fois.

**KEYWORDS:** leaning structure, expansive clay, loess, differential settlement.

### 1 INTRODUCTION

As a result of the analysis performed over time on a large variety of soils and taking into account soil behaviour in the presence of external factors, the foundation soils can be divided in two categories, considering their capacity to support loads from constructions: good and difficult foundation soils.

The entire existence of the building system depends on the stability and strength of the foundation soil and this is the main reason why a special interest is given to the second category of soils and therefore to the specific issues that must be considered in the design, execution and operating period of a construction.

### 2 DIFFICULT FOUNDATION SOILS

The sites that have a construction soil with good geotechnical characteristics are rapidly decreasing. Large urban areas are a particular problem because, due to the lack of space, it is necessary to reconsider the possibility of placing a building on a soil that was unsuitable for constructions until now.

#### 2.1 Difficult foundation soils - classification

These soils are classified as follows:

- macroporous soils (present large cavities in their structure and have the ability to suffer large settlements when are subjected to a wetting process);
- collapsible soils (are characterised by the fact that when in high humidity develop large deformations);

- liquefiable soils (especially non-cohesive soils consisting of saturated fine sand which under the action of a dynamic load suddenly loose their shear strength);
- expansive soils (cohesive soils such as clays, which change their volume when water content varies);
- soils that during the freezing and thawing phenomena change their structure and properties;
- peaty soils (organic matter is present in its structure, have a high and very high compressibility and a low shear strength);
- eluvium (formed as a result of decomposition and alteration of existing rocks);
- saline soils (are characterized by the settlement phenomena that occurs during a long lasting wetting);
- fillings (occur as a result of unconsolidated alluvial deposits) (Iliesi 2012).

#### 2.2 Methods of soil improvement

Given the frequency of soils that present unfavourable characteristics for constructions over time were developed methods to improve their mechanical properties, such as:

- soil compaction which can be made on surface (rolling, dynamic, cushions) or in depth (columns, pre-wetting, dynamic);
- chemical soil stabilization (cementation, silicization, jet grouting, bentonite etc.);
- electrochemical methods (electrophoresis and electroosmosis);
- thermal treatment of soils.

The case study refers to the problems that can occur with an improved foundation soil. The method used for improvement is soil replacing (soil cushion).

### 3 CASE STUDY

Within the areas with difficult foundation soils, Iași City is the largest urban settlement located in the eastern part of Romania. The city lies at the contact between Jijia Meadow and the Moldavian Plateau. The landscape is varied, forming a region consisting of eroded hills crossed by Bahlui plateau.

#### 3.1 Soil types in the studied area

Studies performed over the last decades into the existing terraces of the region show that almost 70% from the current area of the city have medium and low suitability for construction purpose, this reason being more or less a natural barrier for city expansion. Theoretical and practical solutions offered for solving the issues caused by these types of soils present a special interest in the current context (Vieru 2010). Among these types of soils there are two specific categories: loess and expansive soils.

The different types of soils existing in the studied area have either a normal behaviour under loads, or an atypical one.

Therefore, upper and medium terraces consist of a succession of coarser sediments at the bottom followed by a loess soil sensitive to wetting. Loess layer is yellow-brown with variable thickness from 8.00 m to 15.00 m lying in the highest areas of the city. Loess deposits usually consist of silty clay and clayey silt.

The loess of Iași region has medium plasticity with the liquid limit  $LL = 30 \div 50\%$ . Grain-size distribution is:  $25 \div 29\%$  clay,  $43 \div 47\%$  silt and  $24 \div 32\%$  sand. Regarding the uniformity coefficient, the loess of Iași City is considered to have a good uniformity (Ciornei & Răileanu 2000).

Figure 1. Structural rearrangement for collapsible soils

Bahlui Meadow is characterized as a mixture of sand and gravel layers at the base of the stratification, followed by a layer of fat swelling and shrinking clay. The sand layer has a thickness of almost 4.00 m and the clay is between 5.00 m and 6.00 m. This clay is actually the foundation soil from the area, requiring good knowledge of soil characteristics.

As far as the soil properties are concerned, Bahlui clay falls within the category of high swelling and shrinking soils. Climatic conditions of the area, with temperatures decreasing in the summer with  $10^{\circ}\text{C} \dots 20^{\circ}\text{C}$  from day to night and heavy rainfall, lead to changes in soil volume. To avoid foundation deterioration the minimum foundation depth has been set at -2.00 m, as deep as the effects of seasonal variations in moisture content and temperature may not be felt (NE 001-96 1996).

Other factors influencing the volume variation are:

- soil activity – volume variation is influenced by molecular and electro-molecular phenomena reflected by adhesive and capillary water, their size depending on the mineralogical nature

of the particles making up the clay fraction and the nature of the absorbed ions;

- hydro-geological conditions – groundwater is present both through deep under pressure aquifers and also through free flow ones. Deep layers have a high mineralization, being intercepted only by drilling. They have an ascending nature, sometimes an artesian one. Shallow drillings revealed the presence of captive water with low mineralization, which can be used locally;

- layer thickness – the thicker the layer is, the bigger its swelling;

- moisturized area – if the wet surface under an existing building is insignificant, the deformations increase and the probability of deterioration grows (Alupoae et al. 2011).

Figure 2. Contraction breaks and cracks

#### 3.2 On site situation

The case study follows a residential area placed on one of the hills in Iași City, Romania. The increase of water content inside the foundation soil determined a differential settlement and the buildings placed on site were switched from their initial vertical position.

##### 3.2.1 Data regarding the constructions from the studied area

The constructions were built during two different time frames:

- Stage 1 – between 1994 and 1998, consists of a two section building 22.0 x 12.0 meters (Section I and Section II), has a total ground surface of 530 m<sup>2</sup>, a structure made of reinforced concrete frames placed on network of foundation beams. The foundation rests on a soil cushion, 1.0 meter thick. In 1998 the foundation system was checked and the results showed that the soil cushion placed under the foundation had a degree of compaction of 95.15%. Thus it can be stated that the operations of soil improvement using mechanical means were correctly carried out. On site, a layer of loess, sensitive to wetting, was intercepted in drillings up to 9.0 meters from the ground surface. Under the soil cushion the thickness of the loess layer is about 5.0 ÷ 6.0 meters.
- Stage 2 – the construction of Section III started in 2001, with a built area of about 850 m<sup>2</sup> and a structure and height similar to the initial sections. This section is not entirely finished and the main problem is the fact that no systematization works are carried out. Also, the systems of rainwater collection and disposal are not finished. Because of this, in 2010 a movement was observed.

After the initial observations, measures have been taken to analyze the technical condition of the building and to establish the necessary actions to ensure a proper exploitation for the constructions.

Figure 3. Photos showing on site displacements

### 3.2.2 Causes that led to differentiated settlements

The main cause that led to settlements on the studied case was determined by the increased humidity in the foundation soil. This happened as a result of a deficient vertical systematization: no sidewalks, there were no gradients on site to discharge the water and also there were not built ditches and surface drainage systems. The lack of systematization works led to rainwater infiltrations in the filling layer above the soil cushion used as an improving method for the loss soil on the site. Water bags were formed in the filling layer which supplied the permanent moisture on the layer above the cushion. The humidity of the cushion became 3.14% higher than the optimum compaction humidity (19.40%). Also the filling layer recorded higher values for humidity: 25.07% ÷ 27.52%.

Table 1. Humidity evolution on the site – filling layer

Section	Humidity 1998 [%]	Average humidity 1998 [%]	Humidity 2010 [%]	Average humidity 2010 [%]	Increase of humidity [%]
I	16.98 ÷ 29.16	24.78	19.57 ÷ 30.07	25.83	+4.20
II	17.18 ÷ 24.15	22.45	22.99 ÷ 32.85	26.90	+19.80
III	---	---	18.31 ÷ 33.04	24.40	---

Table 2. Humidity evolution on the site – soil cushion

Section	Humidity 1998 [%]	Average humidity 1998 [%]	Humidity 2010 [%]	Average humidity 2010 [%]	Increase of humidity [%]
I	21.15 ÷ 24.15	21.29	16.37 ÷ 23.81	20.53	-3.70
II	17.11 ÷ 23.69	20.63	18.40 ÷ 24.45	21.77	+5.50
III	---	---	17.61 ÷ 20.64	19.03	---

Figure 4. Humidity variation on the site, in the filling layer, for the three sections of the building

Figure 4. Humidity variation on the site, in the earth pillow, for the three sections of the building

Table 3. Humidity evolution on the site – surrounding area

Section	Humidity 1998 [%]	Average humidity 1998 [%]	Humidity 2010 [%]	Average humidity 2010 [%]	Increase of humidity [%]
I	20.70 ÷ 33.42	26.85	18.90 ÷ 29.36	22.30	-20.0
II	20.70 ÷ 33.42	26.85	18.90 ÷ 29.36	22.30	-20.0

Topographic measurements were made, on the site, for verifying settlements that appeared due to moistening of the foundation soil. By analyzing the results obtained after four cycles of measurements, the following conclusions can be drawn:

- for section I the measured values of settlements are insignificant. This happened because the values fall within the margin of error of the measurements and also because the variations determined at the markers considered stationary must be taken into consideration;
- for section II were found higher values of the settlements at the joint between section II and III. This occurs where the surface water penetrated the ground and produced a pronounced moistening of the foundation soil;
- for section III were also found higher values of the settlements at the joint between section II and III. This occurs where the surface water penetrated the ground and produced a pronounced moistening of the foundation soil.

Established settlements have small values and pose no danger to the behaviour of the building in time. Relative settlements have also small values,  $3.65 \cdot 10^3$  millimetres, much lower than the admissible relative settlement, which is, according to Romanian Standards, 0.001 millimetres.

The settlement speed decreases from 0.213 mm/day, after 9 days, to 0.061 mm/day after 22 days and further to 0.006 mm/day after 83 days. This led to the conclusion that settlements are slowing down.

### 3.2.3 Proposed solutions

Continuous monitoring of building settlements and conducting topographic readings at least every three months until the constructions are stabilized.

Efficient vertical and horizontal systematization can be done by making sidewalks, gradients for water discharge, ditches and surface drains.

For stopping water infiltration in the foundation soil is mandatory to check utility networks and repair them where is necessary.

## 4 CONCLUSIONS

Difficult foundation soils are frequently found on sites located in large urban areas.

Over time, a series of methods and techniques for improving the difficult foundation soils were developed. The implementation of this methods and techniques must take into consideration the soil characteristics intercepted on the site.

In the case of loess soils that are improved using soil cushions a good vertical and horizontal systematization is required to drain the rainwater or the water from other surface sources and to avoid the appearance of settlements.

## 5 ACKNOWLEDGEMENTS

This paper was realised with the support of POSDRU CUANTUMDOC “DOCTORAL STUDIES FOR EUROPEAN PERFORMANCES IN RESEARCH AND INNOVATION” ID79407 project funded by the European Social Fund and Romanian Government.

# Centrifugal and numerical analysis of geosynthetic-reinforced soil embankments

## Etude par centrifugeuse et analyse numérique des remblais renforcés par géotextile

Bo L., Linli J., Ningyu Z., Sinong L.

School of Civil Engineering and Architecture, Chongqing Jiaotong University, Chongqing, China

**ABSTRACT:** Centrifuge models and numerical analysis of geosynthetic-reinforced and unreinforced soil embankments are presented. The results obtained from the centrifuge tests were compared with those from the numerical analysis. It is found that the filamentous fiber (polypropylene) is effective in constraining lateral displacement and reducing vertical settlement for the case of geosynthetic-reinforced soil embankments. Also, the distribution of stress in the geosynthetic-reinforced soil embankment is significantly ameliorated compared with the unreinforced. The presence of geosynthetic filamentous fibers in reticular structure provides the reinforced soil embankments strength to resist crack.

**RÉSUMÉ :** Dans cet article, les résultats de modèles de centrifugeuse et les analyses numérique des remblais renforcés par géotextile et non-renforcés sont présentés. Les résultats obtenus à l'aide de la centrifugeuse sont comparés avec ceux des analyses numériques. Les fibres filamenteux (polypropylène) sont efficaces pour restreindre les déplacements latérales et réduire les tassements verticaux dans le cas du remblais renforcé. De plus, la répartition des contraintes dans le remblai renforcé est améliorée de façon significative comparé avec celle du remblai non-renforcé. La présence des fibres dans une structure réticulaire dans le remblai renforcé donne une résistance contre la fissuration.

**KEYWORDS:** Embankment ; Geosynthetic-reinforcement ; Centrifuge test ; Numerical analysis

## 1 INTRODUCTION

The concept and design theory of reinforced soil were proposed by the French engineer Henri Vidal from model tests in the 1960s. The reinforcement materials include metal strips, concrete slabs, bamboo ribs and geosynthetic materials, etc. Now-a-days, geosynthetics was commonly used in reinforcing soil owing to its easy-controlled properties of structure type and size, strength, impermeability, acid dissolution and durability.

“Cohesion” of filamentous fiber reinforced soil comes from friction between soil and fibers, as well as the constraint force of the fiber network. The magnitudes of CBR and unconfined compressive strength(UCS) increase with augment of filamentous fibers linearly(Xiong Youyan 1989). Soil reinforced with continuous filamentous fibers is obviously effective in reducing the vertical deformation of sand under the vertical pressure; it is superior in reducing horizontal tension than geogrids(A.F.L.Hyde and M.Ismail 1988). In recent years, this technique has applied successfully by reinforcing the embankment using filamentous fibers in embankment projects, and datum are available from researches (Bao Chenggang and Ding Jinhua 2012). However, the interaction micro-mechanism of interface between soil and filamentous fibers is still unclear (Tang Chaosheng, Shi Bin and Gu Kai 2011, Jie Yuxin and Li Guangxin 1999).

In this paper, the behavior of geosynthetic-reinforced embankments has been explored using centrifugal and finite element modeling. The objectives of this paper include: (1) to probe the mechanism of filamentous fibers in improving the stability of the embankment, and (2) to examine the effectiveness of filamentous fiber reinforcement.

## 2 CENTRIFUGE TESTS

Centrifuge model testing, because of its ability to reproduce same stress levels, same deformation and same failure mechanism in an 1/n scale model as in a full-scale prototype, is widely used in studying geotechnical problems. Jie Yuxin and Guang-Xin Li studied the stability of cohesive soil slope and fiber-reinforced soil slope with different densities through centrifugal model tests; Yang Xiwu and Ouyang Zhongchun

obtained the deformation behavior of embankments which reinforced with various fiber styles. It should be pointed out that idealized conditions may be created in centrifuge models carefully to avoid problems caused by stress errors, boundary effects, particle scale effects and geometrical scale effects.

### 2.1 Centrifuge tests—Equipment and procedure

#### 2.1.1 Equipment

In the present study, centrifuge model tests were performed using the TLJ—60 centrifuge in Chongqing Jiaotong University. The main parameters of the centrifuge are indicated in Table 1.

Table 1. The main parameters of the centrifuge

Characteristic	Value
Maximum volume weight	60g·t
Maximum load	600kg(100g) 300kg(200g)
Effective radius	2.0m
Maximum acceleration	200g
Acceleration control accuracy	±0.5%F·S
Model box size	600mm×350mm ×500mm

#### 2.1.2 Model scale

Due to the inherent symmetry of the embankment about its centerline, only one half of it was modeled. In order to simulate the actual project accurately and satisfy the boundary effects, 1:90 scale centrifuge model was constructed. Fig.1 shows the details of test model and its full-scale prototype.

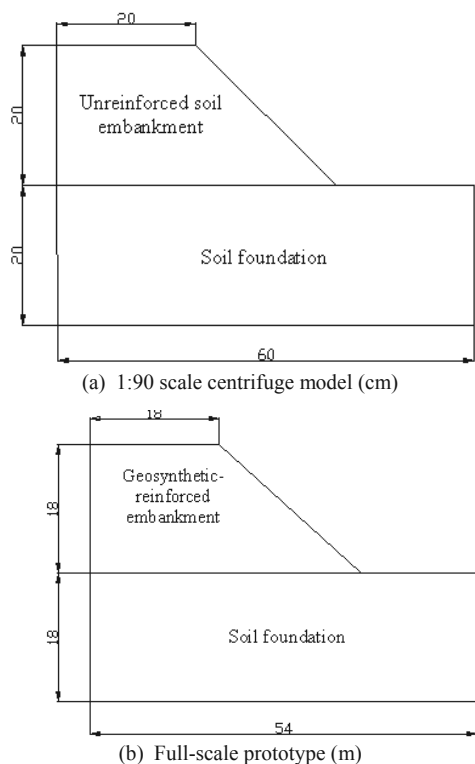

Figure 1. Arrangement of model for centrifuge test and its prototype

2.1.3 Parameters of soil and fiber

( 1 ) The physical parameters of the soil

Table 2 gives the parameters of the brown weathered shale that obtained from compaction test and liquid and plastic limit combined test.

Table 2. Brown weathered shale material properties

Optimm water content (%)	Maximm dry density (g/cm <sup>3</sup> )	Liquid limit (%)	Plastic limit (%)	Plasticity index
8.9	2.15	26.928	20.193	6.735

Before the centrifuge test, soil sample was experienced airing and grinding, then sieved by 6mm sieve to remove impurities.

( 2 ) The parameters of the fiber

Polypropylene fiber with 19mm length was proposed to construct the fiber reinforced soil embankment model. Table 3 gives the triaxial test strength of the embankment soil with the fiber ratio of 1 ‰, 2 ‰ and 3 ‰ respectively.

Table 3. Embankment soil material parameters

Embankment soil	Cohesion(kPa)	Friction angle(degrees)
Unreinforced soil	49.167	34.077
19mm-0.1%-Polypropylene-reinforced soil	94.005	35.717
19mm-0.2%-Polypropylene-reinforced soil	138.294	36.362
19mm-0.3%-Polypropylene-reinforced soil	228.356	35.951

2.1.4 Deformation measuring

An array of pins was installed on the front face of the embankment model as deformation marker. This was used for measuring the model vertical and horizontal displacement from coordinate difference between beginning of test and the end of test through the front perspex window. Fig.2 shows the details of the marked model.

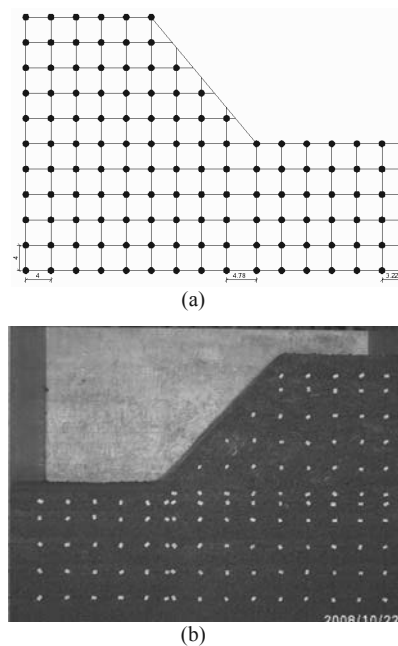

Figure 2. The marked model

2.2 Centrifuge tests—summary of results

2.2.1 Comparison analysis of deformation and displacement

In this section, the results obtained from unreinforced embankment test are compared with the results obtained from reinforced embankment test. The deformation of unreinforced embankment was slightly larger than the deformation of reinforced embankment. The settlements under the shoulder of the unreinforced embankment and the slope gradient were considerably greater than those of reinforced embankment. Two cracks on the top of the unreinforced embankment and (heave) beyond the toe of the unreinforced embankment were observed at the end of the centrifuge tests. Fig.3 and Fig.4 show the displacement vectorgraph of unreinforced and reinforced embankment respectively. From the close comparison between unreinforced and reinforced embankments, it is evident that fiber reinforcement reduced the displacement of embankment, and enhanced the embankment obviously.

Figure 3. Deformation of the unreinforced model

Figure 4. Deformation of geosynthetic-reinforced model

2.2.2 Comparison analysis of settlement

The maximum lateral displacement of unreinforced model was 72cm, which located in the distance of 8m from the toe of the embankment. The maximum settlement was 48.6cm, which located in the distance of 10.8m from the centerline; For reinforced case, the maximum lateral displacement emerged in the distance of 8.2m from the toe of the embankment with 35cm, and the maximum settlement was 41.2cm (located in the distance of 10.4m from the centerline). It is safely to conclude that the maximum displacement of both unreinforced and reinforced embankment approximately close to the same point, whereas the maximum lateral displacement of reinforced embankment is approximately equal to 48.6% of the maximum lateral displacement of unreinforced embankment and the maximum settlement of reinforced embankment is approximately equal to 84.8% of the maximum settlement of unreinforced embankment.

The comparison between computation analysis and centrifuge tests of the embankment discloses that fibers help to resist the lateral thrust and lateral deformation of the embankment effectively. This is due to the fact that fibers unified the overall redistribution of stress and reduced asymmetric settlement of embankment.

3 FINITE ELEMENT MODELLING

3.1 Assumptions of computing

In the analysis presented in this paper, the unreinforced and reinforced embankments are modeled using the Drucker-Prager constitutive model (D-P model).

Two-dimensional plane strain models were constructed with boundary conditions similar to those of centrifuge models. The modeling based on follow assumptions: (1) taking geotextile reinforced soil as homogeneously isotropic material, the parameters obtained from triaxial tests; (2) without considering the influence of temperature to embankment; (3) consolidation was completed under its gravity, and without considering the impact of pore pressure.

3.2 Parameters

Table 4. Material parameters specified for the finite element analysis

Characteristic	Unreinforced embankment	Polypropylene-reinforced embankment (19mm-0.1%)	Foundation
Density (kg/m <sup>3</sup> )	2150	2180	2150
Cohesion (kPa)	49.167	94.005	49.167
Friction angle(degrees)	34.077	35.717	34.077
Poisson's ratio	0.27	0.23	0.27
Depth of embankment(m)	18	18	36

3.3 Displacement comparison

The computed results indicated that the values of deformation and stress as well as its fluctuation range were marginally less for reinforced embankment than for unreinforced embankment. The maximum lateral displacement of unreinforced model was 79.442cm (located in the distance of 11.4m from the toe of the embankment), and the maximum settlement was 51.498cm (located in the centerline); The maximum lateral displacement of reinforced model was 38.246cm (located in the distance of 11.4m from the toe of the embankment), and the maximum settlement was 48.318cm (located in the centerline). Fig.5 and

Fig.6 present computed displacement and stress contours of the unreinforced and reinforced models respectively.

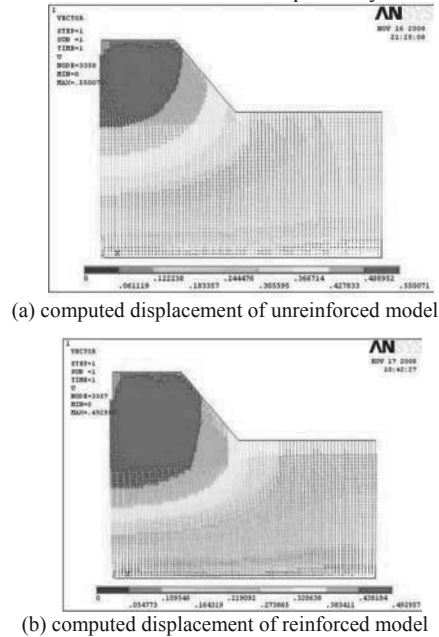

Figure 5. Computed displacement of unreinforced and reinforced model

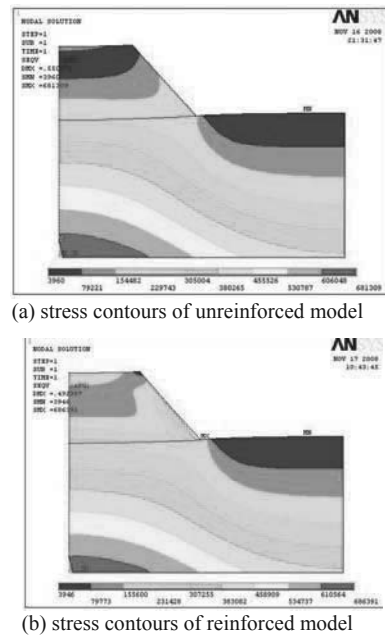

Figure 6. Stress contours of unreinforced and reinforced model

4 RESULTS AND COMPARISONS

Fig.7 shows the variation of lateral displacement and vertical displacement of unreinforced embankment from centrifuge tests. Superimposed on the measured variation are the variations computed by numerical modeling analysis. It can be seen from Fig.7 that there is a close agreement between the observed and computed displacements for centrifuge test and numerical analysis.

Figure 7. measured and computed displacement of unreinforced model

The comparison between the computed and observed displacement both in the horizontal direction and in the vertical direction for the reinforced embankment are shown in Fig.8. The computed displacement is quite close to the observed values for both lateral displacement and vertical displacement.

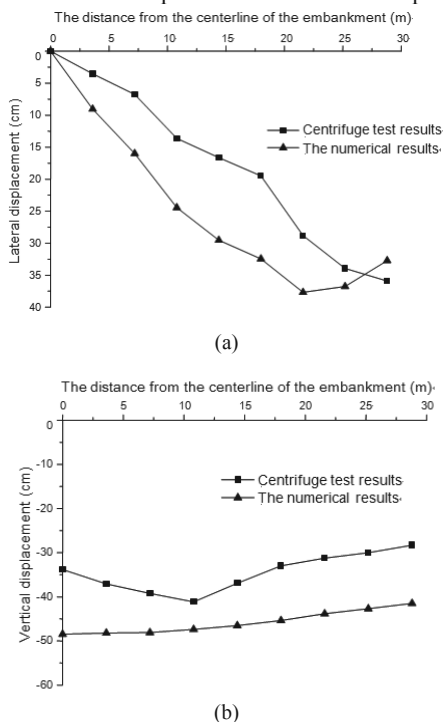

Figure 8. Measured and computed displacement of reinforced model

The behavior of reinforced embankment and unreinforced embankment was successfully investigated using centrifuge modeling and finite element analysis. The comparisons between the centrifuge tests and computed results indicated the utility of fibers can enhance overall stability of embankment. For the case of reinforced embankments with fibers, it was found that the deformation, the magnitude of stress, and their variation range was considerably less than those for unreinforced case. Also, the fiber reinforcement constrained the lateral displacement

effectively, and the distribution of stress and deformation was harmonious comparing with the unreinforced.

When using geosynthetic fibers to reinforce embankment, it also shows two advantages: (1) reinforced embankment can resist cracks due to the network of intertwined fibers, and(2) the fiber reinforced soil is closer to a homogeneous, isotropic material than unreinforced soil.

**ABSTRACT:** Moisture-sensitive or collapsible soils are materials with high porosity that under the loads transmitted by the foundations present additional settlements once the soil is saturated. This category includes loess deposits and other high silt content soils with uneven porosity. A method often used for foundation on these soils is the realization of local loessoid material compacted columns. According to the Romanian legislation, it is forbidden to use granular material in loessoid soils. A compromise may be reached by using a mixture of granular material and local loessoid soil in columns. This paper presents the experimental laboratory program aiming to achieve an optimal mixture of local material (loess) and monogranular sand in order to improve the values of the mechanical soil parameters while keeping the permeability coefficient values as low as possible. This objective can be achieved by adding bentonite. On the experimental polygons, 1:5 scale compacted soil columns were made using a dynamic penetrometer. The aim of the dynamic penetration tests performed in the center and between the columns was to obtain results concerning the improvement of the mechanical characteristics of the columns and the foundation soil.

**RÉSUMÉ :** Les sols effondrables sont des matériaux avec une porosité élevée, qui, suite à la saturation, présentent des tassements supplémentaires sous l'effet des charges transmises par les fondations. Cette catégorie inclue les dépôts de loess et d'autres sols ayant un contenu élevé de silt avec une porosité irrégulière. Une des méthodes de fondation souvent utilisée sur ce type de sols est la réalisation de colonnes de matériel loessique compacté. Bien que la législation roumaine interdise l'utilisation de matériaux sableux dans des sols loessiques, ceux-ci peuvent toutefois être utilisés pour la réalisation de colonnes dans un mélange avec du sol loessique. Cet article présente un programme expérimental de laboratoire qui vise à réaliser un mélange optimal de matériaux loessiques avec du sable pour améliorer les valeurs des paramètres mécaniques du sol, en maintenant toutefois les valeurs du coefficient de perméabilité le plus bas possible. On peut atteindre cet objectif par l'addition de bentonite. Dans le cadre d'un programme expérimental, on a réalisé des essais à l'aide d'un pénétromètre dynamique sur des colonnes de sol compacté à une échelle de 1:5. Le but des essais de pénétration dynamique a été d'obtenir des résultats concernant l'amélioration des caractéristiques mécaniques des colonnes et du terrain de fondation.

**KEYWORDS:** collapsible soils, compacted soil columns, dynamic penetration test, soil mixtures.

## 1 INTRODUCTION

Moisture-sensitive or collapsible soils are unsaturated macroporous cohesive soils that, upon saturation with water, undergo sudden and irreversible changes of the internal structure, reflected by additional settlements with collapsing character and decreases in the values of geotechnical parameters of mechanical behaviour (NP 125: 2010).

Figure 1. Collapsible soil spreading in Romania (Bally, Antonescu 1971)

In Romania, moisture-sensitive soils cover about 19% of the country's territory (approx. 40.000 km<sup>2</sup>) and it is common particularly in the eastern part of the country (Figure 1).

In order to characterize a soil as moisture sensitive, it must meet at least one criterion regarding the physical characteristics and one criterion regarding the mechanical behaviour, the main criteria being the following:

A. Criteria regarding physical characteristics:

- ratio of silt fraction: 50 – 80%
- degree of saturation:  $S_r < 0,8$
- porosity in natural state:  $n > 45\%$

B. Criteria regarding mechanical behaviour:

- the index of the additional settlement caused by saturation under a loading of 300 kPa (in oedometric test):  $i_{m300} \geq 2\%$ .

## 2 IMPROVEMENT METHODS FOR COLLAPSIBLE SOILS

Difficult foundation soil improvement methods are continuously progressing, not only quantitatively, but also qualitatively, as a result of both the development of new technologies and the recognition of economic and environmental protection benefits of modern methods.

A significant number of techniques aimed at improving the mechanical characteristics of difficult foundation soils have

been developed. Methods are divided into two wide categories (Schlosser 1997):

- physical methods – soil improvement technologies, by which soil structure is mainly improved in what concerns contacts between particles by additives or by reducing porosity in order to increase the tamping state - physical characteristics improvement methods;
- mechanical methods – soil reinforcing technologies, by which structural elements are introduced in the ground in order to increase the mechanical strength – mechanical characteristics improvement methods.

Classification of results sought by difficult foundation soil improvement (Kirsch, Sonderrmann 2003):

- increasing density and shearing strength
- reducing compressibility
- influencing permeability in order to reduce infiltrated water flow or to speed up consolidation process
- improving homogeneity.

### 3 LABORATORY TESTS

In the experimental programme, various mixtures of loessoid material with different natural mineral materials have been proposed, in view of eliminating moisture sensitiveness, improving geotechnical parameters of mechanical behaviour and limiting permeability (Burlacu 2012).

To this purpose, a series of mixtures have been proposed: loess with sand 1-2 mm ( $C_u = 1.5$ ) and loess with sand and bentonite powder addition in two variants of mixture. The obtained mixtures are presented below:

Mixture 1: 80% loess + 20% sand (1-2 mm);

Mixture 2: 60% loess + 40% sand (1-2 mm);

Mixture 3: 50% loess + 40% sand (1-2 mm) + 10% bentonite;

Mixture 4: 50% loess + mixture from (40% sand (1-2 mm) + 10% bentonite);

The difference between the last two mixtures consisted in the way they were mixed. In the first case, all the three materials were simultaneously mixed and then water was added to reach different degrees of humidity in order to perform the normal Proctor test. In case of the last mixture, the sand was first mixed with the bentonite and with water and then, after this mixture had dried, it was also mixed with the loess (Olinic 2012).

As a first step, the optimal compaction characteristics of the proposed mixtures were determined and then, based on the compacted samples, the compressibility and shearing mechanical characteristics and the possible moisture-sensitivity of the compacted material were determined. The samples used for carrying out the mechanical tests were the ones surrounding the optimum compacted sample. In order to reach uniform results, the variation of the density in dry condition depending on the height of the compacted sample was analyzed and confirmed (Figure 2). This is why a certain sampling order was followed.

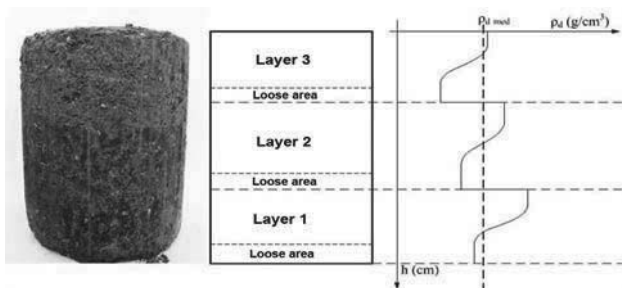

Figure 2. Dry density theoretical variation depending on the height of the compacted sample.

As a result of the Proctor test outcome analysis (Figure 3), it has been observed that along with adding up and increasing the

percentage of sand in the mixture (from 20% to 40%), the maximum density in dry condition increases. At the same time, the optimal compaction moisture of the mixtures decreases

The synthesis of the oedometre compressibility tests depending on the oedometric moduli values indicated that the same values  $E_{oed\ 200-300}$  could be obtained for the mixture containing an addition of sand of 20%, at smaller humidity values and at a better tamping state than in case of the natural loess samples. This trend disappeared once the percentage of sand in the mixture was increased (40%). In what concerns samples with bentonite, similar values of oedometric moduli were obtained at a better tamping state that in case of medium loess samples, but at a reduced tamping state than in case of samples with sand, which was also confirmed by the values obtained following Proctor tests.

Figure 3. the results of the Proctor trial for all the mixtures obtained.

If, in case of mixture 3, the Proctor diagram has a maximum point ( $\rho_{dmax}, w_{opt}$ ), in case of mixture 4, the same tamping state was obtained for humidity values between 11% and 15%.

The Proctor diagram resulted for mixture 4 indicated that sample 3 could have represented a maximum point. Therefore, in order to validate the results, tests on this sample were carried out again and similar values were obtained (Figure 4). Given that, humidity plays a key role in the real scale compaction process, the last indication regarding mixture 4 is important because it allows compaction at humidity values belonging to higher humidity domains.

Figure 4. Results of Proctor test for mixtures 3 and 4.

As to the values of the permeability coefficient, these have been of the order of  $10^{-5}$  cm/s for the average loess sample rising up to values of  $10^{-4}$  cm/s in case of the mixture containing 40% sand, while in case of the mixtures containing an addition of bentonite, the measured values were below  $10^{-9}$  cm/s.

#### 4 IN SITU TESTS

In-situ tests first aimed at identifying the effect of the cone shape on: the rate at which the cone advances in the ground, the tamping of the surrounding ground and the compaction degree of the material in the column body. Three types of cones with a diameter of 7 cm were made. (Figure 5).

Figure 5. Cones made: a) C1 – 30°; b) C2 – 60°; c) C3 – hemisphere.

##### 4.1 Column execution technology

Collapsible soils improvement by soil columns is regulated by normative C29 - 85. The experimental polygon met the column execution methodology described in the normative but adapting it to the equipment that has been newly proposed for their execution (LMSR-Hk dynamic penetrometer).

Column execution steps are: column hole execution, filling by fill material portions and fill material compaction until rejection.

The fill material portion was set for a column with a diameter of 7 cm and for a height of the compacted material of 21 cm (3 diameters), resulting 1,5 kg of material having optimal compaction humidity.

Successive tests regarding the obtained compaction degree indicated that rejection (compaction stopping) was reached after an advance of maximum 7mm/blow.

##### 4.2 Optimal cone shape

On the experimental polygon, columns were executed by using the three types of cones. Figure 6a presents the blow number variation per an advance of 10 cm in DPM tests performed in the centre of the columns and Figure 6b presents the same tests carried out at a distance of 2 diameters towards the column.

Figure 6. Results of DPM tests carried out in the centre of the columns and at a distance of 2Dc (14cm) towards the columns.

In case of DPM tests carried out in the centre of the columns, the results obtained were similar for all the columns. Therefore, an optimal shape of the cone that leads to a better compaction of the column body could not be found.

Then, for determining the cone with a wider influence radius, DPM tests were carried out at a distance of  $2D_c=14$  cm towards the columns. These tests indicated [as expected given its shape (the smallest angle at the top)], that cone no. 1 ( $30^\circ$ ) had the greatest influence on the tamping state of the soil around the column.

The tests indicated that cone 1 shape ( $30^\circ$ ) was optimal for soil columns execution.

##### 4.3 Compacted loess columns

Therefore, 2 m long columns were executed, arranged as an equilateral triangle network (Figure 7) with a distance of  $3D_c - 21$  cm between the columns.

After finishing the group of columns, average dynamic penetration tests were conducted both between the columns and at different distances towards them.

Figure 7. Columns and DPM tests disposal.

Figure 8. DPM tests results: a) between the columns; b) @ 1Dc; c) @ 2Dc; d) @ 3Dc.

It may be observed that, at a distance of  $3D_c$  near the columns, the improvement effect has no longer been perceived (Figure 8d). When the DPM test was carried out in the centre of the column group (Figure 8a), the improvement effect recorded an obvious increase.

#### 4.4 Loess and sand mixture compacted columns

Finally, on the experimental polygon columns of 60% local material (loess) and 40% sand were executed. For the execution of these columns, cone 1 (30°) was also used as rammer.

Figure 9. DPM tests results for the column executed from a mixture of loess and sand (N1): a) DPM in the centre of C1 and N1 columns; b) DPM at 2Dc towards C1 and N1 columns

Figure 9a indicates that the results of the DPM tests carried out in the centre of the column executed from a mixture of loess and sand are better than those of the column made entirely of loess. Moreover, it may be noticed that, unlike the compacted loess column, the one made of mixture led to the improvement of the material under the column's body.

Nevertheless, the results of the medium dynamic penetration test carried out near the columns at a distance of 2Dc (~14 cm) indicate that the tamping effect is higher than in case of the loess column.

## 5 CONCLUSIONS

Laboratory tests aimed at identifying a mixture of loess and natural mineral materials, with better mechanical characteristics and with reduced permeability compared to the one the loess has in its natural state. From all the solutions proposed (compacted loess, mixture of loess and sand and mixture of loess, sand and bentonite) the last one (mixture 4 - sand and bentonite, mixed with loess after drying) seems to be the optimal one due to the wide domain in which optimal compaction parameters are reached.

Concerning mechanical characteristics, no significant differences seem to exist between the analysed mixtures, but one can notice that water sensitivity is significantly reduced and that, compared to the flooded loess, the values obtained are significantly better.

In-situ tests, performed with a penetrometer, simulated the execution of loess columns and of loess with compacted sand columns, at a scale of 1:5. Both the quality of the material in the column body and the effect on the surrounding ground were verified by typical tests. The sand improves the mechanical behaviour of the material in the column body, without significantly exceeding the mechanical behaviour of natural loess that has not been flooded.

By executing columns of compacted local material with natural mineral materials, the mechanical behaviour of the columns - loess complex that has not been flooded does not improve, but this technique leads to some nuclei capable of reducing the negative effect of the accidental flooding of loess.

# Selected problems connected with the use of the jet grouting technique

## Certains problèmes liés à l'application de la technologie d'injection de jet

Bzówka J., Juzwa A., Wanik L.  
*The Silesian University of Technology, Gliwice, Poland*

**ABSTRACT:** The paper presents selected problems connected with the use of the jet grouting technique. It is one of the most popular methods for subsoil strengthening, enhancement for existing foundation, vertical and horizontal waterproof cut-off walls. Columns made using this method feature a high bearing capacity (very high friction on the shaft). The newest achievements of the numerical explanation of the interaction between jet grouting columns and subsoil are presented in the paper. The created models will be used to verify engineering methods of jet grouting columns dimensioning. Computational analyses are conducted using software based on the finite element method (Z\_Soil).

The computational model describes the interaction between a group of jet grouting columns and soil. The main element of this analysis consists of selection and calibration of computational model of the "group of jet grouting columns – subsoil" interaction. The model space is divided into three zones: columns, soil and the contact layer formed between the columns and the soil massif. The computational model allows for a plastic character of deformation under load and especially for a non-linearity of contact zone. The description of shape of a shaft surface of jet grouting columns is very difficult, so the fractal theory is used to describe this shape. Fractal and box dimensions are used to estimate the irregular surface. This model allows a precise selection of formation parameters, like the injection rod pull out velocity and number of rotations, injection pressure and the water/cement ratio, which define the geometry of jet grouting columns.

**RÉSUMÉ :** Cet article présente quelques problèmes liés à l'utilisation de la technique d'amélioration des sols : le jet grouting. Cette technique est une de méthodes les plus utilisées pour renforcer le sous-sol, les fondations déjà existantes et on s'en sert aussi comme les parois verticales et horizontales étanches (imperméables à l'eau). Les colonnes réalisées par cette méthode se caractérisent par la grande capacité portante (coefficient de frottement très élevé sur la surface latérale). Dans cet article, on présente les découvertes les plus récentes liées aux modélisations numériques de l'interaction entre les colonnes de jet et du sol. Les modèles développés seront utilisés pour vérifier les méthodes d'ingénierie et pour dimensionner les colonnes de jet grouting. Les analyses numériques sont effectuées par les programmes basés sur la méthodes des éléments finis (Z\_Soil).

Le modèle de calcul décrit l'interaction entre un groupe de colonnes de jet grouting et le sol. L'apport le plus important de cette analyse réside dans le choix et le calage du modèle de calcul pour l'interaction « groupe de colonnes de jet grouting – sol ». L'espace du modèle est divisé en trois zones: colonnes, sol et couche de contact formée entre les colonnes et le massif du sol. Le modèle de calcul permet d'avoir des déformations plastiques et en particulier de déformation non-linéaire de la zone de contact.

La description de la forme des surfaces latérales de ces colonnes est extrêmement difficile, alors on a introduit la théorie de fractales pour la décrire. Les dimensions de type fractal et de boîte, sont utilisées pour estimer la surface latérale irrégulière des colonnes. Ce modèle permet de choisir d'une manière précise des paramètres de formation des colonnes tels que: vitesses - de rotation et d'avancement en descente de la tige de forage, le nombre de rotation, la pression de coulis injecté, rapport eau/ciment, qui définissent la géométrie des colonnes de jet grouting.

**KEYWORDS:** jet grouting technique, interaction between columns and subsoil, shape and dimensions of jet grouting column.

### 1 JET GROUTING COLUMNS INTERACTION WITH SUBSOIL

The jet grouting method is frequently used in the engineering practice. It may be used for nearly all types of soils, both natural and man-made. It does not work only for a subsoil built of organic soils. The method consists in a high-pressure injection into the subsoil of an injectant stream (most often being a cement grout), which cuts and disintegrates the soil body, forming – after binding with soil fractions – a petrified soil-cement composite of any geometrical form, e.g. close to a column cylinder shape. This solution – because of the speed of performance and very good parameters of subsoil strengthening – is frequently used to strengthen a weak subsoil under high transport embankments or bridge abutments (Bzówka 2009; Juzwa 2012b; Modoni and Bzówka 2012).

To explain the interaction between the jet grouting columns and the strengthened subsoil it is suggested to apply numerical methods and to build models reflecting the operation of a single column and the interaction of jet grouting columns group in

transferring the load to deeper soil layers. A solution is sought, which would allow optimising design solutions of jet grouting columns, would ensure safety of a structure designed this way and at the same time would contribute to the works costs cutting. The authors emphasise especially as precise as possible reflection of real conditions, existing on a site.

A single column and a group of columns are the subject of numerical and in situ analysis. A single column is an idealised form, seldom existing in practice. However, the analysis of its behaviour is a starting point to make models more realistic and built of a group of columns. For the needs of analysis of interactions occurring between jet grouting columns strengthening a weak subsoil and the soil body numerical models were constructed, considering the environment division into three material zones: the soil-cement material of jet grouting columns – the contact layer – the subsoil (Bzówka 2009, 2010).

Because of a physical inhomogeneity and of a complicated geometrical arrangement the finite element method was used to

build models and the Z\_Soil software was used for computations. An elastic – ideally plastic model of Coulomb – Mohr boundary surface with non-associated law of flow were adopted to describe the mechanical behaviour of the soil environment and the jet grouting columns material.

To perform computer simulations it is necessary to give the following parameters: angle of internal friction  $\Phi$ , angle of dilatancy  $\Psi$ , cohesion  $c$ , modulus of elasticity  $E$  and Poisson's ratio  $\nu$ . Values of parameters for soils building the model subsoil were taken based on in situ tests on a test site. The following values were taken, for sand:  $E = 55.5$  MPa,  $\nu = 0.3$ ,  $\Phi = 31.8^\circ$ ,  $c = 1$  kPa, for a cohesive soil interbedding:  $E = 33.8$  MPa,  $\nu = 0.3$ ,  $\Phi = 18.0^\circ$ ,  $c = 30$  kPa. The value of angle of dilatancy was introduced from the range of values  $\Psi = (0.35-0.40) \cdot \Phi$ . Determination of material parameters for a cement–soil material depends on the subsoil ground characteristics, cement type in the grout, the method of columns performance. To determine them it is necessary to take core samples from the column performed (Fig. 1). These samples are then tested for uniaxial and triaxial compression. For the needs of this study 10 samples were tested for each case, obtaining results of significant scatter (Bzówka 2009). A statistical analysis of result values was carried out and after approximation with the first type regression function the following parameters were taken for calculations:  $E = 9888$  MPa,  $\nu = 0.186$ ,  $\Phi = 59.3^\circ$ ,  $c = 1772$  kPa. Values of soil parameters ( $E$ ,  $\nu$ ,  $\Phi$ ,  $c$ ) were taken for the contact zone based on CPT sounding performed in this area. Their values equal to soil parameters reduced by 1/3.

Figure 1. Core samples for strength tests (Bzówka, 2009).

A 2D model was built cutting from the space around columns an area large enough, allowing idealisation of boundary conditions. Boundary conditions were taken in the form of: full fixing of the base of the half–space cut and partial fixing, allowing a vertical shift, on side surfaces of the half-space

In the model of a flat system a group of 3 columns was taken, each of them 4.0 m long and 0.8 m in diameter, arranged at a distance of 2.5 m, while the subsoil is stratified. Division into quadrilateral isoparametric elements was assumed. The grid was concentrated in the area of contact zone. An incremental load (uniform for all columns) was applied to such system, reflecting a real transport embankment 4.0 m high, laid at fixed intervals in layers 0.5 m thick.

The image of system deformations caused by columns loading is presented for two stages in Fig. 2. Corresponding stresses are shown in Fig. 3. The stress maps perfectly show the range of transition zone, which parameters affect the distribution of internal forces values in the system (Bzówka et al. 2012; Juzwa 2012a).

## 2 GEOMETRY OF JET GROUTING COLUMNS

The shape of columns made by the jet grouting technique, due to specific nature of this technology, is very diversified and difficult to predict. It depends inter alia on the type and condition of soils making the subsoil, the injection system used (single, double or triple) and on technological parameters (injection pressure, size and shape of injection nozzles, speed of injection rod pulling out and rotations and others) (Wanik and Bzówka 2012).

To determine precisely the geometry of jet grouting columns they are excavated, making their measurement and macroscopic visual inspection possible. The shaft may have various shapes (Fig. 4) depending on the aforementioned factors.

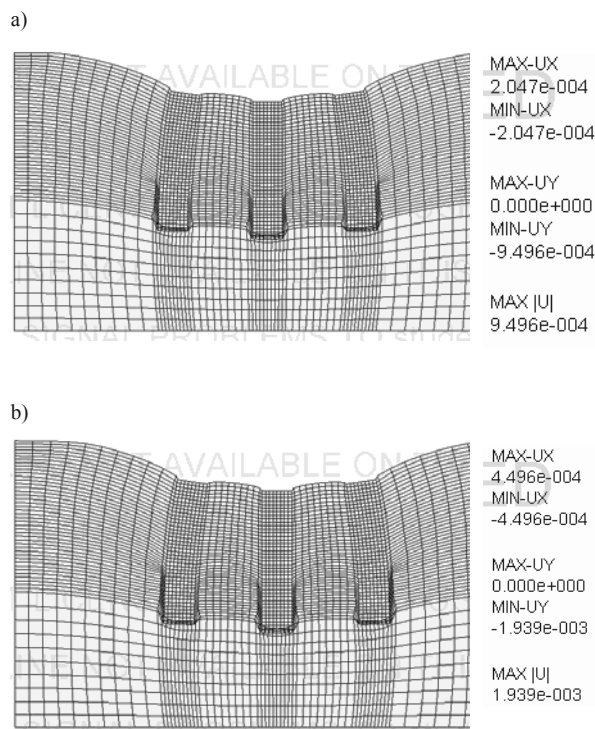

Figure 2. Model deformations [m] under influence of the load of embankment: a)  $h=2.0$  m; b)  $h=4.0$  m high (Z\_Soil) (Bzówka et al. 2012; Juzwa 2012a).

Fractal theories may be used to describe an irregular surface of jet grouting columns. Using a fractal and a box dimension it is possible to describe better an irregular shaft surface of a jet grouting column, its shape and roughness. A more precise description of roughness and geometrical parameters of soil particles allows a more detailed determination of such properties as: porosity, density and shear strength (Bzówka and Skrzypczyk 2011).

The paper presents an example of fractal dimension and box dimension calculation for an excavated jet grouting column made in a single system (see Fig. 6÷8). Results of studies presented in papers (Kawa and Wieczorek 2005; Wanik 2012a, 2012b; Wanik and Bzówka 2012) have been used.

The described jet grouting column was made in average compacted medium sand, under which a stiff silty clay was situated. After column excavating and cleaning, an irregular shaft surface was disclosed and also a clear change of column diameter on the boundary of two layers forming the subsoil (see Fig. 5).

Figure 3. Map of vertical stresses of the model under influence of the load of embankment: a)  $h=2.0$  m; b)  $h=4.0$  m high ( $Z_{Soil}$ ) (Bzówka et al. 2012; Juzwa 2012a).

### 3 SUMMARY

Issues presented in the paper show the scale of problems related to the representation of actual interaction of jet grouting columns with the surrounding subsoil. Theoretical models require repetitions and calibration, making the obtained results realistic. It is especially important to determine the thickness and parameters of the contact zone formed at the contact of column material and the subsoil.

The shape and dimensions of formed jet grouting columns depend on the type and condition of soils building the subsoil and on technological parameters of columns forming, such as: the injection pressure, the injection rod pulling out and rotation speed, the density of injected cement grout as well as the number and size of injection nozzles.

A large number of factors affecting geometry and hence related columns bearing capacity and the soil-cement material strength causes problems in designing. To verify geometry of columns made it is necessary to perform excavations and to measure the diameter, circumference shape and to assess the shaft structure. Mathematical issues from the field of fractal and box dimension allow creating a clear description of a complicated shape of jet grouting columns shaft.

**ABSTRACT:** Ground improvement methods based on column-type elements are analyzed regarding the influence of the column properties on serviceability and safety of the Column Supported Embankments (CSE). Particularly, treatments made by rigid inclusions are analyzed and compared with stone columns. Stiffness of column-type elements determines the design and risks involved. Rigid inclusions are analyzed according to the recent French national project ASIRI. In the case of these elements, a considerable mobilization of negative skin friction and punching effects governs their behavior in the Ultimate Limit State, which represents a non-ductile mechanism of failure. Whereas stone columns present a ductile behavior determined in the domain of Serviceability Limit State (SLS). It is pointed out, that possible damages on CSE systems may extend settlement stabilization due to the consolidation process, if no drainage elements are adopted. It is also noted that risks related to rigid columns in the SLS under cyclic loading, may be decisive in the design of CSE composed by low-heights embankments. Briefly, it could be stated that rigid inclusions present higher risks, increasingly when their diameters are smaller than 30 cm.

**RÉSUMÉ :** On analyse les méthodes d'amélioration des sols avec des colonnes pour la fondation des remblais sur sols mous. En particulier, on analyse les inclusions rigides selon les recommandations du récent projet national français ASIRI, et on présente la comparaison avec des colonnes ballastées. La rigidité de la colonne détermine la conception et les risques associés. Dans le cas des inclusions rigides, une mobilisation considérable du frottement négatif et la portance résultante gouvernent leur comportement dans l'état limite ultime, ce qui représente un mécanisme non-ductile de rupture. Au contraire, les colonnes ballastées présentent un comportement ductile déterminée dans le domaine de l'état limite de service. Il a été observé que les risques de colonnes rigides dans les ELS peut être retardés à moins que on installe quelques éléments de drainage. On a remarqué aussi que les risques associés aux inclusions rigides soumises aux chargements cycliques peuvent être décisives pour remblais de faible hauteur. Ainsi, les inclusions rigides présentent des risques plus élevés, de plus en plus lorsque leur diamètre est plus petit que 30 cm.

**KEYWORDS:** Load Transfer Platform, geosynthetic, embankment, rigid inclusion, stone columns, risk, stiffness, arching effect

## 1 INTRODUCTION

Column Supported Embankments (CSE) represent an innovative solution for transport infrastructure over soft soils, in order to reduce execution time and general earthworks. Hence, the use of low-height embankments based on column-type elements tends to be preferred, whenever possible, instead of direct soil replacement or preloading with or without vertical drains. Recently, the use of CSE is increasing, and consequently growing interest in developing reliable and unified criteria for their design and construction is observed.

However, due to the possibility of application of a wide range of ground improvement techniques, further risk assessment has to be done. Risks and reliability related to CSE could be largely analyzed considering the influence of column stiffness in Ultimate and Serviceability Limit States. Furthermore, column stiffness also affects consolidation process and the system behavior against cyclic or dynamic loading, very often decisive for safety and serviceability.

## 2 COLUMNS SUPPORTED EMBANKMENT SYSTEMS

### 2.1 Type of columns

Typical elements of CSE systems are shown in Figure 1. Initially, reinforced piles with concrete cap were applied, in order to absorb the largest load of embankment as possible. In

order to optimize the solution, ground improvement methods have been increasingly used in the last years.

Ground improvement methods should intent not to take the entire action by the supporting elements, but only the difference between the required and existing bearing capacity without improvement (Wehr et al. 2012). This is applicable to stone and sand columns, which take important part of the foundation load, and make the most of soil confinement to ensure its own capacity. These two types of columns accelerate the consolidation process and do not need any embedment to transfer the loads to stiffer soil layers; thereby they can be considered as authentic ground improvements.

On the other side, the columns made by the addition of bonding agents, mortar or concrete into the ground, do not accelerate consolidation. The improvement introduced by such columns mainly consists of the load transfer to the stiffer layers in the same way as piles, thus, to ensure their correct application the largest embedment is frequently desired.

Figure 1. Elements of Column Supported Embankment Systems

Figure 2. Mechanism of load transfer in the CSE: (a) approaches of arching-effect shape; (b) results of laboratory test performed by Chen et al. (2008); (c) load transfer mechanism proposed by Combarieu (1974, 1988); (d) influence of confined modulus on improvement factor (Kirsch 2004).

These kinds of columns, with predominantly round cross-sections of 25 cm to 80 cm diameter, are denominated Rigid Inclusion according to the French national research project ASIRI (Améliorations de Sols par Inclusions Rigides). Rigid inclusions may be arranged in a regular grid, although, due to horizontal stresses sometimes have to be distributed in wall or panel form in order to overcome slope and internal instability.

### 2.2 Load Transfer Platform

The design and operation of CSE is largely influenced by the load transmission mechanism toward the columns, through a Load Transfer Platform (LTP) laid out at the base of embankment. LTPs are generally composed by a layer of compacted granular material that in many cases has to be reinforced by geosynthetics, or composed by layers treated with hydraulic binder.

LTP behavior is essentially determined by two parameters. The efficacy or efficiency  $E$ , defined as the ratio between load on the column head  $Q_p$  and the total load on the surrounding soil within a unit cell ( $W + Q$ ), where  $W$  is the weight of embankment and  $Q$  is the force due to surcharge on the surface; and the critical Height  $H_c$ , which indicates the height of embankment where differential settlements in between column head and middle of the grid are negligible. As stated by several authors,  $E$  and  $H_c$  depend on many factors such as column rigidity, shear strength of LTP layers, spacing between columns, and soft soil stiffness (Zaeske and Kempfert 2001, Okay 2010).

Most theoretical methods focus on the requirements of the geosynthetic within LTPs for piled embankments, considering a void between rigid elements. The geosynthetic takes the load that remains in the middle of columns and delivers it to the column heads by means of membrane effect. Consequently almost all load is acting on the columns heads. According to these methods only a minor part or even any soil reaction is considered. Several guidelines or recommendations documents deal with these methods (BS8006 2010, EBGeo 2010, Nordic Handbook 2005). Such approaches could be classified according to the shear stress form-distribution that governs the mechanism of arch load-transfer and differential settlements within the LTP (Han and Colling 2005), see Figure 2a. According mentioned approaches  $H_c$  varies from 0.7 to 1.6 times the clear distances between columns ( $s - a$ ).

Figure 3. Influence of column modulus on the differential settlements within Load Transfer Platform (Gangakhedar 2004).

Otherwise, the method proposed by Combarieu (1974, 1988), and adopted in the ASIRI Recommendations, deals not only with the load transfer into LTP but also along the entire length of rigid columns. Furthermore, ASIRI project's recommendations are based on various physical and numerical modelling (Jenck 2005, Chevalier et al. 2008).<sup>1°</sup>

Figure 2c shows the mechanism of load transfer proposed in the ASIRI, where differential settlements between soil and columns produce negative skin friction in the upper part of the column; at certain depth where settlements are the same in soil and columns, the skin friction is equal to zero, and below this neutral plane the load in the columns is transferred through positive skin friction and tip resistance. It can be noted that such mechanism is quite similar to those exhibited by the combined pile-raft foundations (CPRF).

## 3 INFLUENCE OF THE COLUMN CHARACTERISTICS

### 3.1 Columns stiffness

Unfortunately, so far there is not any analytical method (commonly used) that takes into account the variation of column stiffness, and accordingly numerical modelling usually have to be performed to analyze the influence of column stiffness. However, even the most relevant numerical modelling that can be found in the literature has no focus on the risks and suitability aspects related to the column stiffness.

Kirsch (2004) analyzed the influence of the ratio between confined modulus of columns and soil on the improvement factor  $\beta$  (ratio of settlements with and without improvement). Results indicate that confined modulus ratios beyond 40 to 50 do not suppose considerable increments on improvement factor  $\beta$ , (Figure 2d). Similarly, Gangakhedar (2004) performed a numerical analysis of the influence of Young's modulus of the columns, on the differential settlements at the base of geosynthetic reinforced embankment. Figure 3 shows that differential settlements increase with increasing column modulus. Although it can be noted that there exists a greater increase of differential settlements when modulus are higher than those usually obtained for stone columns, of about 80 to 120 MPa, and that differential settlements tends to be much higher with the increase of column modulus if no geosynthetic reinforcement is considered.

Therefore, the cost-operating inefficiency of columns may be stated when column modulus are higher than 120 MPa, or modulus ratio are larger than 40 to 50, approximately. If columns rigidity exceeds this limits, CSE system requires an increase on the capacity of geosynthetic-reinforcement and the additional improvement is negligible.

It is well known that stone columns have a load-carrying mechanism by lateral bulging, whereas rigid inclusions transmit the load by skin friction and punching effect on their tip and head. In the latter case, the usual amount of differential settlement obtained in the column head implies a behavior controlled by its ultimate limit state (ULS), and governed by mobilization of negative skin friction. Figure 3 depicts that such

Figure 4. (a) Estimation of evolution of negative skin friction with degree of consolidation (Alonso et al. 1984); (b) chart for geosynthetic design based of allowable differential settlement (Lawson 2000); (c) influence of height and friction angle of embankment on Efficacy factor (Jenck 2005).

deformation in the head of rigid inclusions may suppose the failure state, as settlements may reach levels corresponding to large percent of column diameter. Furthermore, the punching failure in the head and toe of columns occurs immediately after the application of embankment load, and associated risk increases with smaller diameters of rigid inclusion, being quite sensitive to the variation of the soil parameters also.

On the other side, flexible elements like stone columns tend to reduce the punching effects at the base of embankment. In this case the system gives a ductile behavior, whereas, due to column compressibility and its drainage characteristics, the ultimate limit state is reached after large deformation and at the end of consolidation. Therefore, the behavior of such system takes place in the domain of serviceability limit state (SLS).

Wehr et al. (2012) proposed three categories of increasing risks, in order to assess the reliability of ground improvement methods according to their ductility and sensitivity to the variation of soil and materials parameters, taking as a reference the standards DIN 1054 and Eurocode 7. Thus, regarding to columns-type elements, flexible columns with small risks (stone columns, vibro compaction, sand columns) are in category A; rigid columns with diameter larger than 30 cm, which presents an average risk, are in category B; and rigid inclusions with diameters less than 30 cm and non-ductile behavior, which represent a high risk, are in category C.

### 3.2 Consolidation process

The addition of cement agents disables the drainage capacity of rigid columns, whereby settlements stabilization is obtained only due to a high load concentration on the columns. However, during the consolidation of pore pressures produced by the remaining part of embankment load that act on the soil, an important negative skin friction is generated in the part of columns above the neutral plane, very similar to piles, but without any capacity and structural connections. Consequently, the risk should be assessed due to possible reduction or loss of the load concentration on columns (or efficiency factor) along the lifetime of the CSEs. This situation could occur if certain loss of arching effect happens, as a consequence of possible LTPs deteriorations, e.g. due to internal failure of geosynthetic-reinforcement. In this case, the consolidation would occur in the long term, according to the permeability of the natural soil.

Moreover, it would involve the evolution of neutral plane over the time, dominated by the increase of negative friction. Figure 4a shows an example of this complex mechanism reported by Alonso et al. (1984).

In the case of stone columns, the rapid settlements stabilization is expected due to their drainage capability. Castro and Sagaseta (2009) analyzed the evolution of stress concentration on the stone columns, showing that in the very beginning entire load is carried by the soil, and the final load concentration on the columns is obtained after consolidation (Figure 5). However, after short period of consolidation,

effective stress of soil tends to increase, and additionally provides greater confinement to the columns. Such results suppose an improvement of the whole column-soil system.

Figure 5. Time development of soil and column stresses, (Castro and Sagaseta 2009)

## 4 GENERAL ASPECTS OF SAFETY VERIFICATION

There is a range of recommendations that attempt to unify design of LTPs composed by geosynthetic-reinforcement layers, basically used in piled embankments (BS8006 2010, EBGE0 2010, Nordic Handbook 2005). However, the design of column-type elements is redirected to typical pile standards. As it was mentioned in section 2.2, it has to be emphasized, that these recommendations deal with systems where almost entire load is transferred to bearing elements heads, hence negative skin friction is practically negligible. According to what has been stated here about the higher level of risk exhibited by the rigid inclusions with small diameter, the most important safety aspects of such elements will be commented.

### 4.1 Large-height embankment

The ASIRI recommendations define two different situations:

Domain 1: if the ULSs are not guaranteed without improvement, rigid inclusions are used to ensure the global stability, and bearing capacity of rigid inclusions for both ULSs and SLSs have to be checked, similarly to the French Eurocode 7 application for piles.

Domain 2: if the ULSs are analyzed for the situation without improvement, then rigid inclusions are used as settlement reducers, and only SLSs have to be proceeded.

Taking into account the ASIRI recommendations, it could be distinguished that when the CSE system comprises embankments with more than 3 to 5 m height, the design is usually focused to guarantee the ULSs. Regarding to the external bearing capacity (GEO) for rigid inclusions, the most important checks against the permanent loads will be punching at their heads and tips, as well as the horizontal stresses, bending moments and shear stresses due to slope failures. Buckling effects have to be checked when soft soil has pressuremeter modulus smaller than 3 MPa.

Figure 6. (a) Factor of soil arching reduction (Heitz et al. 2008); (b) stress conditions in the subgrade due to moving load on the pavement surface; (c) pavement deformation due to hard-point effects associated with the presence of rigid inclusions.

Regarding to the structural bearing capacity (STR), a minimum compressive strength of 7 MPa has to be adopted, and no shear stress is allowed for unreinforced columns smaller than 30 cm. Besides, if tension can develop, for Domain 1 the rigid inclusions have to be reinforced, whereas for Domain 2 only an adequate tensile strength of concrete could be adopted.

On the other hand, Katzenbach et al. (2012) have compared the safety checks outlined in the ASIRI recommendations with other guidelines for similar foundation systems usually used in Germany (CSV, CRPF), according to the partial safety factor approach. They reported that ASIRI has lower values of safety factors than those the compared guidelines indicate.

#### 4.2 Low-height embankment

In the case of embankments with heights less than 3 meters, the design is usually aimed to guarantee the SLSs, according to the Domain 2. Basically, the geometry of the CSE systems has to be set to avoid excessive deformation in the surface of the embankments, in order to allow an adequate traffic operation. For this objective Lawson (2000) proposed the chart depicted in Figure 4b, for the design of the height and geosynthetic-reinforcement of LTP layers considering the columns as hard points, and according to typical thresholds adopted in transport projects related to differential settlements.

The differential settlements also depend on the LTP strength. Figure 4c shows the analysis of Jenck (2005) related to the influence of the height of the embankment and the strength of unreinforced LTPs in terms of friction angle. Results indicate that efficiency factor  $E$  increase with height of embankments until a maximum value similar to the critical height  $H_c$ . Also, it can be seen that when LTP is composed by materials with friction angle less than 20 degree the efficiency factor is drastically reduced, and practically negligible when  $\phi = 0$ .

So far it is not fully analyzed the behavior of CSE against the cyclic loading of traffic. Heitz et al. (2008) have demonstrated that the arching mechanism to transfer load of LTP can only be formed in a very limited extent if geosynthetic reinforcement is not placed. Based on laboratory model tests under cyclic loading, they proposed a soil arching reduction factor,  $\kappa$ .

Figure 6a shows this factor depending on the ratio of fill height and column spacing  $h/s$ , the frequency  $f$  and amplitude of the cyclic load  $\sigma_c$ . For rigid inclusion application negative influence of the traffic loading has to be considered during construction and operation stages. Figure 6b illustrates that cyclic loading of traffic can generate the rotation of principal stresses in the subgrade layers, which could cause severe damages to the rigid inclusions and pavement serviceability in the long term, especially for low-height embankments.

Finally, Figure 6c shows an example of pavement deformation due to a combination of the effects mentioned.

#### 5 CONCLUSIONS

The influence of columns stiffness commonly used on the Column Supported Embankment (CSE) systems has to be rigorously investigated in order to establish the implications on the safety and serviceability issues. The facts that indicate the higher risks of rigid inclusions compared with flexible ground

improvement methods like stone columns are exposed, especially when diameters of rigid inclusions are smaller than 30 cm. Moreover, the requirements of LTPs in terms of strength and thickness, has to be more strict for rigid inclusion comparing with stone columns, in order to ensure the arching load transfer in the long term behavior of the CSEs, for both static and cyclic loading.

# Foundations of embankments using encased stone columns

## Fondations de remblais avec des colonnes ballastées entourées de géotextile

Castro J., Sagaseta C., Cañizal J., Da Costa A., Miranda M.  
*University of Cantabria, Santander, Spain*

**ABSTRACT:** Stone columns are a common improvement technique for foundations of embankments in soft soils. When the soft soil does not provide enough lateral support, the columns are encased with a geosynthetic. This paper presents a closed-form solution to study soft soil improvement, both reduction of settlement and consolidation time, by means of encased stone columns. An end-bearing column and its surrounding soil, is modelled in axial symmetry under a rigid and constant load. Soil is assumed as elastic but plastic strains are considered in the column. An elasto-plastic behaviour is also considered for the encasement by means of a limit tensile strength. Parametric studies of the settlement reduction and stress concentration show the efficiency of encasing the columns, which is mainly ruled by the encasement stiffness compared to that of the soil. The analytical results are in good agreement with numerical analyses. Finally, the encasement length is analysed using the closed-form solution.

**RÉSUMÉ:** Les colonnes ballastées sont une technique d'amélioration de sol pour les remblais en sols mous. Lorsque le sol mou ne fournit pas assez de soutien latéral, les colonnes sont entourées avec un géosynthétique. Cet article présente une solution analytique pour étudier l'amélioration des sols mous, la réduction des tassements ainsi que le temps de consolidation, au moyen des colonnes entourées en géotextile. Une colonne ne reprenant les efforts que par la pointe et le sol environnant sont modélisés en axisymétrie sous une charge constant. Le comportement du sol est supposé élastique mais les déformations plastiques sont considérées dans la colonne. Un comportement élasto-plastique est également pris pour le géosynthétique au moyen d'une résistance à la traction limite. Des études paramétriques de la réduction du tassement et de concentration de contraintes montrent l'efficacité de l'enveloppe géosynthétique des colonnes, ce qui est principalement régie par la rigidité de l'enveloppe géosynthétique par rapport à celle du sol. Les résultats analytiques présentent une bonne concordance avec les analyses numériques. Finalement, la longueur de l'enveloppe géotextile est analysée en utilisant la solution basée sur une cellule élémentaire constituée d'une colonne et d'un volume élémentaire de sol.

**KEYWORDS:** soft soils, ground improvement, encased stone columns, analytical solution, numerical analyses.

### 1 INTRODUCTION

Stone columns, either by the vibro-replacement or vibro-displacement methods, are one of the most common improvement techniques for foundation of embankments or structures on soft soils. The inclusion of gravel, which has a higher strength, stiffness and permeability than the natural soft soil, improves the bearing capacity and the stability of embankments and natural slopes, reduces total and differential settlements, accelerates soil consolidation and reduces the liquefaction potential. Alteration of the natural soft soil caused by stone column installation (Guetif et al. 2008, Castro and Karstunen 2010) is not usually considered in their design.

Stone columns may not be appropriate in very soft soils that do not provide enough lateral confinement to the columns. It is generally accepted that those are soils with undrained shear strengths below 5-15 kPa (Wehr 2006). To increase the lateral confinement of the columns, and consequently their vertical capacity, encasing the columns with geotextiles has proved to be a successful solution in recent years.

A high tensile stiffness of the encasement is recommended as it will be shown in this paper; and therefore, other geosynthetics, such as geogrids, are also used to encase the column (Sharma et al. 2004, Gniel and Bouazza 2009). However, geogrids do not act as a filter and do not avoid contamination of the column with fines.

The development of encased stone columns as a ground improvement technique has come with an increasing number of studies in the last decade. However, most of the research is done using numerical methods (e.g. Murugesan and Rajagopal 2006, Malarvizhi and Ilamparuthi 2007, Smith and Filz 2007, Yoo 2010, Lo et al. 2010) and there are very few analytical solutions available in the literature (Raithel and Kempfert 2000, Pulko et al. 2011). That recently motivated the authors to develop a new closed-form solution to study the deformation and consolidation

around encased stone columns (Castro and Sagaseta 2011). That solution is an extension of another previous analytical solution developed for non-encased stone columns (Castro and Sagaseta 2009).

This paper analyses the main features of that closed-form solution, showing its limitations and range of applicability, the influence of the key parameters for routine design and a comparison with numerical analyses.

### 2 CLOSED-FORM SOLUTION

#### 2.1 Model

The vertical capacity of the columns is a fundamental issue when the applied load is concentrated on the columns. Therefore, column encasement is very useful in those cases (Murugesan and Rajagopal 2010, Khabbazian et al. 2010); but also under distributed loads, such as tanks or embankments, because the increase of lateral confinement reduces the settlement.

The authors' closed-form solution (Castro and Sagaseta 2011) is limited to distributed uniform loads because it is based on a "unit cell" model, i.e. only one column and its surrounding soil are studied in axial symmetry. Furthermore, the column is assumed to be fully penetrating in the soft soil and the applied load is considered as rigid, i.e. uniform settlement. The area of soft soil,  $A_b$ , that is improved by each column,  $A_c$ , is generally expressed by the area replacement ratio,  $a_r = A_c/A_b$ , but sometimes is also defined in terms of the relation between diameters or radii,  $N = r_i/r_c = 1/\sqrt{a_r}$ .

The solution is developed for a horizontal slice at a depth  $z$  of the unit cell, and consequently, shear stresses between slices at different depths are not considered (Figure 1). The overall

behaviour of the whole unit cell is obtained by means of integration of the solution at the different depths.

Figure 1. Analytical model.

## 2.2 Consolidation

The analysis of consolidation around encased stone columns as a fully coupled problem is difficult to deal with. As a simplifying assumption, the solution uses the average value of the excess pore pressure along the radius,  $\bar{u}$ , which is a simple way of getting a reasonably accurate solution. The details of this kind of approach can be found in Castro and Sagaseta (2009). Multiple instantaneous load steps may be considered. The column (drain) is considered to be fully permeable, which is doubtful for conventional stone columns but is reasonable if the columns are coated with a geotextile. In this way, consolidation around encased stone columns is studied using any conventional solution for radial consolidation (e.g. Barron 1948) and a modified coefficient of consolidation that accounts for the influence of column and encasement.

## 2.3 Encasement

The encasement is modelled as a cylindrical shell of negligible thickness around the column. Therefore, it is valid for different types of coating, such as geotextiles, geogrids... Encasement behaviour is supposed to be linear elastic-perfectly plastic and characterized by a tensile stiffness,  $J_g$ , and a maximum tensile strength,  $T_{g,max}$ . During column installation, the encasement is pre-stressed to an initial tensile stress,  $T_{g,i}$ . The encasement tensile stress obtained with the analytical solution is the increment from that value,  $\Delta T_g$ .

Figure 2. Equilibrium and compatibility conditions of the encasement.

The encasement is compressed in vertical direction, and as it can only take tension, it does not have any influence in vertical direction. Its equilibrium and compatibility conditions (Figure 2) are those of a thin tube under internal,  $\sigma_{rc}$ , and external pressure,  $\sigma_{rs}$ .

$$\sigma_{rc} = \frac{T_g}{r_c} + \sigma_{rs} \quad (1)$$

$$T_g = J_g \frac{s_r}{r_c} \quad (2)$$

where  $s_r$  is the radial displacement of the interface.

Combining these two equations, the radial equilibrium between soil and column at their interface depends on the encasement properties (stiffness and radius) and its radial expansion.

$$\sigma_{rc} = \frac{J_g s_r}{r_c^2} + \sigma_{rs} \quad (3)$$

Those simple equations (Eq. 2 and 3) show how the encasement influence depends on its stiffness and radius.

## 2.4 Formulation

The detailed formulation of the solution can be found in Castro and Sagaseta (2009, 2011). Three different possible phases are identified: (a) soil, column and encasement in the elastic range, (b) column yielding and (c) encasement yielding, which will occur after column yielding in a real situation.

A sensible design should cause yielding of the column but not of the encasement. Therefore, the last phase of the solution may not be considered and it is just necessary to check that the tensile stress of the encasement does not exceed its strength.

The solution considers just one instantaneous load step, but it is quite straightforward to generalize it for multiple loading steps (Castro and Sagaseta 2008), taking the initial stresses as the final ones of the previous load step. However, modelling the real loading steps is only necessary to study the consolidation process but not for the final values as it gives the same results.

## 2.5 Drained solution

The studied closed-form solution models the consolidation process. However, consolidation around stone columns, especially if the columns are coated with a geotextile, may be nearly as fast as the loading pace, which means that for these cases drained condition is a more reasonable assumption.

In any case, depending on the soil permeability and the loading pace, the real behaviour is between drained condition and an undrained loading followed by consolidation. Fortunately, both cases yield very similar final values as can be shown numerically.

Nonetheless, analytical solutions use simplifying assumptions that have different consequences in each situation. The most evident example is disregarding the elastic strains in the column once it has reached its active state. This assumption gives acceptable results for non-encased columns or when the consolidation process is modelled but not if drained conditions are considered for encased columns (Castro and Sagaseta 2011). Hence, in that last case it is necessary to account for those elastic strains in the column (Pulko et al. 2011).

## 3 PARAMETRIC STUDY AND NUMERICAL ANALYSES

### 3.1 Numerical model

Numerical simulations are included in the parametric study to evaluate the accuracy of the closed-form solution and the influence of its simplifying assumptions, such as neglecting the shear stresses and using an average pore water pressure along the radius. Coupled numerical analyses of the unit cell were performed using the finite element code Plaxis v8.6 (Brinkgreve 2007). For comparison purposes, the same boundary conditions and material properties of the analytical solution were chosen for the numerical models. Therefore, a rigid plate was set on top

of the unit cell, the soil was modelled as elastic and the encasement and the column as elastic-perfectly plastic.

### 3.2 Stress concentration

The ratio between the vertical stress on the column and on the soil is usually called the stress concentration factor ( $SCF = \sigma_{zc} / \sigma_{zs}$ ) and gives an idea of the part of the applied load that the soil transfers to the column. Figure 3 shows its variation with time. The vertical stresses on the soil and on the column may vary with the radius, and therefore, their averaged values are used to calculate the  $SCF$ .

A higher encasement stiffness provides a better lateral confinement to the column, and hence, the column supports a higher load. A good agreement is found between the analytical and the numerical results. However, as it happens for the stone column solution (Castro and Sagasta 2009), the agreement for low degrees of consolidation (<30%) is not very good due to inherent assumptions of Barron's solution.

Figure 3. Stress concentration on the column with time.

### 3.3 Settlement reduction

The settlement reduction decreases with the applied load,  $p_a$ , from an elastic value,  $\beta^e$ , and approaches a plastic one,  $\beta^p$ , at the same rate as plastic strains develop in the column (Figure 4). The applied load is normalized by the initial vertical stress because column yielding depends on that factor,  $p_a/(L\gamma'_s)$ .

On the other hand, the settlement reduction introduced by the encasement is nearly the same for different area replacement ratios (Figure 5), which means that column encasement is equally useful for different area replacement ratios, yet columns of smaller diameters are better confined. In Figures 4, 5 and 6, the numerical results validate the accuracy of the analytical solution, but the agreement gets slightly worse as the tensile stiffness of the encasement increases. Hence, the only assumption that has a slightly noticeable effect in the results is neglecting the elastic strains in the column during its plastic deformation. A future improvement of the analytical solution including those elastic strains is currently being developed.

Figure 4. Settlement reduction. Influence of the applied load.

Figure 5. Settlement reduction. Influence of the encasement stiffness for different area replacement ratios.

Figure 6. Time-settlement curve.

### 3.4 Encasement length

The effectiveness of encasing the columns in reducing the settlement is directly related to the tensile stress of the encasement, which provide lateral support to the column. Some authors (e.g. Khabbazian et al. 2010, Gniel and Bouazza 2009, Murugesan and Rajagopal 2006) have proposed a partial encasement of the columns, limiting it to the upper part where

the initial lateral stresses are lower. Then, the analysis focuses on the length of the column that should be encased. Here, a preliminary study of the encasement length is presented using the authors' closed-form solution.

The closed-form solution provides the vertical strain of the column at different depths. Figure 7 shows that those strains are higher at shallow depths and linearly decrease with depth, as initial horizontal stresses increase. If the column is encased, those strains are lower but follow a similar pattern. Therefore, encasing the columns is more effective in their upper part but that varies linearly with depth and there is not a critical length of the encasement that should specifically be used.

Figure 7. Vertical strain at different depths.

#### 4 CONCLUSIONS

The main features of a closed-form solution, recently developed by the authors (Castro and Sagaseta 2011), to study soft soil improvement, both reduction of settlement and consolidation time, by means of encased stone columns are presented. The analytical solution pretends to be a simple and useful tool for design. Therefore, only a unit cell, i.e. an end-bearing column and its surrounding soil, is modelled in axial symmetry under a rigid and constant load.

Parametric studies of the settlement reduction and stress concentration show the efficiency of encasing the columns, which is mainly ruled by the encasement stiffness compared to that of the soil. Therefore, encasing stone columns is recommended in very soft soils and the encasement should be stiff enough. Besides, the settlement reduction decreases with the applied load. Column encasement is equally useful for common area replacement ratios but columns of smaller diameters are better confined.

The results of the closed-form solution agree well with numerical analyses. The only assumption of the solution that has a slightly noticeable effect in the results is neglecting the elastic strains in the column during its plastic deformation. Therefore, including those elastic strains is an improvement of the presented solution under development.

Finally, a preliminary analysis of the encasement length shows that is more efficient to encase the columns in the upper part, as expected, but there is not a critical length of the encasement that should specifically be used.

#### 5 ACKNOWLEDGEMENTS

The work presented is part of a research project on "An integrated calculation procedure for stone columns, considering the influence of the method of installation", for the Spanish Ministry of Science and Innovation (Ref.: BIA2009-13602).

# Consolidation theory for combined vacuum pressure and surcharge loading

## Théorie de la consolidation sous l'action combinée du vide et d'un pré-chargement

Chai J.-C.

*Saga University, Japan*

Carter J. P.

*The University of Newcastle, Australia*

**ABSTRACT:** A theory describing the consolidation of a uniform clayey deposit with and without prefabricated vertical drain (PVD) improvement under the combination of a vacuum pressure and a surcharge load has been developed and expressed as closed-form equations. For the case of a soil layer without PVD improvement, both one-way and two-way drainage boundary conditions are considered. Laboratory consolidation tests using combinations of vacuum pressure and surcharge load were conducted under oedometer conditions with vertical or radial drainage. The measured excess pore water pressures are compared with values predicted by the theory presented in the paper. It has been demonstrated that the theory is valid and can be used for designing preloading projects that involve the combination of a vacuum pressure and a surcharge load.

**RÉSUMÉ :** Une théorie décrivant la consolidation d'un dépôt argileux uniforme avec et sans amélioration par drains verticaux préfabriqués (DVP) sous l'action combinée du vide et d'un pré-chargement a été développée avec un système fermé d'équations. Pour le cas d'une couche de sol sans amélioration par DVP, des conditions aux limites drainantes par un côté et par deux côtés sont considérées. Des essais de consolidation au laboratoire sous des conditions oedométriques ont été réalisés sous vide et pré-chargement avec des drains verticaux ou radiaux. La surpression interstitielle mesurée est comparée avec les valeurs prévues par la théorie présentée dans le présent article. Il a été démontré que la théorie est valable et peut être utilisée pour définir des projets de pré-chargement qui impliquent l'utilisation combinée du vide et d'un pré-chargement.

**KEYWORDS:** consolidation, vacuum pressure, embankment, laboratory test, soft clay

## 1 INTRODUCTION

Preloading a soft clayey deposit with the combination of a vacuum pressure and a surcharge load (embankment fill) has several advantages, such as increasing the preloading pressure and reducing lateral displacements of the deposit, etc. (e.g., Chai et al. 2006). Its use in engineering applications has increased in recent years (e.g., Kelly and Wong 2009; Hirata et al. 2010; Indraratna et al. 2011).

Vacuum consolidation has different characteristics compared with consolidation induced by direct application of a surcharge load (Chai et al. 2009). For a soil deposit without any improvement in consolidation performance that might result from the installation of prefabricated vertical drains (PVDs), when a vacuum pressure is applied water is drained out of the soil layer only at the boundary where that vacuum pressure is applied. This applies for both cases of one-way and two-way drainage conditions. However, for a deposit with one-way drainage constrained to deform under one-dimensional (1D) conditions, the final state is a uniform vacuum pressure distribution throughout the deposit and consequently zero flow rate. But for a deposit with two-way drainage, at the bottom boundary the excess pore water pressure is fixed at zero and effectively no vacuum pressure can be applied at this location, and so the final state involves the steady flow of pore water toward the boundary at which the vacuum pressure is applied. Considering these complicating factors, Chai and Carter (2011) recently derived a consolidation theory for soils subjected to vacuum pressure. However, their theory cannot be applied directly for cases that involve a combination of vacuum pressure and surcharge loading, and therefore there is a need to develop a reliable theory for such cases.

This paper presents a newly developed consolidation theory applicable to soils subjected to a combination of vacuum pressure and surcharge loading. This theory is applicable to the

case of a uniform soil deposit with or without PVD improvement. Predictions obtained using this theory are compared with the results of laboratory tests conducted under oedometer conditions, for cases that involve both vertical and radial drainage conditions, with the latter designed to simulate the consolidation of a deposit improved by PVDs. It has been shown that the theory is valid and can be used for designing preloading projects that involve a combination of vacuum pressure and surcharge loading.

## 2 CONSOLIDATION THEORY

### 2.1 Uniform layer without PVDs

Under the same assumptions as those made in Terzaghi's 1D consolidation theory (Terzaghi 1943), the governing equation and the boundary conditions for the generation and dissipation of excess pore water pressure in a saturated soil layer under a combination of vacuum pressure and surcharge load are as follows:

$$c_v \frac{\partial^2 u}{\partial z^2} = \frac{\partial u}{\partial t} \quad (1)$$

$$u(0, t) = -p_{vac} \quad (2)$$

$$\frac{\partial u(H, t)}{\partial z} = 0 \text{ for } t > 0 \text{ (one-way drainage)} \quad (3)$$

$$u(H, t) = 0 \text{ for } t > 0 \text{ (two-way drainage)} \quad (3a)$$

where  $z$  = the spatial coordinate;  $t$  = time;  $u$  = the excess pore water pressure;  $c_v$  = the coefficient of consolidation of the soil;  $p_{vac}$  = the magnitude of the applied vacuum pressure at  $z = 0$ ; and  $H$  is the thickness of the deposit.

With the presence of a vacuum pressure, the final state is not a condition with zero excess pore pressure in the deposit. Therefore, the solution to the governing equation must consist of two parts, namely the steady state solution ( $Y(z)$ ) and the transient solution ( $v(z,t)$ ) (Chai and Carter 2011). With the boundary condition defined by Eq. (2),  $u(z, t)$  can be expressed in the following form:

$$u(z, t) = -p_{vac}Y(z) + p_{vac}v_1(z, t) + p_s v_2(z, t) \quad (4)$$

where  $p_s$  = the magnitude of the applied surcharge load. The term  $-p_{vac}Y(z)$  is the final steady state excess pore water pressure distribution and  $(p_{vac} v_1(z, t) + p_s v_2(z, t))$  is the time-dependent component of the excess pore water pressure.

### 2.1.1 One-way drainage

For this case the excess pore water pressure distribution is given by:

$$u = -p_{vac} + (p_{vac} + p_s) \cdot \left( \frac{4}{\pi} \sum_{n=1}^{\infty} \frac{1}{2n-1} \sin(a_n z) e^{-a_n^2 c_v t} \right) \quad (5)$$

where  $a_n = (2n-1)\pi/(2H)$ . In this case,  $Y(z) = 1$ , and the  $v_1(z, t) = v_2(z, t)$  and its expression is given in the last set of parentheses of Eq. (5). The average degree of consolidation is given by:

$$U = 1 - \frac{8}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^2} e^{-\frac{c_v t}{4H^2} (2n-1)^2 \pi^2} \quad (6)$$

### 2.1.2 Two-way drainage

In this case the excess pore water pressure distribution in the soil is given by:

$$u(z, t) = -p_{vac} \left( 1 - \frac{z}{H} \right) + \frac{2}{\pi} \sum_{n=1}^{\infty} \left[ \frac{p_{vac} + p_s}{n} \sin(\lambda_n z) + \frac{p_s}{n} \sin(\lambda_n (H - z)) \right] e^{-\lambda_n^2 c_v t} \quad (7)$$

where  $\lambda_n = n\pi/H$ . The average degree of consolidation is given by:

$$U(t) = 1 - \frac{8}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^2} e^{-\frac{c_v t}{H^2} (2n-1)^2 \pi^2} \quad (8)$$

## 2.2 Uniform layer with PVD improvement

The theory for a PVD-improved soil deposit is derived here for the case of one-way drainage conditions using a unit cell model, as shown in Fig. 1. The governing equation for consolidation is as follows:

$$\frac{\partial u}{\partial t} = c_h \left[ \left( \frac{\partial^2 u}{\partial r^2} \right) + \frac{1}{r} \left( \frac{\partial u}{\partial r} \right) \right] \quad (9)$$

where  $r$  = the radial distance and  $c_h$  = the coefficient of consolidation in the horizontal direction. The boundary conditions are:

Figure 1. Unit cell model and boundary conditions

$$\frac{\partial u(r_e, z, t)}{\partial r} = 0 \quad (10)$$

$$\frac{\partial u(r, 0, t)}{\partial z} = 0, \quad \frac{\partial u'(r, 0, t)}{\partial z} = 0 \quad (11)$$

$$\frac{\partial u(r, l, t)}{\partial z} = 0, \quad \frac{\partial u'(r, l, t)}{\partial z} = 0 \quad (12)$$

$$u'(r_w, 0, t) = -p_{vac} \quad (13)$$

where  $u$  and  $u'$  = the excess pore water pressures in the undisturbed zone and the smear zone, respectively (Fig. 1),  $z$  = depth from the ground surface,  $r_w$  = equivalent radius of a PVD, and  $r_e$  = radius of the unit cell. The solutions for  $u$  and  $u'$  can be expressed as:

$$u(r, z, t) = -p_{vac} + (p_{vac} + p_s)v(r, z, t) \text{ for } (r_s < r \leq r_e) \quad (14)$$

$$u'(r, z, t) = -p_{vac} + (p_{vac} + p_s)v'(r, z, t) \text{ for } (r_w < r \leq r_s) \quad (15)$$

where  $r_s$  = radius of the smear zone. The additional conditions for getting explicit expressions for  $v$  and  $v'$  are the following water flow continuity conditions.

- (1) The total inflow of pore water through the boundary of a cylinder with a radius of  $r$  has to be equal to the change in volume of the hollow cylinder with outer radius of  $r_e$  and inner radius of  $r$ .
- (2) The pore water flow into the PVD from a horizontally cut soil slice is equal to the change of vertical flow rate in the PVD.

At the interface between the smear zone and the undisturbed zone, the radial flow rate from the undisturbed zone is equal to the flow rate into the smear zone.

With these conditions and using the same assumptions as those adopted in obtaining Hansbo's (1981) solution, it can be shown that the expressions for  $v(r, z, t)$  and  $v'(r, z, t)$  are as follows:

$$v'(r, z, t) = \frac{k_h}{k_s \cdot r_e^2 \cdot \mu} \left[ \frac{r_e^2 \ln \frac{r}{r_w} - \frac{r^2 - r_w^2}{2}}{+ \frac{k_s}{k_w} (n^2 - 1)(2lz - z^2)} \right] \exp\left(\frac{-8T_h}{\mu}\right) \text{ for } (r_w \leq r \leq r_s) \quad (16)$$

$$v(r, z, t) = \frac{1}{r_e^2 \cdot \mu} \left[ \frac{r_e^2 \ln \frac{r}{r_s} - \frac{r^2 - r_s^2}{2} + \frac{k_h}{k_s} \left( \frac{r_e^2 \ln s}{- \frac{r_s^2 - r_w^2}{2}} \right) \right] \exp\left(\frac{-8T_h}{\mu}\right) \text{ for } (r_s < r \leq r_e) \quad (17)$$

where:  $n = r_e/r_w$ ,  $s = r_s/r_w$ ,  $k_h$  and  $k_s =$  the hydraulic conductivities in the horizontal direction of the undisturbed zone and the smear zone respectively,  $k_w =$  the hydraulic conductivity of the drain (PVD),  $l =$  the drainage length of a PVD, and  $T_h = c_v t / (4r_e^2)$ . Parameter  $\mu$  represents the effects of PVD spacing, smear zone and well resistance. Adopting an average well resistance and with some approximation, the expression for  $\mu$  is as follows (Hansbo 1981):

$$\mu = \ln(n/s) + (k_h/k_s) \ln(s) - \frac{3}{4} + \frac{2l^2 \cdot k_h}{3r_w^2 k_w} \quad (18)$$

The average degree of consolidation ( $U_h$ ) of the unit cell is (Hansbo 1981):

$$U_h = 1 - \exp(-8T_h / \mu) \quad (19)$$

### 3 COMPARISON OF TEST RESULTS AND PREDICTIONS

Laboratory consolidation tests involving the combination of a vacuum pressure and a surcharge load have been conducted under oedometer conditions with both vertical and radial drainage (the latter to simulate the effects of PVD drainage), and the measured excess pore pressures have been compared with the predicted values.

#### 3.1 Test details

Figures 2(a) and (b) show the set-up of the tests, with vertical (V-test) and radial (R-test) drainage conditions, respectively. During testing, the settlement, the excess pore water pressure at the bottom of the sample (V-test) or the middle height of the consolidation ring (R-test), and the horizontal earth pressure at the middle height of the consolidation ring can be measured. For the R-test, the centre drainage porous stone tube has an outer diameter of 8 mm, which is inserted into a predrilled hole at the center of a sample with a filter paper placed between the soil sample and the tube. The soil samples were re-consolidated from Ariake clay slurries under a surcharge pressure of 20 kPa.

Two series of tests, V-tests and R-tests, were conducted. Here only one test from each series has been chosen to compare with the values predicted by the theory presented above. In the case of the V-test, the test with one-way drainage conditions has been selected, because for two-way drainage conditions no pore water pressures were measured with the device used. The two series of tests were conducted at different times and different soil samples were used. Some of available soil properties as well as the test conditions are listed in Table 1. In this table, the vertical effective stress,  $\sigma'_{v0}$ , indicates that the soil sample was first consolidated under  $\sigma'_{v0}$  (simulating the initial effective stress of the soil sample at a specified depth in the deposit) and then the consolidation test was conducted by applying additional incremental consolidation pressures (vacuum pressure and surcharge load).

Figure 2. Sketch of the set-up of the tests

Figure 3. Comparison of predicted and measured  $u_b$  values

#### 3.2 Comparison of measured and predicted pore pressures

##### 3.2.1 V-test

After initial consolidation under  $\sigma'_{v0} = 40$  kPa, the thickness of the sample was 18.7 mm (or compression of about 1.2 mm). Further, under 80 kPa vacuum pressure and 80 kPa surcharge load, the additional compression was about 3.2 mm. Since the thickness of the sample is also the vertical drainage path length, in the predictions an average sample thickness of 17.2 mm was adopted. Comparison of the measured and the predicted excess pore water pressures at the bottom of the sample ( $u_b$ ) is shown

Table 1. Some soil properties and test conditions

Test	Soil	Plasticity limit, $W_p$ (%)	Liquid limit, $W_L$ (%)	Coefficient of consolidation $c_v$ or $c_h$ (m <sup>2</sup> /min)	$C_c$	$e_{0\clubsuit}$	$\sigma'_{v0}$ (kPa)	$p_{vac}$ (kPa)	$p_s$ (kPa)
V-test	Ariake clay-1	60.3	120.5	$2.3 \times 10^{-5} \#$	0.75	2.5	40*	80	80
R-test	Ariake clay-2	56.8	120.3	$5.0 \times 10^{-6}$	-	-	0	80	80

\*: Initial vertical effective stress in the sample; #: The value was obtained by fitting the measured consolidation rate;  $\clubsuit$ : After pre-consolidation under 20 kPa pressure.

in Fig. 3. Except for the fact that the measured initial value of  $u_b$  of about 72 kPa is slightly lower than the 80 kPa applied surcharge load, the prediction almost matches the measured data. The slightly lower initial  $u_b$  value may indicate that the specimen was not 100% saturated.

Although two-way drainage test was not conducted, using the same soil parameters as for one-way drainage test, and assuming the thickness of the soil sample is 20 mm, the predicted excess pore water pressure ( $u$ ) distribution within the sample at different elapsed times are given in Fig. 4 to demonstrate the capacity of the proposed theory.

Figure 4. Predicted  $u$  variation in soil sample under two-way drainage boundary condition

Figure 5. Comparison of predicted and measured  $u_{re}$

### 3.2.2 R-test

The geometric parameters required to calculate the predictions for this case are:  $r_e = 30$  mm;  $r_w = 4$  mm; and  $l = 20$  mm. The assumed radius of the smear zone,  $r_s = 7$  mm; the hydraulic conductivity ratio,  $k_h/k_s = 5$ ;  $k_h = 10^{-9}$  m/s; and  $k_w = 10^{-4}$  m/s. In the case of radial drainage, with Eqs. (16) and (17) the initial condition of a uniform excess pore water pressure ( $u_0$ ) distribution in a unit cell is not satisfied (which is a particular limitation of this theory). These equations only ensure that the average initial value of  $u_0$  is the same as the applied value. The predicted initial value at the periphery of the sample (unit cell) is higher than the applied value. The predicted values are compared with the measured data from the time at which the predicted value at the periphery was equal to the applied initial value. In the physical test at the corresponding time, the pore

water pressure at the periphery of the sample starts to reduce. Comparison of the excess pore water pressures at the periphery of the sample ( $u_{re}$ ) is given in Fig. 5. For this case, during the consolidation period the measured excess pore water pressure initially decreased but then increased for a brief period before finally exhibiting further dissipation. Furthermore, the measured final excess pore water pressure did not reach the applied vacuum pressure of 80 kPa. Nevertheless, the trends of both the measured and the predicted dissipation curves are similar.

From the above comparisons, it can be seen that the theory provides reasonable predictions of the measured soil behaviour and so it should be able to be used reliably for designing preloading projects that adopt a combination of vacuum pressure and surcharge load to consolidate the soil deposit.

## 4 CONCLUSIONS

A consolidation theory, expressed in closed-form equations, for soil consolidation under the combination of a vacuum pressure and a surcharge load has been developed for a uniform clayey deposit with and without prefabricated vertical drain (PVD) improvement. For cases without PVD improvement, both one-way and two-way drainage boundary conditions have been considered.

Laboratory consolidation tests were conducted, adopting a combination of vacuum pressure and surcharge loading under oedometer conditions with both vertical and radial drainage. The excess pore water pressures measured in these test were compared with values predicted by the suggested theory. It has been demonstrated that the theory is valid and can be used for designing preloading projects that adopt a combination of vacuum pressure and surcharge load to pre-consolidate soft soil deposits.

**ABSTRACT:** In soils with poor mechanical properties and in areas where the generation of excavation debris is an issue, given the restrictions regarding its disposal, the solutions of massive soil improvement with displacement rigid inclusions solve both needs. In this paper we describe the basis of the constructive procedure of displacement rigid inclusions. We explain the concept of improvement with this kind of inclusions; we itemize the bases of their design, and describe their construction sequence, highlighting the controls during the execution to ensure quality.

**RÉSUMÉ:** Dans les sols ayant des propriétés mécaniques faibles comme dans les zones où l'élimination des matériaux produits des travaux représente un problème, les Inclusions Rigides avec refoulement de sol donnent des solutions à ces deux situations. L'article explique le concept des solutions d'amélioration des sols en utilisant la technique des Inclusions Rigides, donne les bases du dimensionnement, et décrit la séquence de construction des inclusions Rigides en insistant sur les contrôles utilisés pour assurer la qualité finale.

**KEYWORDS:** soft soil, rigid inclusion, displacement of soil, excavation debris.

### 1 INTRODUCTION

When studying what type of foundation is best suited to withstand the shock that a new building (structure) will impose on the soil, it is necessary to check not only the limit conditions for failure, but also the limit conditions of service, including total and differential settlements.

Being successful in the choice and design of the type of foundation to be built largely depends on the control of two variables: load and settlement. Nevertheless, there are additional parameters that also play an important role in the decision process, such as the cost of the foundation with respect to the total cost of the project, construction time and —increasingly— the impact on the environment.

The foundations based on rigid inclusions (system structure massive soils improvement) have experienced a boom in recent years, especially in works on large areas subjected to uniform vertical loads. While this is not a new concept (wooden inclusions were used since prehispanic times in Mexico —see Auvinet, G., 2006—), there is now specialized equipment capable of building concrete rigid inclusions following special procedures that not only achieve higher production results, but also greater depths and better loadbearing capacities. They also respect strict quality controls. This gives us the possibility to propose foundations based on the installation of grids of rigid inclusions made of poor concrete that meet specific technical requirements regarding load bearing capacities and the reduction of settlements. They are also attractive: economically and for their constructive feasibility, as well as for their reduced construction times and the quality of their execution.

Displacement inclusions in particular have the great advantage of not generating construction debris, which benefits the environment and reduces or eliminates the cost of its removal. In soils with a large frictional component, the ratio of voids surrounding the inclusion is reduced by the incorporation of the concrete so that the relative compactness of the material

increases, as well as the perimeter friction of the inclusion-ground. The construction process of the displacement rigid inclusion guarantees quality control in the execution, so the concrete is placed continually and safe from contamination.

### 2 BASES OF DESIGN

The goal is to install a set of inclusions in soils with low bearing capacity and/or highly compressibility to create a layer of compound soil-inclusions material that has better mechanical properties.

The improvement or reinforcement of soils with rigid inclusions is commonly used to ensure bearing capacity and/or reduce settlements in the following types of work:

- Slabs,
- Superficial footings (isolated or continuous),
- Embankments, landfills,
- Work or storage yards.

The solution is characterized by the fact that the traditional mechanical link between the pile and the structure in deep or mixed foundations does not exist. A distribution layer, also called a Load Transfer Platform (LTP), is usually placed between the inclusions and the structure to be supported, and this is what marks the difference between piles and inclusions.

The distribution layer spreads the acting loads on the slab or other covering surface towards the underlying soil-inclusions setup. The system described is configured as shown in Figure 1. If there are concentrated vertical loads from one column, isolated or continuous footings can be used to directly transmit the loads to the soil-inclusions setup.

Figure 1. Inclusion under a load uniformly distributed on the surface. Side and top views.

In this case the LTP may not be required and a significant portion of the load from the superstructure will be supported by the grid of inclusions and the remainder will be supported by the soil surrounding the inclusions —see Figure 2—.

Figure 2. Model setup of inclusions under an acting strut load on a footing. Side view.

In the same way that the inclusion-soil system supports vertical loads —uniformly distributed or concentrated— from buildings, this application can be extended to the case of embankments and landfills in which the system will receive the weight of the material that forms the embankments or landfills. A particular case occurs when the embankment or landfill is significantly high and the soil reinforced with inclusions participates in its stabilization —see Figure 3—.

Figure 3. Inclusions that help stabilize an embankment or landfill constructed on the surface.

The inclusions will generally be subjected to the action of vertical forces caused by discharges from the building or due to the weight of the embankment or landfill. However, in cases where the inclusions participate in the stabilization of embankments or landfills, or when they are subjected to the action of seismic forces, the generation of lateral forces will also have to be taken into account in the design.

Several approaches and ways of analyzing and designing inclusions have been developed. Some of them have been recently brought together in the ASIRI (*Amélioration des Sols par Inclusions Rigides*—see ASIRI National Project, 2012—).

### 3 CONSTRUCTIVE SEQUENCE

The equipment used for the construction of displacement rigid inclusions kind must circulate over a flat working platform, drained and stable, generally constructed of granular material. The inclusions are built from this platform.

The drilling equipment consists of a crane supported on caterpillars with a cab for the operator and a mast that supports a cylindrical auger of a defined length. The auger is hollow and has a special geometry —see Figures 4a, 4b—, capable of displacing soil laterally when drilling. This is the most important feature of displacement rigid inclusions because the surrounding soil becomes laterally compressed. Lateral friction increases in the case of mainly granular soils or soils with a large content of sand.

At the bottom part of the tip there is a hinged lid that remains closed during the drilling phase to prevent the entry of material into the inner tube and which opens to allow the exit of the concrete to form the inclusions.

Besides the necessary drilling equipment there has to be a concrete pump which feeds the upper side of the drilling tool through flexible hoses.

Figure 4a. Diagram of the typical point of the hollow auger for displacement rigid inclusions.

Figure 4b. Point of the hollow auger for displacement rigid inclusions developed for Soletanche-Bachy, RefSol system.

With the topographic location of the inclusion to be built, the process begins by placing the mast of the crane upright and lowering the auger into the ground. A rotor torque and a descending vertical force are applied to the auger to cut, penetrate and displace the soil laterally. This action is performed continuously until the drill reaches the specified depth —see Figure 5A—.

At this point, the concrete is pumped from the tank of the pump through a flexible hose to the upper part of the hollow auger to fill it completely and to generate sufficient pressure on the concrete.

Figure 5. Execution sequence of a displacement rigid inclusion.

Then the auger is lifted a few centimeters from the soil at the bottom of the perforation, which causes the lid at the lower end of the auger to open. The concrete, subject to pressure, pours into the bottom of the hole, filling it. While still pouring concrete and controlling the pressure, at this point the operator lifts the auger continuously by means of a rotor torque and a vertical pulling force —see Figure 5B—. This process continues until the auger is fully above ground —see Figure 5C—. The concrete is poured continuously from the bottom of the perforation until it reaches the level defined as the head of inclusion, which can be between the working platform level and a few dozen centimeters below it.

Throughout the process of building an inclusion (Figures 5A, 5B and 5C) real time and continuous monitoring of the parameters that intervene in its execution are done with electronic devices located in the cab of the crane. They detect the signals sent by various sensors installed at strategic points of the construction equipment. Through this monitoring, the operator has control of the different construction parameters and can ensure the quality of the construction of the inclusion at all times and along its entire height. Among the parameters controlled are: the drilling depth, the pressure and the volume of the concrete, the upward and downward speeds, rotation and the auger's torque.

The equipment is also able to store the record of the controls for each inclusion, to be processed later on a personal computer. Continuous records are obtained along the depth (see Figure 6).

Figure 6. Record of monitoring in continuous real time: (A) Inclusion profile (mm), (B) Perforation energy (bar), (C) Perforation speed (m/h), (D) Rotation torque (t.m), (E) Rotation speed / Bearing force.

The start and stop of the concrete pump is wirelessly controlled by the crane operator from the cab. The speed at which the auger advances, the rotor torque, the rotation speed and down force or extracting force of the auger is controlled manually through the hydraulic system of the crane.

The procedure described is a clean process that leaves practically no perforation debris on the work platform. There are also no vibrations or damage to the surface layers, which makes working in areas adjacent to sensitive structures possible. Additionally, the method is capable of achieving high industrial production compared with traditional methods of pile construction.

For quality control, it is also necessary to carry out strength tests on samples of the concrete used. There will be as many tests as are needed or as required by local regulations. The common values of resistance to compressive strength of the concrete used for the construction of displacement rigid inclusion range from 10 to 15 MPa at 28 days, with modulus of elasticity usually set between 5,000 and 10,000 MPa, although higher resistance and rigidity levels can be used according to the needs of each project.

The commercial diameters of displacement rigid inclusion construction range between 250 and 500 mm and can reach depths of up to 30 m.

To guarantee the quality of the implementation and the design criteria, this construction procedure has been certified by the international bureau of control and certification Bureau Veritas.

#### 4 CONCLUSIONS

Soil improvement and reinforcement with displacement rigid inclusions kind solves a great number of foundations in which not only increasing bearing capacity, reducing settlements or ensuring slope stability play an important role, but where also cost and execution times are factors to be considered.

Given the type of auger used in the construction these inclusions are defined as displacement inclusions where the surrounding soil is displaced and laterally compressed at the moment of drilling, which increases the compactness of soils whose frictional component is significant.

During construction of displacement rigid inclusion there is real-time monitoring of parameters such as drilling depth, pressure and volume of the poured concrete, advancement speed and auger rotation, downward force of the rotor torque of the auger, which ensures a high quality control of the construction. Due to the advantages provided by the design of soil improvement systems with rigid inclusions, plus the geotechnical and environmental benefits of displacement rigid inclusions, numerous projects worldwide are being approached with this technique.

# Prediction of the unconfined compressive strength in soft soil chemically stabilized

## Prévision de la résistance à la compression non confinée dans sols mous chimiquement stabilisés

Correia A.A.S.; Venda Oliveira P.J., Lemos L.J.L.  
*Department of Civil Engineering – University of Coimbra, Portugal*

**ABSTRACT:** The chemical stabilization of soils is a ground improvement technique consisting on the mechanical mixing of the in situ natural soil with binders. The chemical stabilization of soils can be applied with either slurries (wet method) or powder (dry method) binders. When the stabilizing binders are mixed with the soil, physico-chemical interactions take place and are responsible for the stabilization effect, which has a major influence on the mechanical behaviour of the improved material. This stabilizing effect is dependent on a range of parameters which should be analysed through a long and extensive laboratory and field trial test program, as stated in the european standard (EN 14679:2005). In order to minimize the number of tests during the optimization process, this paper presents a simple method to predict the unconfined compressive strength, which is independent of the binder content and state (powder or slurry). The method is successfully applied to a wide range of soils, showing its versatility (Correia, 2011). Applying the generalised relationship of the method, it is possible to predict the unconfined compressive strength for any binder content and state from one single unconfined compression test.

**RÉSUMÉ :** La stabilisation chimique de sols est une technique de l'amélioration des sols qui consiste en le mélange mécanique dans situ du sol naturel avec liants. La stabilisation chimique de sols peut être appliquée avec coulis (méthode mouillée) ou poudre (méthode sec) liants. Quand les liants stabilisateurs sont mélangés avec le sol, ils produisent interactions physique-chimique lesquels sont responsables pour l'effet de la stabilisation, qui a une influence majeure sur le comportement mécanique du matériel améliorée. Cet effet stabilisateur est dépendant d'une gamme de paramètres qui devraient être analysés à travers d'un long et étendu programme d'essais en laboratoire et sur terrain, comme énoncé dans la norme européenne (EN 14679:2005). Pour minimiser le nombre d'essais pendant le processus de l'optimisation, cet article présente une méthode simple de prédire la résistance à la compression simple, qui est indépendant du contenu de liant et état (poudre ou coulis). Le méthode est appliquée avec succès à une grande gamme de sols, montrant sa versatilité (Correia, 2011). Appliquant la version généralisée du méthode, c'est possible prédire la résistance à la compression simple pour tout contenu de liant et état basé d'une seule essais à la compression simple.

**KEYWORDS:** chemical stabilization, unconfined compression test, soft soils, strength prediction.

### 1 INTRODUCTION.

Over the last few decades, infrastructure requirements and land occupation policies have demanded construction on soils with poor geotechnical properties (in particular, soft soils). These soils are usually characterized by low strength and high compressibility, demanding from geotechnical engineers new and challenging solutions to overcome these undesirable engineering characteristics. One of the ground improvement techniques that have been used with success in practice is the chemical stabilization, where the natural soil is mechanically mixed in situ with binders (usually called Mass Stabilization, or, Deep Mixing when applied in depth). This technique has given good results when applied to soft soils, becoming a prominent subject nowadays, rapidly growing and wide spreading around the world due to its technical and economical benefits when compared with other ground improvement techniques.

At first the chemical stabilization of soils used the quicklime as the hardening agent. Later on, the use of Portland cement has permanently been outpacing the use of quicklime, not only because Portland cement is readily available at reasonable cost but also because cement is more effective than quicklime (Horpibulsuk et al 2011, Åhnberg 2006, Lorenzo and Bergado 2004, Kitazume and Terashi 2002). However, additives such as granulated blast furnace slag, fly ash, gypsum and silica dust, among others, may be used specially for the improvement of soft soils with high water content or organic soils (Kitazume and Terashi 2002, Edil and Staab 2005).

The chemical stabilization of soils can be applied with either slurries (wet method) or powder (dry method) binders. When the stabilizing binders are mixed with the soil, physico-chemical interactions take place and are responsible for the stabilization effect, which has a major influence on the mechanical behaviour of the improved material. This stabilizing effect is dependent on a range of parameters which should be analysed through a laboratory and field trial test program, as stated in the european standard (EN 14679:2005).

The fundamental mechanical properties of cement based admixed soft soils have been experimentally investigated by many researchers (Correia 2011, Åhnberg 2006, Hernandez-Martinez 2006, Lorenzo and Bergado 2006 and 2004, Horpibulsuk et al 2004, Kamruzzaman 2002, Horpibulsuk 2001, Miura et al 2001, Uddin et al 1997, Locat et al 1996). Most of these previous investigations mainly focus on the influence of the water content and binder content, as well as on the ratio between them. Based on some of these parameters, Horpibulsuk et al (2003 and 2011) and Lorenzo and Bergado (2006) have introduced phenomenological models for predicting laboratory strength development in cement based stabilized soft soils. This paper presents a new simple model which aims to predict the laboratory strength (expressed by the unconfined compression test) for various combinations of water content and cement content. This model intends to minimize the number of laboratory tests needed to specify the quantity of cement and water to be admixed with the soft soil. Although the model is

developed for a particular soft soil, its versatility is demonstrated for a wide range of soils. A generalized strength equation is presented, which allows the strength prediction based, at lower limit, on a single unconfined compression test.

## 2 EXPERIMENTAL TESTS

### 2.1 Materials

Table 1 presents the geotechnical and chemical properties of the soft soil deposit of “Baixo Mondego” (located near Coimbra city, Portugal), used in the study. In general, the soil is predominantly clayey-silt with a high organic matter content, which has a strong influence on some characteristics of the soil, namely, low unit weight, high plasticity, high natural water content, high void ratio, low undrained shear strength and high compressibility although this fact is not consistent with the grain size distribution, particularly due to the low clay content, (Coelho 2000, Venda Oliveira et al. 2010).

Table 1. Principal properties of the soft soil of “Baixo Mondego”.

Natural water content, $w_{nat}$ (%)	80
Unit weight, $\gamma_{sat}$ (kN/m <sup>3</sup> )	14.6
Natural void ratio, $e_{nat}$ (-)	2.1
Clay fraction (%)	8-12
Silt fraction (%)	71
Sand fraction (%)	17-21
Density, $G$ (-)	2.55
Organic matter content, OM (%)	9.3
Liquid limit, $w_L$ (%)	71
Plastic limit, $w_P$ (%)	43
Undrained shear strength, $c_u$ (kPa)	< 25
CaO (%)	0.74
SiO <sub>2</sub> (%)	62
Al <sub>2</sub> O <sub>3</sub> (%)	16
Fe <sub>2</sub> O <sub>3</sub> (%)	4.8
MgO (%)	1.1
pH (-)	3.5

The binders used in the present study to produce stabilized “Baixo Mondego” soft soil samples were a Type I Portland cement, designated CEM I 42.5 R (EN 197-1 2000), and a blast furnace granulated slag, here simply designated as SLAG. These two binders, on a dry weight proportion of 75/25 as proposed by Correia (2011), were thoroughly mixed to obtain a uniform binder. The binder added to the soil was defined by the parameter binder content,  $a_w$  (ratio of the dry weight of binder used in the mixture to the dry weight of the soil). The composition and the specific surface of the binders are presented in Table 2.

Table 2. Composition and specific surface of the binders.

	CEM I 42.5R	SLAG
CaO (%)	63.02	37.02
SiO <sub>2</sub> (%)	19.70	38.74
Al <sub>2</sub> O <sub>3</sub> (%)	5.23	11.59
Fe <sub>2</sub> O <sub>3</sub> (%)	2.99	0.85
MgO (%)	2.38	6.75
Specific surface, $S$ (m <sup>2</sup> /kg)	321.5	363.0

### 2.2 Chemical stabilization of the soft soil of “Baixo Mondego”

In order to evaluate the influence of the water content and binder content on the chemical stabilization of the soft soil of “Baixo Mondego”, several samples were prepared for various water contents (equivalent to a liquidity index  $I_L$  of 1.35, 1.96 and 2.49) and binder contents (from 9 to 27, step 3). The laboratorial procedure to produce stabilized samples followed

the laboratory procedure presented in EuroSoilStab (2001) with the modifications proposed by Correia (2011). During the curing time, fixed as 28 days, all samples were subjected to a vertical pressure of 24 kPa and stayed submerged in a water tank at a controlled temperature (20±2°C). After this period, the samples were submitted to the unconfined compression test in order to evaluate its strength ( $q_{u\ max}$ ).

Table 3 and Figure 1 summarizes the main results of the chemical stabilization of the soft soil of “Baixo Mondego”. The results show that, as expected, the unconfined compressive strength increases with the binder content and with the decreasing of the water content (or liquidity index). As the binder content increases, more binder is admixed with the soil allowing the construction of a stronger skeleton matrix. As the water content increases the void ratio also increases, promoting the particles’ spacing with obvious reflects on the fabric of the stabilized soil and on its strength.

Table 3. Unconfined compressive strength results of the chemical stabilization of the soft soil of “Baixo Mondego”.

$I_L$ (-)	$a_w$ (%)	$q_{u\ max}$ (kPa)
1.35	9	209
	12	644
	15	1143
	18	1618
	21	1831
	24	1936
1.96	27	1995
	9	118
	15	694
	21	1266
	27	1383
2.49	9	90
	15	552
	21	965
	27	1032

Figure 1. Unconfined compressive strength results of the chemical stabilization of the soft soil of “Baixo Mondego”.

From Figure 1 it can be seen that the curves for different liquidity index exhibit a similar shape (are homothetic). Thus the unconfined compressive strength ( $q_{u\ max}$ ) can be normalised by the liquidity index ( $I_L$ ) multiplying both parameters ( $q_{uL} = q_{u\ max} \times I_L$ ). Figure 2 presents these results which are well fitted by a linear logarithmical regression. This is a simple way to predict the unconfined compressive strength at 28 days of curing time for the cement based stabilized softy soil in study. As it is a linear regression it only requires two test data made for different binder contents.

In order to validate this simple method, it will be applied to other soft soils as presented in the next section.

Figure 2. Normalized unconfined compressive strength results of the chemical stabilization of the soft soil of "Baixo Mondego".

### 3 DATA FROM OTHER CEMENT BASED STABILIZED SOFT SOILS

Table 4 presents the main results of 7 other cement based stabilized soft soils whose geotechnical properties are described in Horpibulsuk (2001) and Kawasaki et al (1981). Figure 3 presents the results of the unconfined compressive strength normalized by the liquidity index, from which it can be concluded that each cement based stabilized soft soil has its normalization (fitting curve). Thus the method here proposed is versatile as it is valid for other soft soils.

Table 4. Unconfined compressive strength results of cement based chemical stabilization of other 7 soft soils (Horpibulsuk 2001, Kawasaki et al 1981).

Soft soil	$I_L$ (-)	$a_w$ (%)	$q_{u \max}$ (kPa)

		20	2436
		30	3952

Figure 3. Normalized unconfined compressive strength for other cement based stabilized soft soils.

### 4 GENERALIZING THE PROPOSED METHOD

As it was observed in Figures 2 and 3, the method proposed can be applied satisfactory to a wide range of soft soils. However, each cement based stabilized soft soil has its own fitting parameters (see the equations for  $q_{IL}$  in Figures 2 and 3), different for each soil.

In order to find a generalized strength equation, independent of the soft soil, the  $q_{IL}$  data of a particular soft soil was normalized by the unconfined compressive strength defined for a liquidity index of 1.0 and for a constant binder content (it was considered the value 18% for all soft soils),  $q_{IL=1}(a_w=18\%)$ . For each soft soil, this last value was evaluated from the fitting curves presented in Figures 2 and 3. All data are presented in Figure 4, where it can be seen that the values are in a narrow linear band, fitted relatively well by a linear logarithmical regression ( $R^2 = 0.94$ ). Thus, the method proposed in this paper seems to be independent of the soft soil type, being valid for the prediction of the unconfined compressive strength at 28 days of curing time of cement based stabilized soft soils, which is helpful for the laboratory optimization process of the chemical stabilization. The number of unconfined compression tests required can be reduced to one if it is applied the generalized equation and the binder content chosen is 18%.

Figure 4. Generalized strength equation for the unconfined compressive strength of cement based stabilized soft soils.

## 5 CONCLUSION

The paper presents a new simple method to predict the unconfined compressive strength at 28 days of curing time of cement based stabilized soft soils, whatever be the water content and binder content. The method was initially developed for the soft soil of “Baixo Mondego” chemically stabilized, and then was successfully applied to a wide range of cement based stabilized soft soils. Thus, this new method seems to be independent of the soft soil, which allows the definition of a general relationship (presented in Figure 4). At limit, the number of unconfined compression tests required can be reduced to one if it is applied the generalized equation and the binder content chosen is 18%. The method proposed in this paper is helpful for the laboratory optimization process of the chemical stabilization at the pre-design stage.

## 6 ACKNOWLEDGEMENTS

The authors would like to express their thanks to CIMPOR for supplying the binders used in the work and to the institutions that supported the research financially: University of Coimbra, CIEC and FCT (PTDC/ECM/101875/2008).

**RÉSUMÉ :** Cet article présente les résultats d'un travail de modélisation numérique visant à simuler un essai de chargement axial sur une colonne de sol-ciment, réalisée par soil-mixing en voie humide. Quatre modèles ont été bâtis dans le cadre de ce travail : trois modèles en éléments finis, et un modèle semi-analytique simplifié. Les résultats des quatre modèles sont confrontés à ceux obtenus par un essai de chargement monotone en vraie grandeur, réalisé sur une colonne de sol – mixing de 400 mm de diamètre et 5 m de hauteur, mise en œuvre dans un sol limoneux à sablo-graveleux. Ces résultats permettent notamment de reproduire le mode de rupture observé lors de l'excavation de la colonne, et mettent en évidence la nécessité de modéliser correctement le comportement non linéaire du matériau sol-ciment qui influe significativement sur le comportement global, à la différence des pieux « rigides ».

**ABSTRACT:** This article shows the results of a numerical modelling study aiming at simulating an axial load test on a soil-cement column, carried out using the wet soil-mixing method. Four models were built as part of this study: three finite element models and one simplified semi-analytical model. The results from the four models were compared with those from a full-size monotonic load test, performed on a Ø400 mm diameter and 5m high soil-mixing column, installed in silty to sandy-gravelly soils. These results allow to reproduce the failure mode observed during the column excavation, by emphasizing the need of an accurate modelling of the non-linear soil-cement material which has a significant influence on the general behaviour, unlike with "rigid" piles.

**KEYWORDS:** Numerical modelling, soil reinforcement, Soil-mixing, load test.

## 1 INTRODUCTION

La technique du soil mixing permet d'améliorer les caractéristiques d'un sol meuble par mélange mécanique *in situ* avec un liant hydraulique. Le sol initialement présent sur le chantier est alors valorisé comme un matériau de construction, avec le double intérêt de diminuer les déchets (sols excavés) et de réduire la consommation de matériaux et d'énergie.

Le procédé Springsol® utilise un outil ouvrant, pour réaliser des colonnes de sol-ciment de diamètre variable, ce qui limite au maximum l'impact des travaux sur les existants. Ce procédé offre des perspectives aussi bien dans le domaine de la maintenance des plateformes ferroviaires (possibilité de renforcer les structures ferroviaires sans avoir à déposer les voies), que dans celui du renforcement des fondations existantes (empreinte des forages sur les structures limitée au diamètre de l'outil fermé).

Cette souplesse et le caractère économe en déchets et en matériaux permettent au procédé Springsol de répondre aux nouvelles exigences environnementales et économiques des projets. C'est donc dans le but de développer ces solutions que Soletanche Bachy, la SNCF et Terrasol collaborent au sein du projet de recherche RUFEX (Renforcement et réUtilisation des plateformes et Fondations Existantes) avec l'IFSTTAR, l'INSA de Lyon et l'Ecole des Ponts ParisTech.

Cet article présente les résultats d'un travail de modélisation numérique d'un essai de chargement monotone conduit jusqu'à la rupture sur une colonne de soil mixing réalisée sur un chantier de validation du projet RUFEX.

## 2 ESSAI DE CHARGEMENT EN VRAI GRANDEUR

Un essai de chargement sur une colonne de soil-mixing de 400 mm de diamètre et 5 m de hauteur a été réalisé sur le site expérimental du projet Rufex situé sur la commune de Vernouillet (78). Le contexte géotechnique est caractérisé par des remblais en surface suivis d'une couche de limon sableux reposant sur un sable graveleux. Aucune nappe phréatique n'a été rencontrée lors des reconnaissances. Le Tableau 1 récapitule les caractéristiques géo-mécaniques issues des essais réalisés.

Tableau 1. Caractéristiques géotechniques des sols du site.

Nature	Limon sableux	Sable graveleux
Profondeur du toit (m)	0,5	3,5
Pression limite nette $pl^*$ (MPa)	1	2,5
Module pressiométrique $E_m$ (MPa)	10	20
Cohésion $c'$ (kPa)	2	0
Angle de frottement ( $^\circ$ )	27	37

La colonne testée a été forcée avec l'outil Springsol®. Le malaxage du sol avec le liant hydraulique (ciment de type CEM III) a été effectué *in situ* par voie humide. La quantité de ciment injectée dans la colonne sous forme de coulis était d'environ 230 kg / m<sup>3</sup>.

L'essai de chargement a été réalisé 90 jours après l'installation de la colonne, avec des paliers de chargement de 50 kN maintenus pendant 30 min. La courbe de chargement obtenue est présentée sur la Figure 1. Le chargement a été arrêté pour une charge maximale de 400 kN, lorsque le tassement de la tête de la colonne a dépassé 40 mm (1/10<sup>ème</sup> du diamètre).

Figure 1. Courbe de chargement sur colonne de soil-mixing.

Après 180 jours, l'excavation de la colonne testée a permis de distinguer une partie supérieure (de 0 à 2,5 m) constituée de limon traité et une partie inférieure composée de sable traité. Une zone de transition faite d'un mélange de limon et de sable traité a été observée entre 2,5 et 3,5 m. Des fragments de la colonne ont été prélevés, carottés en laboratoire, et soumis à des essais mécaniques pour déterminer la résistance et le module de déformation du matériau constitutif de la colonne (Tableau 2).

Tableau 2. Résultats des essais en laboratoire sur les éprouvettes provenant de la colonne excavée.

Nature	Limon traité (1)	Transition (2)	Sable traité (3)
Profondeur (m)	0,5 - 2,5	2,5 - 3,5	3,5 - 5,0
Résistance Rc (MPa)	3,7	7,6	11,9
Module local E <sub>50</sub> (MPa)	1280 Rc	1280 Rc	1280 Rc
Angle de frottement (°)	42	42	42
Cohésion (kPa)	700	1700	2800

Vers 1 m de profondeur, la colonne de limon traité apparaît particulièrement fissurée et fracturée (Figure 2), ce qui fait suggérer que la rupture s'est produite au sein du matériau constitutif de la colonne. Ce constat est conforté par le fait que la portance de la colonne (estimée à partir des résultats des essais pressiométriques) était a priori supérieure à sa résistance interne (estimée à partir des résultats des essais sur les éprouvettes carottées).

Zone de limon traité fissurée et fracturée vers 1 m de profondeur

Figure 2. Excavation de la colonne après l'essai de chargement.

### 3 MODÉLISATION DE L'ESSAI DE CHARGEMENT : MODÈLES ÉLÉMENTS FINIS

Le résultat de l'essai de chargement est utilisé comme référence pour l'évaluation de quatre modèles numériques dont trois basés sur un traitement complet en éléments finis. Ces modèles sont construits selon la coupe schématique suivante (Figure 3) et sur la base des paramètres donnés dans les Tableaux 1 et 2.

Figure 3. Coupe de calcul retenue

#### 3.1 Modèle 1 (logiciel GEFDyn)

Ce modèle est bâti à l'aide du logiciel éléments finis GEFDyn. Il s'agit d'un modèle tridimensionnel où la colonne est modélisée par des éléments volumiques à 8 nœuds formant un quart de cylindre de 400 mm de diamètre et 5 m de long, noyé dans un milieu continu de 20 m de profondeur. Des éléments d'interface ont été introduits entre la structure de la colonne et les éléments de sol.

Le modèle de comportement choisi est un modèle linéaire élastique parfaitement plastique avec un critère de rupture de Mohr Coulomb (noté MC par la suite) pour les différents matériaux (sol et colonne). La loi de l'interface est celle d'Aguiar et al (2011) dont la formulation est basée sur les mêmes hypothèses de comportement que le modèle dit de Hujieux (1985) qui se révèle très adapté au comportement non linéaire des sols. La richesse de ce type de modèle réside dans la possibilité, en fonction des paramètres de la surface de charge et du type d'érouissage, de modéliser des comportements qui peuvent aller du simple « élastique parfaitement plastique » à un comportement élasto-plastique à érouissage déviatorique et volumique. Pour le présent calcul, les paramètres de l'interface sont choisis de manière à représenter une surface de charge de Mohr Coulomb avec un comportement élastique parfaitement plastique. L'angle de frottement à l'interface a été choisi égal à celui du sol environnant. Cela est justifié par le mode de réalisation de la colonne (malaxage local) qui produit une interface rugueuse mobilisant ainsi un mécanisme de rupture mettant en jeu la résistance intrinsèque du sol (Figure 4).

Figure 4. Etat de la surface d'un tronçon de colonne excavée

### 3.2 Modèle 2 (logiciel ABAQUS)

Le modèle 2 est bâti sous le logiciel ABAQUS. Il s'agit d'un modèle axisymétrique qui intègre une loi de comportement avancée de type « Drucker-Prager » modifiée avec cap (DPC). Ce modèle permet de prendre en compte l'effet d'écroutissage du sol, l'historique de contraintes, ainsi que l'effet de compaction en pointe sous la colonne. La surface de charge est composée de trois parties : une limite de rupture en cisaillement de type Drucker-Prager, un cap elliptique, et une zone de transition (Figure 5).

Figure 5. Loi de Drucker-Prager modifiée avec cap (DPC)

Les paramètres  $\beta$  et  $d$  s'expriment en fonction de l'angle de frottement interne  $\varphi$  et la cohésion  $c$  à l'aide de la relation (1) :

$$\tan \beta = \frac{6 \sin \varphi}{3 - \sin \varphi} \quad \text{et} \quad d = \frac{18c \cos \varphi}{3 - \sin \varphi} \quad (1)$$

Les autres paramètres sont choisis soit par calage, soit d'une manière forfaitaire sur la base d'éléments bibliographiques. En particulier, le paramètre  $p_b$  qui délimite la surface d'écroutissage, doit en toute rigueur être calé sur le résultat d'un essai de consolidation isotrope. Dans le présent exercice, ce modèle (DPC) a été considéré pour caractériser le comportement des sables graveleux. Pour les autres matériaux (colonne et limons sableux), il a été retenu une loi linéaire élastique parfaitement plastique avec critère de rupture de Mohr Coulomb (MC). Pour la définition de la loi DPC dans les sables graveleux, les paramètres suivants ont été considérés :  $R = 0,10$ ,  $\alpha = 0,01$  et  $p_b$  fonction de la déformation volumique plastique selon la loi d'écroutissage des sables d'Ottawa (Helwany 2000). Enfin, des éléments d'interface ont été introduits avec une loi MC.

### 3.3 Modèle 3 (logiciel PLAXIS)

Le 3<sup>e</sup> modèle est un modèle axisymétrique bâti sous le logiciel PLAXIS. Les éléments utilisés sont des éléments triangulaires à 15 nœuds et 30 degrés de liberté. Pour le sol et la colonne, on choisit une loi de contraintes-déformations de type « HSM » (Hardening Soil Model - Figure 6) qui est une loi hyperbolique tenant compte de l'écroutissage en cisaillement et en compression.

Figure 6. Principe de la loi HSM sous PLAXIS

Ce modèle permet par ailleurs de tenir compte de la variation du module de déformation sécant  $E_{50}$  (à 50% de la contrainte de rupture) avec l'état de contraintes. Cette variabilité est contrôlée par un paramètre « puissance » noté  $m$ , qu'on prend usuellement égal à  $m = 0,5$  pour le sol en place (le module sécant est proportionnel à la racine de la contrainte appliquée). Pour la colonne, ce paramètre est pris égal à  $m = 0$  (pas de variation du module sécant avec l'état de contraintes). Enfin, cette loi est combinée avec un critère de rupture de type Mohr Coulomb.

Des éléments d'interface ont été par ailleurs introduits sur toute la frontière de la colonne avec une loi de contraintes-déformations et un critère de rupture identiques à ceux des sols environnants.

### 3.4 Mise en œuvre et résultats

Pour les trois modélisations réalisées, les données géotechniques ont été complétées par les valeurs du module de déformation sécant  $E_{50}^{h/2}$  à mi-épaisseur dans chaque couche :  $E_{50}^{h/2} = 25$  MPa pour les limons sableux et  $E_{50}^{h/2} = 100$  MPa pour les sables graveleux. La Figure 7 présente la courbe de chargement simulée à l'aide des trois modèles présentés ci-dessus. Une très bonne concordance est observée entre la modélisation et les mesures jusqu'à 300 kN (75% de la charge de rupture mesurée). Les modèles 2 et 3 mettent en évidence un palier de rupture net situé entre 350 et 400 kN, ce qui correspond, à 10% près, au palier obtenu par l'essai de chargement sur site.

Figure 7. Simulation de la courbe de chargement par modélisation numérique en éléments finis

Dans les modèles 2 et 3, le palier de rupture obtenu correspond au développement d'une zone de plastification « conique » dans la partie supérieure de la colonne vers 1 m de profondeur (Figure 8). Ce constat est corroboré par les observations faites sur site lors de l'excavation de la colonne.

Figure 8. Développement d'un mécanisme de rupture localisé dans la colonne (modèle 3)

#### 4 MODÈLE SEMI-ANALYTIQUE SIMPLIFIÉ

##### 4.1 Principe du modèle

On utilise à présent un modèle semi-analytique simplifié basé sur la méthode dite « t-z » : la colonne est assimilée à une poutre verticale travaillant en compression axiale, tandis que le frottement latéral  $\tau$  et la contrainte en pointe  $q$  suivent une loi de mobilisation de Frank et Zhao (1982), et sont donc fonctions du déplacement vertical de la colonne  $w$ . Chaque loi est caractérisée à l'aide de deux paramètres : un paramètre de pente ( $K_t$  ou  $K_p$ ) et une contrainte unitaire limite ( $q_s$  ou  $q_p$ ). Ces lois sont couramment utilisées en France pour estimer le tassement d'un élément de fondation profonde, et se révèlent très efficaces dans les exercices de calage par rapport à un essai de chargement en vraie grandeur.

Figure 9. Lois de mobilisation de type Frank et Zhao

Les courbes de mobilisation ci-dessus sont combinées avec la loi de comportement de la colonne, qui relie la contrainte appliquée  $\sigma$  au taux de déformation axiale de la colonne  $\epsilon$ . A la différence des pieux « classiques » pour lesquels le contraste de rigidité pieu/sol est tel que l'essentiel des tassements est obtenu en pointe, la particularité d'une colonne de soil-mixing réside dans un contraste de rigidité colonne/sol plus faible et une sensibilité notable de la raideur globale en tête vis-à-vis du comportement local. Ces éléments ont justifié le recours à une loi de contrainte-déformation non linéaire pour la colonne : il a été retenu une loi de forme hyperbolique (Figure 10) construite à l'aide de deux paramètres : le module sécant  $E_{50}$  et la résistance à la compression simple  $R_c$ . Lors du présent exercice, cette loi s'est révélée apte à retranscrire le comportement observé, à la différence d'une loi linéaire élastique.

Figure 10. Loi de contrainte-déformation retenue pour la colonne

##### 4.2 Mise en œuvre

La loi de contrainte-déformation de la Figure 10 est construite à partir des paramètres ( $E_{50}$ ,  $R_c$ ) qui figurent dans le Tableau 2.

Les paramètres de pente des lois de Frank et Zhao (Figure 9) s'obtiennent par corrélation avec le module pressiométrique  $E_M$  :  $K_t = 0,8 E_M / B$  et  $K_p = 4,8 E_M / B$ , où  $B$  désigne le diamètre de la colonne. Ensuite, pour le choix du frottement latéral limite  $q_s$ , deux hypothèses enveloppes sont examinées : la première est celle d'un contact béton/sol pour laquelle la valeur de  $q_s$  s'obtient par corrélation avec la pression limite  $pl^*$  ; la deuxième hypothèse est celle d'un contact sol/sol pour laquelle la valeur de  $q_s$  est celle du cisaillement limite de Mohr Coulomb :  $q_s = \tan(\phi^*) \cdot K_0 \cdot \sigma_v'$ , avec  $K_0 = 0,5$  et  $\sigma_v'$  la contrainte verticale effective initiale à l'interface de la colonne. Enfin, la contrainte limite en pointe  $q_p$  est prise égale à 4 MPa.

#### 4.3 Résultats

La Figure 11 présente les résultats obtenus (courbe de chargement). Deux cas ont été étudiés : cas d'un comportement linéaire élastique de la colonne ( $E = E_{50}$ ), et cas d'un comportement non linéaire ( $E = f(\sigma)$ ) selon la loi décrite dans la Figure 10. Pour chaque cas, deux situations sont examinées : frottement de type sol/sol ( $q_s = f(\sigma_v')$ ) et frottement de type béton/sol ( $q_s = f(pl^*)$ ). Les résultats obtenus confirment la pertinence d'une loi de comportement non linéaire pour le matériau constitutif de la colonne, et montrent que le choix d'un frottement de type « sol/sol » est plus représentatif du comportement réel observé. Avec ces hypothèses, le résultat du modèle semi-analytique se révèle très concordant avec celui de l'essai de chargement jusqu'au palier de rupture. Celui-ci est obtenu par plastification en tête de la colonne (contrainte appliquée proche de la résistance à la compression simple  $R_c$ ).

Figure 11. Courbe de chargement – Modélisation analytique simplifiée

#### 5 CONCLUSION

Les enseignements tirés de l'essai de chargement en vraie grandeur ont permis d'orienter le choix des paramètres d'entrée des différents outils numériques développés dans le cadre du projet RUFEX. Les résultats obtenus, tant par les modèles numériques que par le modèle semi-analytique, permettent de bien reproduire le comportement observé lors de l'essai, aussi bien sur le comportement avant rupture que sur le mode de rupture. Ils mettent en évidence la nécessité de modéliser correctement le comportement non linéaire du matériau sol-ciment qui influe significativement sur le comportement global, à la différence des pieux « rigides ».

#### 6 REMERCIEMENTS

Les auteurs tiennent à remercier la DGCIS (Direction Générale de la Compétitivité et des Services) et les Conseils Généraux de la Région Ile de France et 93 qui cofinancent cette recherche.

**ABSTRACT:** Since several decades, the deep soil mix (DSM) technique has been used for ground improvement works. But in recent years, this technique has been increasingly used for structural applications. Standardized guidelines for the execution and the design of this kind of applications are not currently available. For the purpose of developing such guidelines, mechanical characteristics of DSM material were investigated. Within the framework of a Flemish regional research program (IWT 080736), DSM material from 38 Belgian construction sites, with various soil conditions and for different execution processes, has been tested. Internationally QA/QC activities are commonly related to tests on core samples for the determination of the Unconfined Compressive Strength (UCS) and the modulus of elasticity (E) of the material. Both values allow an approach of the design which takes into account the bending characteristics (EI), the deformation (E), the arching effect (UCS) and the structural resistance (UCS) of the element. For the semi-probabilistic design approach presented in Eurocode 7, a “characteristic value” of the UCS has to be defined as part of the design of DSM structures. The present paper discusses the definition of this value.

**RÉSUMÉ :** Depuis plusieurs décennies, la technique du soil mix est utilisée comme procédé d'amélioration du sol. Mais ces dernières années, elle est de plus en plus utilisée pour des applications structurelles. Aucune directive n'est actuellement disponible pour l'exécution et le dimensionnement de telles applications. De manière à développer de telles directives, les caractéristiques mécaniques du matériau soil mix ont été investiguées. Dans le cadre d'un programme de recherche financé par l'IWT, l'agence gouvernementale flamande pour l'innovation, des échantillons de soil mix de 38 sites de construction ont été testés pour différents types de sol et différents systèmes. La qualité du matériau soil mix est généralement contrôlée à l'aide d'essais, réalisés sur des échantillons carottés in situ, par lesquels sont déterminés la résistance à la compression simple (UCS) et le module d'élasticité (E) du matériau. Ces deux grandeurs permettent une approche du dimensionnement tenant compte de la rigidité flexionnelle (EI), des déformations (E), de l'effet de voûte (UCS) et de la résistance structurelle (UCS) de l'élément. Au vue de l'approche semi-probabiliste de l'Eurocode 7, il est important de définir la valeur caractéristique de la résistance du soil mix (UCS) à prendre en compte dans le dimensionnement. Le présent article discute de la définition de cette valeur caractéristique.

**KEYWORDS:** Deep soil mix wall, structural design, ucs characteristic value

### 1 INTRODUCTION

The Deep Soil Mix (DSM) process was introduced in the 70's in Japan and in the Scandinavian countries. Since several decennia, DSM has been known as a ground improvement (GI) technique. According to the classification of GI methods adopted by the ISSMGE TC 211, DSM can be classified as ground improvement with grouting type admixtures. Numerous reviews and recent progresses of the DSM technique are referred in Denies and Van Lysebetten (2012). The results of national and European research programs have also been published in multiple interesting reports (such as Eurosoilstab 2002), while the European standard for the execution of deep mixing “Execution of special geotechnical works – Deep Mixing” (EN 14679) was published in 2005. Most of these research projects focused on the global stabilization of soft cohesive soils such as clay, silt, peat and gyttja (result of the digestion of the peat by bacteria). More recently, DSM is increasingly being used for structural applications such as soil mix walls (SMW) for the retaining of soil and water in the case of excavations.

In the DSM process, the ground is mechanically mixed in place, while a binder, based on cement, is injected. For SMW applications, the DSM cylindrical columns or the rectangular

panels are placed next to each other, in a secant way. By overlapping the different soil mix elements, a continuous SMW is realized. Steel profiles are inserted into the DSM fresh material to resist the shear forces and bending moments. The main structural difference between SMW and the more traditional secant pile walls is the constitutive DSM material which consists of a soil – cement mixture instead of concrete.

Elements such as piles or diaphragm walls only comprise standardized components and their characteristic strength can be defined by the strength class of concrete. The design approach for the DSM material is very different since the existing soil is used as an essential component of the final product. Moreover, the DSM strength depends not only on the soil type, but also on the DSM technique, the amount and the type of binder, etc.

Within the framework of the BBRI “Soil Mix” project initiated in 2009 in collaboration with the KU Leuven and the Belgian Association of Foundation Contractors (ABEF), numerous tests on in situ DSM material have been performed. A good insight has been acquired with regard to mechanical characteristics that can be obtained with the CVR C-mix<sup>®</sup>, the TSM and the CSM systems in several Belgian soils as reported in Denies et al. (2012). BBRI information sheets (BBRI, 2012a and b) have been published for the purpose of helping contractors to improve the quality control (QC) of their finished

product, but guidance rules for the design of SMW are still lacking in particular for the determination of a “characteristic value” representative of the strength of the soil mix material. Neither in the Eurocode 7 nor in the European standards for grouting (EN 12715), jet-grouting (EN 12716) or deep-mixing (EN 14679), specifications are given for the internal strength of the material.

In practice, Quality Assurance (QA) and Quality Control (QC) activities are commonly related to tests on core samples for the determination of the Unconfined Compressive Strength (UCS) and the modulus of elasticity (E) of the material. Both values allowing an approach of the design taking into account the bending characteristics (EI), the deformation (E), the arching effect (UCS) and the structural resistance (UCS) of the element. For engineering purposes and as part of the semi-probabilistic design approach presented in Eurocode 7, it is thus essential to define the UCS characteristic value that can be taken into account in the design of DSM structures. The following paragraphs discuss the definition of this value.

## 2 DETERMINATION OF THE UCS CHARACTERISTIC VALUE OF DSM MATERIAL

### 2.1 On the basis of an X% lower limit value

The first methodology consists in the calculation of the characteristic strength as the X% lower limit on the basis of a statistical distribution function. Nevertheless, in practice, the wrong assumption is often made that the datasets of UCS values of soil mix material are normally distributed (see Fig. 1a). The characteristic UCS value is then erroneously calculated as the X% lower quantile of the normal distribution with parameters corresponding to the dataset. Moreover, this often results into negative and thus useless characteristic UCS values. The mathematically correct solution would be to apply the best fitting standard distribution function, for example a lognormal distribution in case the distribution is skewed and/or does not contain subpopulations. The X% lower limit can then be calculated on the basis of this theoretical distribution function, as illustrated in Denies et al. (2012) for a lognormal distribution (see Fig. 1b). Possibly, a factor  $\beta$  has to be added to the values to obtain an optimal fit with a normal distribution after transformation. However, this way of working is probably too complex to apply in practical situations.

The second methodology to determine the X% lower limit is based on the cumulative frequency curve of the original experimental dataset and thus independent of any theoretical distribution function. Note that to apply this method, enough data points have to be available (for an accurate determination of the 5% lower limit without extrapolation, at least 20 samples are necessary). This approach seems rather simple but any other method probably results in a large uncertainty. Figure 2 presents the cumulative frequency curve for the UCS values of the dataset illustrated in Fig. 1.

### 2.2 On the basis of an average value with safety factor

A second approach to determine the UCS characteristic value is the use of the average value of the dataset in combination with a safety factor:

$$f_{c,k} = \alpha \overline{q_{uf}} \tag{1}$$

where  $\overline{q_{uf}}$  is the mean UCS value and  $\alpha$  a factor representing a certain confidence and safety level ( $\alpha < 1$ ).

In the formalized design approach (DIN 4093, August 2012) used in Germany, the UCS characteristic value is defined as the minimum value of three parameters:

Figure 1. a) Distribution of the UCS values of 41 cores of DSM material from a site in Gent (Belgium) and the corresponding theoretical Gaussian curve. b) Distribution of the logarithm of the UCS values increased with  $\beta = 0.6$  from the same site and the corresponding Gaussian curve. The vertical line indicates the 5% lower limit value, after Denies et al. (2012).

Figure 2. Cumulative frequency curve of all UCS values of the dataset from the site in Gent: a) Full curve. b) Zoom on the part below 50%: presentation of the construction for the evaluation of the 5% lower limit value.

$$f_{c,k} = \min(f_{m,min} ; \alpha f_{m,mittel} ; 12 \text{ MPa}) \tag{2}$$

where  $f_{m,min}$  is the minimum UCS value and  $f_{m,mittel}$  the arithmetic mean UCS value from a series of at least 4 samples.  $\alpha$  is determined in function of  $f_{c,k}$ :  $\alpha$  equals 0.6 for  $f_{c,k} \leq 4$  MPa and 0.75 for  $f_{c,k} = 12$  MPa (linear interpolation is required for intermediate values). This method is described in more detail by Topolnicki and Pandrea (2012).

If the characteristic value  $f_{c,k}$  is smaller than 4 MPa, additional creep tests have to be conducted with a load of  $f_{c,k}/2$  as described in the annex B of the DIN 4093.

The design strength for calculations with the concept of partial safety factors is then computed as follows:

$$f_{c,d} = 0.85 \frac{f_{c,k}}{\gamma_m} \quad (3)$$

where 0.85 is a factor to consider permanent situations and  $\gamma_m$  is the material safety factor as defined in Eurocode 7 (1.5 for permanent and temporary load cases and 1.3 for accidents). For temporary situations, the design strength is computed without the 0.85 coefficient.

As reported in Topolnicki and Pandrea (2012), if independent and separate design calculations are performed for compressive and shear stresses (i.e. no 3D stress analysis), the maximum allowed compressive stress is  $0.7 \times f_{c,d}$  and the maximum allowed shear stress is  $0.2 \times f_{c,d}$ .

For comparison with the previous version of the DIN 4093 (published in September 1987), Table 1 presents cumulated safety factors on material strength ( $f_{m,mittel}$ ) and equivalent global safety factors ( $(\gamma_m \times \gamma_{G,Q}) / (\alpha \times 0.85 \times (0.7 \text{ or } 1))$ ) computed with the new DIN 4093 for permanent design situations. An increase in the number of test samples has no effect on the safety factors.

Table 1. Cumulated safety factors on material strength ( $f_{m,mittel}$ ) and equivalent global safety factors in permanent design situation according to DIN 4093 – August 2012 ( $\gamma_m = 1.5$ ).

	For $\alpha=0.6$	For $\alpha=0.75$
With 3D analysis		
<b>Cumulated safety factor</b>	<b>2.94</b>	<b>2.35</b>
Permanent actions ( $\gamma_G=1.35$ )		
<b>Equivalent global safety factor</b>	<b>3.97</b>	<b>3.18</b>
Variable actions ( $\gamma_Q=1.50$ )		
<b>Equivalent global safety factor</b>	<b>4.41</b>	<b>3.53</b>
Without 3D analysis		
<b>Cumulated safety factor</b>	<b>4.20</b>	<b>3.36</b>
Permanent actions ( $\gamma_G=1.35$ )		
<b>Equivalent global safety factor</b>	<b>5.67</b>	<b>4.54</b>
Variable actions ( $\gamma_Q=1.50$ )		
<b>Equivalent global safety factor</b>	<b>6.30</b>	<b>5.04</b>

For comparison, in the previous version of the DIN 4093 (September 1987), the design value was computed as follows:

$$f_{c,d} = \frac{f_{m,mittel}}{5} \quad (4)$$

for samples with UCS values expected larger than 5 MPa and tested according to the DIN 1048 standard for concrete material, or with the help of:

$$f_{c,d} = \frac{q'_u}{3} \quad (5)$$

for samples with UCS values expected smaller than 5 MPa and tested according to the DIN 18 136 for soil material.  $q'_u$  is the UCS value computed according to the DIN 18136.

Considering the safety factor of 5 and the reduction factor of 0.7 related to the 3D character of the loading, the previous version of the DIN 4093 resulted in a global safety factor of 7.14.

For this second approach based on an average value with safety factor, Denies et al. (2012) have remarked that first, the definition of the most suitable mean (arithmetic mean, median,

etc.) should depend on the type of the distribution of the dataset. Second, problems may arise with limited number of samples, skewed populations and in the presence of subpopulations.

Figure 3 compares the UCS characteristic value computed with the help of the cumulative frequency curve (CC method) or with respect to the DIN approach. The ratio of the two characteristic values is presented as a function of the number of tested samples for each considered dataset. Minimum 20 samples are necessary in order to conduct the statistical analysis on the cumulative frequency curve. As observed in Fig. 3, the UCS characteristic value is always greater when computed with the help of the cumulative frequency curve (all the values are larger than 1). In Fig. 3, results are given for two different X% lower quantiles: X = 5% and 10%. Indeed, for the first category of approaches (based on the lower limit value), a value for the X% has to be defined. A more detailed analysis is necessary to determine if a 5% lower limit, as often stated in Eurocode 7, is a representative characteristic value for the strength of the soil mix material. Actually, one major issue is the representativeness of the core samples with regard to the in situ executed DSM material.

Figure 3. Ratio of the characteristic values ( $f_{c,k}$  (CC) and  $f_{c,k}$  (DIN4093)) as a function of the number of tested samples.

### 3 INFLUENCE OF THE UNMIXED SOIL INCLUSIONS

There is mainly the question of the influence of unmixed soft soil inclusions on the mechanical behaviour of the DSM material. Indeed, as a natural material (i.e. soil) is being mixed, it is to be expected that the entire wall is not perfectly mixed and homogeneous: inclusions of unmixed soft soil are present. As a result, Ganne et al. (2010) have proposed to reject all test samples with soil inclusions  $> 1/6$  of the sample diameter, on condition that no more than 15% of the test samples from one particular site would be rejected. This possibility to reject test samples results from the reflexion that a soil inclusion of 20 mm or less does not influence the behaviour of a soil mix structure. On the other hand, a soil inclusion of 20 mm in a test sample of 100 mm diameter significantly influences the test result. Of course, this condition is only suitable if one assumes that there is no soil inclusion larger than  $1/6$  of the width of the in situ DSM structure. For the purpose of studying this question, 2D numerical simulations were performed at KU Leuven with the aim to quantify the effect of soil inclusions on the DSM strength and stiffness. The following parameters are being considered: size, number, relative position and percentage of soil inclusions. The results of this study are presented in Vervoort et al. (2012) and Van Lysebetten et al. (2013). As illustrated in Fig. 4, they confirm that DSM samples with soft soil inclusions larger than  $1/6$  have a considerable influence on the deduction of the engineering values. Based on this numerical analysis, the “rule of  $1/6$ ” as proposed by Ganne et al. (2010) seems to be justified.

Figure 4. Influence of the dimensions of the soil inclusions on the UCS of soil mix material. Results of 2D numerical simulations performed with the help of the Universal Distinct Element Code UDEC of Itasca®. Details of the model are available in Van Lysebetten et al. (2013). H is the ratio between the height of the soil inclusion width and the sample diameter.

#### 4 INFLUENCE OF THE SCALE EFFECT

Apart from traditional core samples (with a diameter around 10 cm), large scale UCS tests were conducted on rectangular blocks with approximately a square section, with a width corresponding to the width of the in situ SMW (about half a meter) and with a height approximately twice the width (Vervoort et al. 2012). The results of all the tests performed in KU Leuven are presented in Fig. 5 for various soil conditions and different execution systems: the CSM and the TSM.

As observed in Fig. 5, a linear relationship is observed between the test results obtained from the typical core samples and the large rectangular blocks. Although there is a scatter in the test results, the UCS of the full-scale blocks is about 70% of the average UCS of the typical core samples. It is to note that similar conclusion was observed for DSM columns in Japan (CDIT 2002).

Figure 5. Scale effect: relationship between the results of UCS tests on typical cylindrical core samples (10 cm diameter) and on large rectangular blocks tested in KU Leuven (after Vervoort et al. 2012).

#### 5 CONCLUSIONS

Based on the results of the BBRI ‘Soil Mix’ project, a Belgian design methodology for the DSM structures is currently developed. On the one hand to determine the UCS characteristic value of the DSM material and on the other hand to design the SMW as a retaining wall according to the requirements of the Eurocode 7. According to the results presented in this paper, the calculation of the UCS characteristic value should consider:

- the number of tested core samples,
- the possibility to use a statistical approach (based on the cumulative curve) or an approach such as in the DIN,

- the determination of the X% lower quantile for DSM material (in case of statistical calculation),
- the presence of the unmixed soft soil inclusions potentially considering the rule of 1/6 (Ganne et al. 2010),
- the scale effect (with regard to the full-scale factor of 0.7),
- the possibility of 3D analysis,
- and the time effects (with the help of creep test or based on experience with similar technique and soil conditions).

The curing and creep phenomena are currently investigated within the framework of the BBRI ‘Soil Mix’ project. Indeed, while SMWs were previously used only for temporary excavation support, permanent retaining and bearing applications with soil mix are increasingly applied in Belgium. For the evolution of the UCS value with time, it is suggested to consider the value of the UCS at 28 days as the value of reference for the strength of the DSM material.

**ABSTRACT:** Adora residential building is a 6-storey structure, built nearby Ohrid Lake (Ohrid, Republic of Macedonia). The foundation depth of the building is approximately 1,5 m (foundation construction – foundation slab). The foundation soil consists of soil materials which have a poor strength properties and low bearing capacity. The ground water table (GWT) on the location is on 1,0 m bellow the ground surface. On such geotechnical conditions a big settlements are expected. Therefore, a project on soil improvement was prepared. Several preliminary solutions were considered, but most appropriated was the one which involves geosynthetic reinforcement as subsoil improvement measure. In order to evaluate the settlements, performance of the building, axial forces developed in the geogrids and stress-strain condition in the subsoil during static and dynamic loads, detailed analyses were conducted. The software models developed in Plaxis 2D clearly showed the effectiveness on the applied measures for soil improvement.

**RÉSUMÉ :** le bâtiment de résidence Adora est-une construction de 6 étages, bâti à coté du lac d'Ohrid (Ohrid, République de Macédoine). La profondeur des fondations du bâtiment est d'environ 1,5 m (construction de fondation – dalle de fondation). Le sol de fondation est composé de sols de mauvaise qualité et faible capacité portante. La nappe phréatique (NP) du site est située 1,0 m en dessous de la surface de sol. Avec ces conditions géotechniques des tassements du sol sont attendus. Un projet d'amélioration des sols a donc été préparé. Plusieurs solutions préliminaires ont été considérées, mais la plus appropriée est celle qui implique le renforcement par géosynthétiques, comme mesure d'amélioration du sous-sol. Des analyses détaillées ont été menées afin d'évaluer les tassements du sol, la construction du bâtiment, les forces axiales développées dans le géogrid et la relation contrainte-déformation dans le sous-sol sous chargements statique et dynamique. Les modèles logiciels développés dans Plaxis 2D montrent clairement l'efficacité des mesures appliquées pour l'amélioration des sols.

**KEYWORDS:** soil improvement, geogrid, geotextile

## 1 INTRODUCTION

Adora residential building is foreseen to be built on a site which has very poor geomechanical properties or in other words the geotechnical conditions on the site are very unfavorable. In such cases always major problems are low bearing capacity of the subsoil and large differential settlements. The city of Ohrid is located in active seismic area which is classified in the 9<sup>th</sup> seismic zone according to MCS. Moreover, on the site there are layers of loose uniform sand. Having in mind these two facts a liquefaction becomes also a serious danger for the structure. In order to adopt a solution for soil improvement and to check the liquefaction potential of the soil, comprehensive analyses were conducted.

Figure 1. Excavation pit on a site

## 2 GEOLOGICAL SITE PROPERTIES

According to the geological formations on the site, there are present sediments from the Quaternary period (Pleistocene epoch), i.e. lake and swamp sediments, represented with gravel, sand, sandy clays, silt, different types of clay and clayey-silty sediments, as well as occasional presence of peat. The sediments are well sorted, so that they have heterogenic particle size distribution and heterogenic mineralogy composition, i.e. they are fine to medium gravels and sands; fine silty sands, sandy clays and soft lake/swamp clays with low to medium plasticity. The thickness of these sediments varies between 50.0 – 80.0 m. According to the hydrogeological properties, they belong to the group of low permeability sediments with interparticle porosity. A closed type of springs with free level is present in the sediments, at depth to 20.0 m with GWT = 5.0 – 7.0 m, and with permeability  $k = nx10^{-4} - nx10^{-5}$  m/s.

Also there is a closed type of springs under pressure (artesian springs) at depth from 20.0 – 60.0 m with discharge of  $Q = 1.0 - 5.0$  l/sec.

From engineering geological point of view, these sediments belong to the group of weathered rocks, well placed and sorted with heterogenic particle size distribution, low compacted, with smooth surfaces, fully saturated with water. In other words they present materials with poor physical and mechanical properties that have different strength and deformability parameters.

## 3 GEOMECHANICAL SITE PROPERTIES

The site for construction of the new building is located approximately 200 m from the shore of Ohrid Lake, so, as it was mentioned before, the soils found on the site are with

sediment nature. In order to get precise geotechnical profile of the ground, extensive geotechnical field investigations were conducted. On the other hand, soil samples were taken for laboratory testing. With such extensive scope of field investigations, clear view of the ground profile was obtained.

Based on the performed field investigation works, it was concluded that the site is composed of different layers of sedimentary soils. With foreseen depth of the boreholes, no bedrock was detected. On this site there is vast variety of soil materials, from gravels and sands to silts and clays. Because of the high heterogeneity of the ground profile, layers are grouped into two extinguishing layers. The surface layers are low plasticity clays and clayey sands, which are highly compressive and they are present up to approximately 2.0 m from the surface. While the next deeper layer is clayey sand with higher compaction than the previous layer, and they are present up to 10.0 m from the surface. It is supposed that this second layer continues up to depth for which loading stresses have impact on the settlements.

According to the conducted field and laboratory tests, present soil materials are loose and they have very poor strength properties. In addition, the level of ground water table is very high, approximately 1.0 m from the ground surface, because of the nearby Ohrid Lake.

Table 1. Geomechanical properties

Soil	Fill Material	CL/SFc	SFc
$\gamma$ (kN/m <sup>3</sup> )	22.0	18.4	18.5
$c$ (kN/m <sup>2</sup> )	0.0	15.0	10.0
$\varphi$ (°)	35.0	10.0	20.0
Mv (kPa)	80000.0	5000.0	10000.0
SPT	/	4	13

Considering all these facts, it is obvious that ground improvement is necessary under the foundation of the new construction. Moreover, the problem with the settlements is inevitable, so the serviceability of the construction is also an important issue.

Figure 2. Adora building – cross section

#### 4 CONSTRUCTION DETAILS

The Adora building is built on the site which is very close to the Ohrid Lake. The superstructure of the building has 5 floors and the substructure has 1 floor (see Figure 2). The substructure is extended out of the superstructure and it is actually a parking lot. The size of the superstructure in plan view is 52.0x22.0 m, and the total size of the building (including the extensions of the

substructure) is 69.0x41.5 m. The foundation slab under the superstructure is 0.9 m thick and on the extension parts it is 0.5 m thick. The contact pressure transferred on the subsoil varies in range between 100 kPa (on cross-sections in the middle of the building) and 20 kPa (on cross-sections in the extensions).

Figure 3. Cross section of the foundation structure

#### 5 THE SOLUTION

As it was mentioned before, the improvement of the subsoil was done by means of soil replacement and usage of geosynthetic materials.

Because of the foundation level of -1.5 m from the ground surface and the depth of soil replacement of 2.0 m, total of 3.5 m deep foundation pit was excavated. The excavation pit was done by constructing 2:1 slopes. In addition, dry conditions for execution of the construction works in the excavation pit were ensured by dewatering the excavation by extraction wells. On the other hand the excavation pit had greater dimensions in plan view, 2.0 m greater than the contours of the foundation slab. Hence the loading stresses can be spread in the fill material by angle of max 45°.

Table 2. Properties of the geotextile

Raw material	PP multicolored/PET
Method of production	Mechanically bonded
Weight	≥ 300 gr/m <sup>2</sup>
Thickness under 2 kPa load	≥ 3 mm
Ultimate tensile strength	Longitudinal ≥ 4.0 kN/m Transversal ≥ 7.5 kN/m
Strain at ultimate tensile strength	Longitudinal 120% (±40%) Transversal 80% (±40%)
CBR puncture resistance	≥ 1300 N (-300 N)
Opening size O90	0.10 mm (±0.02 mm)
Water permeability index normal to the plane	85 x 10 <sup>-3</sup> m/s (-15 x 10 <sup>-3</sup> m/s)

##### 5.1 Geotextile

At the bottom of the excavation pit, geotextile was used to ensure separation of the fill material from the subsoil. By the separation, it is meant that the geotextile will prevent mixing of the different soils, but it will enable complete water permeability, so with this, complete preservation of the properties of the later placed fill materials will be ensured. Used geotextile has the physical and mechanical properties, listed in the Table 2.

The geotextile was placed all over the bottom of the excavation pit as well as on the excavation slopes. The overlap of two adjacent panels is 60 cm, and it completely wraps the fill material up. Used geotextile with the properties given in the Table 2 has the ability to withstand burst and puncture, and has enough tensile strength to serve a separation function, without being destroyed.

## 5.2 Geogrids and fill material

For increasing the bearing capacity of the subsoil under the foundation slab, geogrids are inserted as reinforcement. For reinforcement three layers of geogrids with different properties are placed in the fill material at different elevations.

The first layer of the geogrids was installed under the middle section of the building where the contact pressure has maximum mean value up to  $P=100$  kPa. The geogrids installed on this position give the geotextile an additional tensile strength, as well as bursting and puncturing resistance.

Figure 4. Cross section of the soil improvement measures

On other hand this first layer provides initial stiffness of the low lifts of the fill material. The overlap of two adjacent panels is 50 cm and anchoring length of 3.0 m. The properties of the first layer of geogrid are shown in the Table 3.

Table 3. Properties of the geogrid 40/40 (first layer of geogrids)

Raw material	PP
Coating	Polymer
Weight	~ 330 gr/m <sup>2</sup>
Ultimate tensile strength	Longitudinal $\geq 40$ kN/m Transversal $\geq 40$ kN/m
Tensile strength at 2% strain	Longitudinal $\geq 16$ kN/m Transversal $\geq 16$ kN/m
Tensile strength at 5% strain	Longitudinal $\geq 32$ kN/m Transversal $\geq 32$ kN/m
Strain at nominal tensile strength	Longitudinal $< 7\%$ Transversal $< 7\%$
Mesh size	40 x 40 mm

Over this geogrid a layer of drainage fill material was placed with thickness of 50 cm. This material has particle size from 16 to 32 mm.

This layer of drainage fill material is foreseen to reduce the possibility of liquefaction. So in case of earthquake, the building up of the pore water pressure will be reduced by draining the water from the subsoil layers into the drainage layer placed with the subsoil replacement works.

Over this drainage fill material, another geogrid was placed but this time with higher strength properties. The use of this geogrid is to reinforce the fill material as well as to ensure additional stiffness, which is gradually increasing from the

bottom of the excavation pit up to the foundation slab. Furthermore, this geogrid will ensure reaching of the requested modulus of compressibility of the upperlayers of fill material. The properties of the second layer of geogrid are shown in the Table 4.

Table 4. Properties of the geogrid 80/30 (second layer of geogrids)

Raw material	PET
Coating	Polymer
Weight	~ 350 gr/m <sup>2</sup>
Ultimate tensile strength	Longitudinal $\geq 80$ kN/m Transversal $\geq 30$ kN/m
Ultimate tensile strength at 3% strain	Longitudinal $\geq 22$ kN/m
Ultimate tensile strength at 5% strain	Longitudinal $\geq 40$ kN/m
Strain at nominal tensile strength	Longitudinal $< 8.5\%$ Transversal $< 8.5\%$
Mesh size	20 x 20 mm

On top of the second geogrid two lifts of fill material are done with thickness of 30 cm, total of 60 cm. The required modulus of compressibility on top of these two layers of fill material should be at least 100 MPa and minimum 98% compaction after Proctor. The fill material is crushed stone base aggregate.

On the extended parts of the building where the contact pressure has maximum mean value up to  $P=20$  kPa, also a geogrids is installed. This geogrid has an ultimate tensile strength of 20 kN/m in both directions. The overlap of two adjacent panels is 60 cm and the anchoring length is 1.0 m. After installation of this geogrid the fill material is placed and compacted in 30 cm thick lifts. The final layer of the fill material at the extended parts of the building should reach at least 80 kPa and minimum 98% compaction after Proctor.

After completion of the earth works ground improvement measures were completely finished. So the works for hydro insulation and constructing the structure commenced.

Table 5. Properties of the geogrid 40/40 (first layer of geogrids)

Raw material	PP
Coating	Polymer
Weight	~ 190 gr/m <sup>2</sup>
Ultimate tensile strength	Longitudinal $\geq 20$ kN/m Transversal $\geq 20$ kN/m
Tensile strength at 2% strain	Longitudinal $\geq 8$ kN/m Transversal $\geq 8$ kN/m
Tensile strength at 5% strain	Longitudinal $\geq 18$ kN/m Transversal $\geq 18$ kN/m
Strain at nominal tensile strength	Longitudinal $< 7\%$ Transversal $< 7\%$
Mesh size	40 x 40 mm

Figure 5. Axis forces in geogrid 80/30 (first layer of geogrids)

Figure 7. Shear stresses distribution

## 6 GEOTECHNICAL ANALYSES

In order to adopt the measures for improvement of the subsoil, detailed analyses were conducted. These analyses involve flow net analyses, analyses of soil-structure interaction due to geostatic and dynamic load as well as analyses of the liquefaction potential of the subsoil. The ground model was developed according to the adopted soil properties shown in the Table 1, and also the exact geometry of the structure was applied to the model. Most of the analyses were carried out in Plaxis 2D software using finite element method.

Figure 6. Plaxis model of the Adora building

The Plaxis model was subjected to several load cases which involves geostatic, hydrostatic and dynamic load. The analyses are conducted with and without applied geosynthetics under the construction. Comparing the results of analyses of both models it was obvious that improvement of the subsoil using geosynthetics is fully justified.

The maximum total settlements of the subsoil after the construction of the hotel are estimated at 30 cm. The estimated differential settlements during the seismic analyses were 0.1 cm. The maximum axial forces developed in the geogrids for geostatics load case are 13,86 kN/m in the middle geogrid and 10,14 kN/m in the lowest geogrids. When the model is subjected to dynamic loads (seismic activity) the axial force in the middle geogrid 35,17 kN/m and in the lowest geogrid the axial force is 19,12 kN/m.

Additional analyses were carried out in order to estimate a liquefaction potential of the subsoil. These analyses were necessary due to the presence of saturated, uniform sand in the subsoil which has a relative density in the range of  $D_r=15-40\%$ . The results showed that the subsoil has a liquefaction potential.

## 7 CONCLUSION

In the last 2,5 years this is the second bigger project of soil improvement using geosynthetics in the Ohrid area. The first, very similar, case was soil improvement under the new Hotel Park 2,5 years ago. The two buildings are approximately 2.0 km apart. On a basis of a obtain data from monitoring of the buildings settlements it can be concluded that the total settlements of both buildings are below the initially estimated settlements.

For example, for monitoring of the settlements of the Hotel Park 8 survey points were positioned. Those points initially were measured after placing them (during the fundaments constructing), later in the time of constructing the structure and after finishing of the whole construction. The first initial measurement of the elevation of the fixed points was undertaken on 11.07.2011, and the last one on 23.03.2012.

In both cases cost-benefit analyses conducted during the designing process showed that soil improvement using geosynthetics is most economical method in such geotechnical conditions. Regardless the economic aspect this method has a major advantage which is a very short period of installation.

# Geoencased columns: toward a displacement based design

## Colonnes renforcée par géotextiles: vers une conception basée sur le déplacement

Galli A., Prisco di C.  
*Politecnico di Milano*

**ABSTRACT:** As is largely testified by the scientific literature, in the last decade geoencased columns have become a quite common alternative solution to standard stone columns. This is essentially due to the possibility of employing reinforcements to better the mechanical response of the inclusions without reducing their drainage efficiency. Although GEC are often used to reduce settlements induced by the construction of large embankments on soft soils, up to now a rational displacement based design approach has not yet been introduced. This is thus the final objective of this paper, that, by starting from a critical review of the standards presently available, will illustrate the results of a series of finite difference numerical analyses. The unit cell of an ideal reinforced soil embankment placed on a soft soil stratum will be accounted for and the effect of the main geometrical/mechanical parameters, as well as the response of the system during the construction stages, is discussed.

**RÉSUMÉ :** Comme il est largement connu dans la littérature de ces vingt dernières années, les colonnes en matériaux granulaires renforcée par géotextiles (GEC) sont devenues une solution très utilisée par rapport aux colonnes ballastées standard. Cela est essentiellement dû à la possibilité d'employer des renforts pour améliorer la réponse mécanique des inclusions sans réduire leur efficacité de drainage. Bien que les GEC soient souvent utilisées pour réduire les tassements induits par la construction de remblais importants sur sols mous, une approche rationnelle de conception basée sur le déplacement n'a, jusqu'à présent, pas encore été mise en place. Cela est donc l'objectif final de cette étude, qui, en partant d'une analyse critique des normes actuellement disponibles, illustrera les résultats d'analyses numériques aux différences finies. Une cellule élémentaire d'un remblai idéal de sol renforcé placé sur un sol mou sera prise en compte et l'effet des principaux paramètres géométriques et mécaniques et la réponse du système au cours des différentes étapes de la construction seront discutés.

**KEYWORDS:** geoencased granular columns, geotextiles, numerical analyses, displacement based design, earth reinforced structures.

### 1 INTRODUCTION.

As it is well documented in the literature (see e.g. Raithel et al. 2005), since mid-nineties the use of geoencased granular columns (GEC) as foundations of earth structures on soft and very soft soils has been progressively increased. GECs have both mechanical and hydraulic functions: they work not only as reinforcement inclusions, capable of preventing the global collapse of the foundation and reducing differential settlements within the structure, but they work additionally as vertical drains, thus reducing the consolidation time of the soft soil.

Figure 1. sketch of an earth embankment on GECs.

The GEC foundation system is composed of an array of granular columns of length  $L$  and diameter  $D$ , placed at a regular spacing  $S$  below an embankment of height  $H$  (Figure 1). The columns are encased by a geotextile with the double aim of reinforcing the column and filtering to prevent the clogging of the column itself. At the base of the embankment, to redistribute vertical stresses, several layers of geotextile are also inserted during the construction. The effectiveness of this foundation system has been clearly proved both on real scale data (see e.g.

Kempfert 2003, where the response of the system is analyzed by varying the spacing among columns and of the stiffness of the encasing geotextile), and by means of numerical and experimental researches (Murugesan and Rajagopal 2006, di Prisco and Galli 2011). The fundamentals of the mechanical behavior of the system is therefore quite well understood. Nevertheless, common design standards are still based on too simplified approaches, unable of capturing the actual mechanical complexity of the system in particular, the interaction between embankment and columns (this point will be tackled in further details in the following section by critically reviewing the most used design standards). Conversely to traditional deep foundation systems (like reinforced concrete piles or jet-grouted columns which can be considered axially rigid with respect to the surrounding soil), GECs are axially deformable inclusions, whose axial deformability is strictly coupled with the stiffness of the surrounding soil. Moreover, since this latter is very often characterized by a very low permeability and high deformability, its mechanical response should be modeled by properly taking into account the hydro-mechanical coupling (for the sake of brevity, this aspect will however be disregarded in the following).

In the present paper the attention will be initially focused on a critical review of the most common design standards. Then an engineering displacement based approach will be briefly introduced, and some numerical analyses, with the particular aim of studying the distribution of differential settlement at the top of the embankment, which are generally neglected by the design approaches, will be presented.

2 REVIEW OF DESIGN STANDARDS

The two most common design standards available for the design of earth embankment on GECs are the British Standard BS 8006 (1995) and the German Standard EBGEO (Chapter 6.9; 2003). Both of them assume the column to be rigid and, estimate the vertical stress distribution at the base of the embankment to be independent of the mechanical interaction with the foundation (i.e. the GEC and the soft soil). From an engineering point of view, however, the vertical stress redistribution at the base of the embankment is the main parameter governing (i) the design of the reinforcement layers (see Figure 1) and (ii) the evaluation of the differential settlements.

According to BS8006, the vertical stress redistribution does not depend on the mechanical properties of the embankment. In particular, the average vertical stress acting at the column's top (in the following this quantity will be called  $\sigma_i$ ) is determined only as a function of the geometry (H, S, D), as was suggested by the approach proposed by Martson (1913) for buried pipes (see also Jones et al., 1990). The estimation of the average vertical stress  $\sigma_e$  acting on the soft soil is instead obtained by means of empirical expressions, depending on the full or partial formation of the arch effect, as a function of the ratio between height H and difference S-D. According to EBGEO, on the contrary, a rather complex analytical procedure, based on the work proposed by Zaeske (2001), is employed to describe the arch effect. This takes into account the geometry (H, S, D) and the friction angle of the granular material constituting the embankment, and imposes the equilibrium of one central slice of a vault shell of the arch that it is supposed to develop within the embankment. No estimation of the vertical stress  $\sigma_i$  at the top of the column is provided. For the sake of brevity, the analytical expressions have not been reported here; for further details, see BS8006 and EBGEO (Chapter 6.9).

As far as the evaluation of settlements is concerned, the procedure prescribed by EBGEO follows the work proposed by Ghionna and Jamiolkowski (1981) and consists in subdividing the length L of the column in slices (each one of them is then assimilated to an axisymmetric triaxial soil sample). The following hypotheses are assumed: (i) the granular soil in the column is at critical state (i.e. no changes in volume are possible for the column), (ii) no relative settlement are considered between the column and the soil. These two hypotheses introduce very strong simplifications that can lead to unphysical results. The second one, in particular, makes impossible the superficial differential settlements to be estimated.

2.1 Parametrical analyses

In this section parametrical analyses on the values of  $\sigma_e$  obtained by employing BS8006, as well as some results concerning the evaluation of the settlement and of the tensile force in the encasing geo-membrane computed according to EBGEO, are presented. In particular, the effect of the embankment height H and of the material friction angle  $\phi'$  is investigated for increasing values of the relative spacing S/D, and by taking into account several diameters D of the column (the authors are aware of the fact that some values of D and S/D considered are unrealistic, nevertheless they have been chosen in order to test even the asymptotic trend of the design approaches).

2.1.1 Stress on the soft soil at the base of the embankment

Figure 2 shows the values of  $\sigma_e$  computed according to BS8006, and highlights that unphysical results of  $\sigma_e < 0$  are obtained for low values of the relative spacing S/D, independently of the embankment height H. This result could in general lead to an overestimation of the arch effect and thus to an unsafe design of the georeinforcement layers at the base of the embankment.

The arch effect tends to vanish for increasing values of S/D, and the value of  $\sigma_e$  tends to the weight  $\gamma H$  of the embankment.

The corresponding values of  $\sigma_i$  computed according to BS8006 (not reported here for the sake of brevity) are independent of S/D, and only slightly dependent on H.

Figure 2. Evaluation of the stress  $\sigma_e$  according to BS8006: (a) H=2.5m and (b) H=10m.

It can be easily demonstrated that  $\sigma_e$  and  $\sigma_i$  (if computed according to BS8006) do not even satisfy the total equilibrium along the vertical direction with respect to the weight of the embankment, and that the values of the tensile force in the geosynthetic layers at the base of the embankment computed according to BS8006 are not continuous with increasing H (Moraci and Gioffrè 2010).

2.1.2 Settlements and tensile force in the encasing membrane

With reference to the values of the mechanical parameters listed in Table 1 (taken from an example of application proposed by EBGEO), in this paragraph a parametrical analyses on the values of the settlement is presented, for increasing values of the embankment weight  $\gamma H$  and by taking into account several values of stiffness J of the encasing geomembrane. The values of the column length L and of the relative spacing S/D are here considered to be constant and equal to 10 m and 2, respectively (with  $D=80$  cm and  $S=1.6$ m).

Table 1. Values of the mechanical properties of the materials considered in the analyses.

	Embankment	Column	Soft soil
Unit weight (kN/m <sup>3</sup> )	20	19	15
Friction Angle (°)	-	35	15
Cohesion (kPa)	-	-	10
Young modulus (kPa), at a reference pressure of 100kPa	-	-	750
Poisson coefficient (-)	-	-	0.4

As it is evident from Figure 3a (where, for the sake of generality, the value of s has been normalized with respect to L), the presence of the encasing geomembrane induces a stiffening effect of the foundation system, thus reducing the expected value of the total settlement (which is considered, according to the adopted hypotheses, to be uniform and coincident with the settlement s at the top of the embankment). The numerical procedure, however, for low values of  $\gamma H$  (i.e. shallow or light embankments) leads to unrealistic results, for

which negative settlements (i.e. uplift) are obtained. This meaningless result is obtained even for a nil value of the stiffness  $J$  of the encasing geomembrane. This essentially derives from the assumption concerning the soil within the column which is imposed to be at the critical state along the entire column (similar results have been observed even for other values of  $L$  and  $S/D$ , but they have not been reported here for the sake of brevity). This is evident when the tensile force  $T_g$  in the encasing geomembrane along depth  $z$  of the column is considered (Figure 3b, where the case of a shallow embankment is analyzed): at the base of the column the vertical stress is not sufficient to induce an active state of stress, and the only possibility for the column to satisfy the hypothesis of critical state is to reduce its radius, thus inducing a compression (i.e.  $T_g < 0$ ) in the encasing geomembrane.

Figure 3. EBGEO: evaluation of (a) settlements and (b) tensile force in the encasing geomembrane.

### 3 A DISPLACEMENT BASED DESIGN APPROACH

In order to overcome the above cited limitations, a consistent and physically based design would require a fully displacement based approach. As was theoretically outlined by Galli and di Prisco (2011), with reference to a single axisymmetric cell (i.e. to a single column together with the surrounding soft soil), the foundation system can be assumed to be composed by two coupled springs, one representing the GEC and the second representing the surrounding soft soil. The two springs work in parallel if and only if the base of the embankment can be considered to be rigid and no differential settlements to arise (Figure 4a). Under this hypothesis, the vertical stress at the base of the embankment is thus uniformly distributed (in Figure 4a  $\gamma$  stands for the unit weight of the granular material constituting the embankment), no differential settlement are observed at the top of the embankment, and no shear stresses develop at GEC-soil interface. The values of vertical stress both in the column and in the soil then can be assumed to depend exclusively on the axial stiffness of the column ( $K_{GEC}$ ) and on the vertical compressibility of the soft soil (represented in Figure 4a by a global stiffness  $K_S$ ).

Real embankments, however, are characterized by a deformable base (Figure 4b), and different values of settlement are expected for the top of the column ( $u_c$ ) and for the soil ( $u_s$ ) at the base of the embankment. Consequently: (i) vertical stresses are redistributed at the base of the embankment between the internal zone of the cell (above the column, characterized by an average stress  $\sigma_i$ ) and the external one (a circular crown above the soil, characterized by an average stress  $\sigma_e$ ) due to the so called arch effect, (ii) shear stresses are

activated at GEC-soil interface, and (iii) differential settlements are expected even at the embankment top.

Figure 4. Mechanical response of the foundation system in case of (a) rigid and (b) deformable embankment.

From a modeling point of view, by assuming an engineering approach based on generalized variables, the mechanical behavior of the embankment can be described by means of a generalized constitutive relationship between the average stresses at the base of the embankment and the differential settlements (assumed to be uniform) between the column and the soil:

$$\sigma_i - \sigma_e = f(u_s - u_c), \quad (1)$$

where the values of  $\sigma_i$  and  $\sigma_e$  must satisfy the equilibrium with respect to the weight of the embankment on the unit cell

$$\sigma_i \cdot D^2 + \sigma_e \cdot (S^2 - D^2) = \gamma H \cdot S^2. \quad (2)$$

The constitutive relationship  $f$  can be in general assumed to be described by means of a non-linear curve, whose average stiffness depends (i) on the geometry of the system ( $S$ ,  $D$ ,  $H$ ), (ii) on the mechanical properties of the granular material constituting the embankment and (iii) on the geo-reinforcements at the base of the embankment. Its limit value corresponds instead to the activation of a failure mechanism within the embankment. Depending on the formation of the arch effect, either a “punching” failure mechanism, or a “dome” failure mechanism, with no (or very limited) superficial differential settlements, might develop (Figure 5a-b).

Figure 5. Failure within the embankment: (a) punching mechanism and (b) domed mechanism due to arch effect.

The pattern of superficial differential settlement  $s=s(r)$  could then be formally described by a transfer function, ranging from a discontinuous function (in case of punching), to a smooth function (in case of formation of the arch effect).

### 4 NUMERICAL ANALYSES ON SETTLEMENT PROFILE

In order to investigate the settlement distribution  $s(r)$  at the top of the embankment for increasing values of  $H$ , some preliminary finite difference numerical analyses have been performed by means of the commercial code FLAC. An axisymmetric geometry has been chosen in order to model the cell, and the simplifying hypothesis of rigid column has been

assumed; the mechanical behavior of both the materials constituting the embankment and the soft soil has been modeled by assuming an elastic perfectly plastic relationship with a non-associated Mohr-Coulomb failure condition. For the embankment, two different types of material have been considered: a loose sand ( $\phi=20^\circ$ , with no dilatancy) and a compacted sand ( $\phi=40^\circ$ , with dilatancy  $\psi=10^\circ$ ). In both cases, for the sake of simplicity the unit weight  $\gamma$  is assumed to be equal to  $20 \text{ kN/m}^3$ , the Young modulus equal to  $3 \text{ MPa}$  and the Poisson coefficient equal to  $0.25$ . No friction has been considered at soil-column interface. For the soft soil, for the sake of simplicity a dry condition has been assumed (i.e. no hydro-mechanical coupling has been modeled). The values of the mechanical parameters are listed in Table 1. Consistently with the parametrical analyses previously discussed, the length  $L$  of the column is  $10 \text{ m}$  and its diameter  $D$  is  $80 \text{ cm}$ . Two ratios  $S/D$  have been considered, and the settlement distribution  $s(r)$  has been normalized at each stage for the current value of  $H$ .

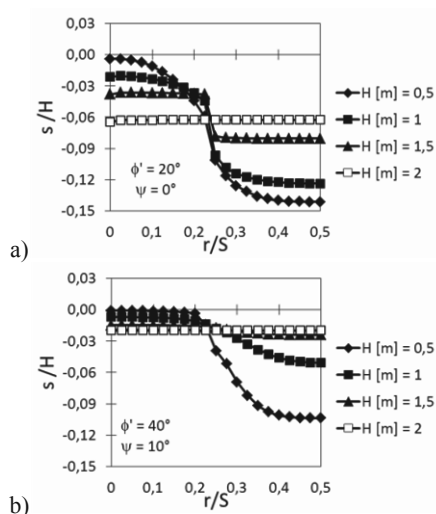

Figure 6. Normalized superficial settlements for  $S/D=2$ : (a) loose and (b) dense material.

Figure 7. Normalized superficial settlements for  $S/D=4$ : (a) loose and (b) dense material.

Figures 6 and 7 describe the evolution of  $s(r)$  at the top of the embankment during the construction stages. It appears clearly that the settlement profile ranges from a well localized punching failure mechanism to a smooth distribution of settlements for increasing  $H$  (witnessing the progressive mobilization of the arch effect). The influence of relative spacing  $S/D$  and of the mechanical properties of the embankment (in terms of both  $\phi'$  and  $\psi$ ) is opposite: an increase in  $S/D$  tends to localize the

failure, whilst an increase in  $\phi'$  and  $\psi$  tends to smoothen the settlement profile.

## 5 CONCLUSIONS

The paper critically discussed some results obtained according to the usual Design Standards, and proved that in some cases these approaches lead to unrealistic results. The codes, moreover, disregard the estimation of relative settlements at the top of the embankment, which is actually one of the most important parameters describing the efficiency of the foundation. A consistent, displacement based conceptual framework for describing the behavior of the system has been formulated, and some preliminary numerical analyses have been shown. These latter, in particular, showed on the contrary that the top settlement profile is remarkably affected by both the geometry and the mechanical properties of the embankment.

# Design prediction of the strengthened foundation base deformation by field tests data

La prèvision de calcul des déformations de la base des fondements reportès à partir des recherches prises en nature

Gotman A., Gotman N.  
*BashNIIstroy, Ufa, Russia*

**ABSTRACT:** The paper presents the solution of the complicated practical geotechnical problem of the skeleton structure foundation strengthening. The strengthening was done due to change of the spatial arrangement of a building and essential load increase. The experience of a foundation strengthening with jet grouted piles is described based on results of the base deformations monitoring. The main design principles of the foundations under strengthening are given. The results of the deformation design prediction based on jet grouted piles test and the base deformation measuring are presented.

**RÉSUMÉ :** Dans cet article on présente la solution d'un problème géotechnique pratique compliqué du renforcement des souches d'un bâtiment en carcasse construit sur les sols de fondation dangereux à cause du karst, en raison du changement lors de la construction de la conception de plan et de volume du bâtiment et de l'accroissement signifiant de charge. L'expérience est décrite du renforcement des souches par des papillons d'injection de forage sur la base des résultats du monitoring des déformations des sols de fondation. Les résultats sont présentés des pronostiques prévisionnelles des sols de fondation des souches renforcées à la base des essais des papillons d'injection de forage et de la mesure des déformations du sol de fondation.

**KEYWORDS:** foundation strengthening, settlements, pile vertical load test

## 1 INTRODUCTION

Design prediction of the strengthened foundation base deformation by field tests data was executed for the new shopping centre located in Ufa (Russia). The 500x250m shopping center was designed as a skeleton one-storey building with column spacing 16x8 m. The building construction was started in April, 2007, then restarted in June, 2009 and finished in 2010. Since May, 2008 till August, 2009 the construction at site has been not performed. In 2007...2008 the foundations and the most part of the bearing structures have been constructed. During construction time, the building part was changed (by investor's demand). The column spacing was increased (8x16m to 16x16m or 12x16m) and foundation loads to the moment of construction stoppage 1,2...1,5 times increased the design ones. After construction restarting, other changes of building frame design have taken place. At the significant area the number of stories and floor loads have been increased. As a result, all these changes provoked 30...70% increase of the foundation loads and the further foundation strengthening.

## 2 ENGINEERING-GEOLOGICAL CONDITIONS

Under the foundation base stiff clays, tough and soft loams occur underlain with water saturated medium coarse sand and gravel at the depth of 8...10 m. (table 3). Maximum predicted ground water level is 2 m under the foundation base. The building site applies to the third category of stability about karst deformations and is divided into sections according to extent of their risk in accordance with Russian Codes. At this site, areas are located that are classified according to their karst risk as potentially not dangerous and potentially dangerous (fig.1) with the probable design diameter of karst hole 7 m. Due to site severe engineering-geological conditions characterized with lack of homogeneity and karst risk, the following foundations were designed: post- and strip foundations on the bed; piled foundations with the in-situ raft (pile groups); strip foundations on the bed and piled foundations

with the strip in-situ raft reinforced considering a karst hole formation.

Severe engineering-geological conditions of site demanded foundation settlement observation and expert investigation of construction.

## 3 TECHNICAL EVALUATION OF THE STRUCTURAL CONCEPT ON FOUNDATION STRENGTHENING

When design working out and the way of the foundations strengthening selecting, the following was taken into attention.

1. To the moment of the strengthening design development, the building was 1,5 years. In axes 1...15' the bearing structures were completely constructed and at the rest part of the area foundations, columns and floors of the ground floor were built.

2. According to monitoring results (table 1), it was stated that to the moment of strengthening design development (August 2009), the settlements on the whole were stabilized. The settlements of the column foundations with the loads exceeding the design ones already in the process of construction were 6...10cm; the settlements of the rest foundations were 3...4 cm. The settlements data were used to evaluate the coefficients of subgrade reaction of strip- and post foundations bases that demanded strengthening (fig.2, table 2).

Taking into account that the significant part of the structures was constructed and more than half of the base loads have already been transferred, when selecting the method of the foundation strengthening the minimum digging out and dismantling (drilling, cutting, etc.) of the existing foundation should have been provided. Method of strengthening with jet grouted piles was selected with loads transfer from the building through the connection of the reinforced concrete column with the in-situ raft rested on piles.

425 mm diameter and 10...11 m length jet grouted piles were deepened into gravel soil to the depth of 1 m and more. To evaluate the pile design load, the pile vertical load test of trial piles with the diameter 425 mm, 10,6 m length (pile No. 1), 10,88 m length (pile No. 2) and 11,5 length (pile No. 3) (table 3) have been carried out. The piling was realized with the unit SBU 100 GA50. The engineering-geological characteristics of soils are presented in table 3.

Pile vertical load tests have been carried out according to standard method. The limit resistances while testing reached 980 kH. Figure 3 presents diagrams of pile tests.

Considering different structural concepts of the foundations and the building, analysis have been carried out according to these features and four types of the foundations strengthening have been suggested (see figures 1 and 4).

I. Strengthening of *post foundations* of a building in axes 15' – 1. Practically all extra load is taken into account to be transferred to jet grouted piles, i.e. the load is not transferred to post foundation, as the construction of the reinforced concrete raft strengthening is not absolutely stiff.

That's why only insignificant part of the extra load is transferred to the foundation base, so the foundation in combination with the strengthening construction and piles behaves as combined piled foundation.

II. Strengthening of *strip foundations without piles* by means of geometrical dimensions increase with use of technology "HILTI".

III. Strengthening of *pile group foundations* with increased loads was carried out by means of jet grouted piling around the raft and including them into pile group behavior through the reinforced concrete slab fixed with the column and the raft (with the anchors HILTI). With such method of strengthening jet grouted piles start to work in a pile group together with the driven piles.

IV. Strengthening of *foundations without piles* in axes 1 – 29 was carried out by means of insignificant part of load transfer to the foundation. Jet grouted piling use is based on insufficient reinforcing with in situ reinforced concrete strip under the columns, the load of which is more than twice increased compared to design one. Such strengthening construction partially loads the existing foundation including it into work. The jet grouted piles together with the foundation accept the ultimate design load. Pile strengthening is carried out along the whole length of the strips, as otherwise the different stiffness of the strip base will lead to its deterioration.

Irrespective of strengthening type, the main design requirement is continuation of foundations loading only after completion of all works on strengthening considering the terms of strength increase of in-situ concrete of structures.

#### 4 THE MAIN DESIGN PRINCIPLES

Analysis of foundation strengthening has been carried out considering the deformability of the foundation base and jet grouted piles. Due to special features of constructions of the foundations under strengthening and different extent of works completion on above foundations structures construction, the following design assumptions were taken.

While the building *post foundations* strengthening in axes 1'...15', analyses of loads transferred to the foundation after its strengthening were carried out i.e. when construction restarting considering the loads after the building starting (fig.5). Analysis of the column joint and strengthening construction was done for the total design load. Deformability indices of the foundation base and jet grouted piles quantitatively evaluated with the coefficients of subgrade reaction of the foundation base under strengthening and pile stiffness respectively, were determined

Fig.4 Types of foundation strengthening with jet grouted piles (technical decision)

by results of pile test at site and monitoring of post foundations settlement (tables 2, 4). While analysis of the number of jet grouted piles, the total load was taken to be transferred to those piles, so the coefficient of subgrade reaction of the foundation base under strengthening was taken to be equal 0.

When *piled foundations* strengthening with jet grouted piles, analyses have been carried out for the total design load. Pile stiffness was determined by data of pile vertical load test of the driven- and jet grouted piles.

The authors of the paper made predictions of the foundation settlement in axes 1' 15', P-S due to foundations load increments, strengthened with the jet grouted piles after the construction restart. The deformations are calculated with regard for the different deformability of the post foundation base and a pile. The coefficient of subgrade reaction in the post foundation base (settlement marks M7 and M31 in fig.1) was determined by results of settlements monitoring (table 2, fig.3a) and stiffness coefficient of jet grouted piles – by tests data (table 4, fig. 3b). The design scheme is presented in fig.5. By results of analysis of the base deformation of the most loaded post foundations strengthened with the jet grouted piles, the settlements after the construction restart with regard for the total load were 13,8 and 12 mm, respectively. At present, when the construction of the shopping center is completed, but the building is not put into operation, the measured base deformations of these foundations are 10,5 and 5 mm, respectively. Such conformity of predicted and measured deformations confirms the efficiency of the base strengthening and high accuracy of the analysis methods based on in-place tests.

Table 4

Test number (table 3)	Pile (JGP) length, m	Pile (JGP) length in soil, m	Pile settlement according to test, mm	Stiffness ratio of pile (JGP) base, kN/m $K = \frac{N_2 - N_1}{S_2 - S_1}$
1	10,6	10	13	50000
2	10,88	10,58	11	60000
3	11,50	11,10	10,35	60000

## 5 CONCLUSION

1. The complicated practical geotechnical problem of strengthening of the skeleton building foundations under construction, the necessity of which was provoked by change of space-planning decision in the process of construction is solved.

Within one 500x250 m building, four types of foundations have been designed: post foundations on the bed without karst protection; strip foundations on the bed designed for 7 m diameter karst hole; piled foundations in kind of pile groups of driven piles without karst protection and pile group foundations combined with karst protected reinforced concrete strips on piles.

2. Four types of foundations strengthening has been developed with the use of jet grouted piles taking into attention loads increase compared to design, acting (already imposed) loads and foundations settlements at the moment of their strengthening, structural concepts of foundations and the extent of karst risk of the base.

3. Analysis of strengthening constructions and base deformations was carried out according to data of jet grouted piles vertical load test and settlements measurements of the foundations under strengthening.

4. The results of the strengthened foundations settlements measurement after the building implementation showed the good precision with analysis data. This proves the correctness of the taken structural and design schemes.

# Standardization of the molding procedures for stabilized soil specimens as used for QC/QA in Deep Mixing application

Normalisation des procédures pour la production d'éprouvettes de sols stabilisés utilisées dans les processus de QC/QA pour des applications de « Deep Mixing »

Grisolia M., Leder E., Marzano I.P.

Department of Civil and Environmental Engineering (DICEA), "Sapienza" University of Rome

**ABSTRACT:** An international collaborative research has been undertaken to establish common understanding of the key issues involved in Quality Control/Quality Assurance (QC/QA) of Deep Mixing technique and propose international standards on design, execution and execution control. The aim of the study is to investigate the influence of the laboratory procedures on the mechanical properties of stabilised soil specimens and develop an innovative method to select the appropriate molding technique. A large laboratory testing program was carried out on seven types of heterogeneous natural soils, as found in Rome, and on Kawasaki clay stabilised with Portland cement. Thirty soil-binder mixtures with different workability were prepared using five different molding techniques, varying initial water content of the soils, water to cement ratio and binder amount. Unconfined compression tests have been carried out systematically on over 800 specimens. The applicability of different molding techniques in function of the workability of the mixture has been investigated and from the results it was possible to define an "applicability index" and therefore the range of applicability for each technique in function of the mixture's workability.

**RÉSUMÉ:** Une étude internationale a été entreprise dans le but de définir des orientations communes pour les procédures QC/QA liés aux travaux effectués par « Deep Mixing » et proposer des normes internationales relatives à la conception, l'exécution et le contrôle des opérations. Le but de cette étude est d'étudier l'effet des procédures de laboratoire pour la réalisation des éprouvettes de sols stabilisés et de développer une méthode innovante pour sélectionner à chaque fois la technique de réalisation appropriée. Un vaste programme d'essais en laboratoire a été réalisé en analysant plus de trente mélanges différents de ciments et sols à partir de huit sols naturels de Rome et Tokyo. Cinq techniques de réalisation ont été utilisées pour la confection d'éprouvettes testées avec des essais de compression simple. L'applicabilité des différentes techniques de réalisation a été étudiée selon l'usinabilité du mélange. A partir des résultats, il a été possible de définir un index d'applicabilité et donc un champ d'application de chaque technique en fonction de l'usinabilité du mélange.

**KEYWORDS:** Deep mixing, workability, laboratory procedures, operational abaci.

## 1 INTRODUCTION

The Deep Mixing Method is a widely spread in situ ground improvement technique using different kind of binders to enhance mechanical and physical properties of soils (Terashi 1997; CDIT 2002).

Laboratory mixing tests are essential to QC/QA processes and performed to obtain the mechanical and physical properties of stabilized soil samples. The laboratory test results provide crucial information for the estimation of the mix design and in-situ properties to utilize in the geotechnical design. (Bruce et al. 2000; Larsson 2005; Marzano et al. 2009; Terashi and Kitazume 2011; Filz et al. 2012). At the moment many laboratories produce and test soil-binder specimens without a standard procedure, therefore the results for the same soil-binder mixture could be very different and not usefully compared. In fact molding techniques have a great influence on the mechanical and physical properties of the stabilized soil specimens (Grisolia et al. 2012; Marzano et al. 2012). This influence is strictly correlated to the workability of the soil-binder mixture defined as the property of the mixture of being easily mixed in the bowl and placed in the mold. High workability refers to liquid type mixtures (easier to place and handle), while low workability to sticky and stiff type ones.

Workability represents diverse characteristics of fresh mixture that are difficult to measure quantitatively, because a soil-binder mixture is a complex material with a wide range of particle sizes and time-dependent properties. The definition of a parameter representative of the mixture's workability and an univocal method for the evaluation of the mixture's workability are currently not available (Koehler and Fowler, 2003) even if

such parameter could be well related to consistency when considering mixtures made up of cohesive soils.

A new method for the evaluation of the mixture's workability was introduced and applied in the study. It is based on the measure of the torque required to turn an impeller in soil-binder mixture through a commercial device which is applied directly on the mixer. This method has the advantage to provide the possibility of measuring the workability for each mixable mixture, independently on the type of the materials used.

Furthermore, the study develops a procedure to select, through an "applicability index" function of the initial mixture workability, the molding technique that provides densest specimens with highest strength and results repetitiveness in order to obtain very useful reference values to set specification limits to be achieved in field applications (ratio between laboratory and field target strength is reported for instance by JGS 0821-2000 and EuroSoilStab 2002).

## 2 MATERIALS AND METHODS

The experimental work consisted in a laboratory investigation on the effect of different molding techniques on the unconfined compressive strength,  $UCS$  (measured according to the JIS A 1216:2009) and wet density,  $\gamma$  (defined as the specimen's weight divided by the volume of the mold) of cement stabilised soil specimens under various mixing conditions.

### 2.1 Materials

Eight types of natural soils stabilised with Portland cement added in wet or dry form were used. The tests were performed on: Kawasaki Clay ( $KC$ ), manmade Silty Deposit ( $SD$ ), Silty

clayey Sand (*SS*), Sand and Gravel (*SG*), Pliocene Clay (*PC*), Black Pozzolana (*BP*), Red Pozzolana (*RP*) and Argillified Tuff (*AT*). For each soil, different mixtures were produced, varying the initial water content and keeping constant the cement content,  $a_c$  (defined as the weight of the introduced dry cement divided by the dry weight of the soil to be stabilized). Specimens with 5 cm diameter and 10 cm height were employed. Each soil was sieved through a 9.5mm sieve, so that the maximum grain size of the soil sample would be less than 1/5<sup>th</sup> of the inner diameter of the mold. The properties of the soil-binder mixtures analyzed are shown in Table 1.

Table 1. Soil properties and Testing conditions.

Soil type	Gravel-Sand-Silt-Clay	Water content, $w_n$ (%)	Cementitious grout	Workability parameter, Torque, $M_t$ (Nm)
<i>KC</i>	0-14-42-44	72	$w/c = 0$	5,32
		66		8,47
		60	$a_c = 5\%$	17,40
		60		29,00
		60	$a_c = 20\%$	40,00
		54		61,00
		54	$a_c = 30\%$	75,00
		49		96,00
		49	$a_c = 20\%$	96,00
		49		120,00

		48		0,60
		53		0,20

## 2.2 Laboratory procedures and testing methods

A Hobart type mixer apparatus was adopted. After placing the natural soil in the mixer, the water content was adjusted to the desired value by adding water. Before adding the binder the soil was homogenised by mixing. The grout made of Portland cement (PC) and water or the PC in dry form was then added to the soil and mixed for ten minutes according to JGS 0821 (2000).

Using a commercial device applied directly on the kitchen mixer apparatus, it was measured the torque required to turn the impeller in a soil-binder mixture just before the molding phase. According to the proposed method the workability was expressed as a torque ( $M_t$ ) applied to mix certain amount of soil-binder mixture ( $V_m$ ) with set impeller shape ( $S_h$ ) and rotational speed ( $R_s$ ). In the study were assumed the following parameters:  $V_{m0} = 3dm^3$ ;  $S_{h0} = "K"$  shape;  $R_{s0} = 10rpm$ .

Since the kitchen mixer has a planetary motion, the test was undertaken continuously on the whole mixture therefore giving more reliable outputs. For each completed revolution it was possible to measure the Torque, and for the test it was decided to set the number or revolution to 10, to obtain more accurate measures.

Afterwards the stabilized soil was placed into plastic molds in three layers and compacted using several molding techniques (Figure 1):

– No Compaction (namely *N.C.*): It simply consisted in placing the stabilized soil into the mold with a spoon.

– Tapping, namely (*TA.*): For each layer, the mold was tapped against the floor 50 times.

– Rodding, (namely *RO.*): It consisted in tamping each layer with a 8mm diameter steel rod for 30 times and eventually pushing down the material attached to the rod.

– Static Compaction (namely *S.C.25* and *S.C.50*): Each layer was statically compressed for 10 seconds by using a heavy rod, 49 mm in diameter. 25 or 50 kPa pressure were applied.

– Dynamic Compaction (namely *D.C.*): Each layer was compacted by a falling weight (1.5 kg) using a special apparatus. Fall height was set at 10 cm, number of blows at 5.

These techniques are those currently used in most of the laboratory all over the world (JGS 0821, 2000; EuroSoilStab, 2002; Kitazume et al. 2009).

Figure 1. Molding techniques used: a) *N.C.*, b) *TA.*, c) *RO.*, d) *S.C.25*, e) *S.C.50*, f) *D.C.*

To prevent water evaporation from the specimen each mold was covered with the sealant and stored in special curing tanks at 95% relative humidity. To reduce the effect of the time of rest between the hydration of binder and completion of molding on the specimens properties, according to Kitazume et al. (2009), all the stabilized soil was molded in less than 45 minutes from binder hydration. After curing times of 28 days, the specimens were removed from the molds and then subjected to unconfined compression tests at a rate of 1.0 mm/min. Unconfined compression tests were conducted on triplicate samples for each case (mixture type and molding technique) analyzed.

## 3 RESULTS

The applicability of a molding technique was evaluated by the “Applicability index”, which is related to “densest specimens with the highest strength” and “results repetitiveness”.

For the same mixture a well made specimen has low cavities/bubbles/voids amount and therefore higher wet density ( $\gamma$ ) if compared to a bad made one. Furthermore it was indeed observed that the specimens produced by different molding techniques could have similar wet density but very different unconfined compressive strength (*UCS*) values. For that reason the *N*-parameter was introduced to condense the indications given by both parameters,  $\gamma$  and *UCS*, into one. *N* is defined as the mean of the normalized unconfined compressive strength ( $UCS_N$ ) and the normalized unit weight ( $\gamma_N$ ) as reported in the Eq. 1. The  $UCS_N$  and  $\gamma_N$  values for a given molding technique

and mixture were calculated by dividing the UCS and  $\gamma$  by the maximum values ( $UCS_{max}$  and  $\gamma_{max}$ ) obtained from all the employed molding techniques. The normalizations are necessary to allow direct comparison between two parameters with different unit of measurements. According to the Eq. 1 the  $N$  parameter values range between 0 and 1. In order to define a criteria for the choice of the applicable techniques, it was set the acceptable limit of  $0.9N$  considering a variation of 10 % from the maximum  $N$  value.

$$N = \text{Average} [ UCS_N ; \gamma_N ] \quad (1)$$

The Figure 2 shows as example the  $N$  parameters vs. torque values obtained for all the analyzed soil-binder mixtures molded by the Rodding technique. From the figure clearly appears that for all the measured mixtures workability the  $N$  values are above the set limit as an expression of the high quality of the specimens realized by Rodding.

Figure 2. Applicability of Rodding technique considering the  $N$  and  $E$  parameters.

Despite the  $N$ -parameter is a good indicator of the applicability of a molding technique, to take into account that the applicability should be also related to the “repeatability” of the tests results the  $E$ -parameter was introduced. Repeatability means that the results related to the specimens produced by a specific molding technique should have a low “scatter” or relative error. Unconfined compression tests was conducted on triplicate samples for each case analyzed, therefore it was possible to evaluate the relative error on the unconfined compressive strength and wet density values for the different mixtures types and molding techniques.  $E$  is defined as the mean of the relative error on the UCS and  $\gamma$  values as reported from Eq. 2. According to its definition also this parameter ranges between 0 and 1. To set a criteria to select the applicable techniques, some literature works were taken into account. For the accuracy or repeatability of the experiments, Richards and Reddy (2010) claimed that a standard deviation of 10 % was not unheard of in geotechnical testing. Al-Tabbaa et al. (2012) also reported an error of 5 – 15% for laboratory mixed specimens tested with unconfined compression tests. Therefore even for the  $E$  parameter the acceptable limit was set equal to 10% of  $E$ .

$$E = \text{Average} [ E_{UCS} ; E_{\gamma} ] \quad (2)$$

The results obtained from the specimens molded by the Rodding technique in terms of  $E$  vs. torque values are shown in Figure 2 as example. It can be clearly seen that also for the  $E$  parameter all the obtained values are below the set limit, expression once again of the high repeatability of the tests results obtained from the specimens molded by the Rodding technique.

In order to take into account the different aspects of a well made specimen, expressed by the  $N$  and  $E$  parameter, an index of applicability  $I_A$  defined in Eq. 3 was introduced.

$$I_A = \frac{N}{1+E} \quad (3)$$

According to the Eq. 3 and to the  $N$  and  $E$  parameters definitions, also the  $I_A$  values range between 0 and 1. To obtain a target value for the choice of the applicable techniques, the limit values given for the two different parameters  $N$  and  $E$  were introduced in the Eq. 3. A target value of  $I_A = 0.82$  was then obtained.

The Figure 3 shows an example of the  $I_A$  vs. mixtures workability graph obtained for all the analyzed soil-binder mixtures molded by the Rodding technique.

Figure 3. Applicability index of Rodding technique.

The figure show that Rodding is applicable for all the measured mixtures workability since  $I_A$  values are all above the set target limit. From the results it is possible to see a very good trend of the  $I_A$  despite the fact that data were obtained from mixtures based on different types of soil (cohesive and granular types), with different grout dosage and water contents. The results obtained also from other techniques show that the  $I_A$  is strictly dependent on the workability of the mixture among other factors.

The results related to the No Compaction technique are shown in Figure 4. It clearly appears that this technique is applicable for  $M_t < 3Nm$  and not applicable for  $M_t > 6Nm$ . In the range  $M_t = 3\div 6Nm$  it is not possible to obtain univocal indication from the data, therefore this technique have been considered marginally applicable in this workability interval.

Figure 4. Applicability index of No Compaction technique.

Similar graphs to the ones shown in Figures 3 and 4 were also obtained for the other molding techniques used in the study. From these graphs it was possible to determine for each molding technique the ranges of workability in which they are

applicable, marginally applicable and not applicable. The results are summarized in the operational abacus of Figure 5.

Figure 5. Ranges of applicability of the different molding techniques.

To allow the standardisation and the use of the method a “calibration curve” was elaborated by drawing the torque versus the water content ( $w$ ) of an easily available kind of soil such as kaolin clay using the set of mixer related parameter  $V_{m0}$ ,  $S_{h0}$  and  $R_{s0}$  (Figure 6).

Figure 6. Calibration curve.

By using different set of parameters ( $V_m$ ,  $S_h$  and  $R_s$ ), function of the mixer type and torque evaluation procedure, other curves can be drawn in the same graph. Therefore for each molding technique the range of applicability (expressed by torque values) corresponding to the used set of parameter can be graphically obtained from the calibration curve, as shown in Figure 6.

By mean of the abaci of Figures 5 and 6, it would be possible to select for every kind of mixable soil-binder mixture the molding technique that gives high quality specimens in a very quick and easy way only by measuring the workability of the material.

#### 4 CONCLUSIONS

The results of the large laboratory study performed on eight types of natural soils confirm that the mixture’s “workability” has a great influence on the mechanical and physical properties of the stabilised soil specimens. The results provide very useful operational abaci to select the molding technique that produces high quality specimens in function of the soil-binder mixture’s workability.

The results obtained represent a useful data set for the correct selection of the molding technique for different kind of soils and mixing conditions headed for the international standardisation. This study represents a significant step forward towards the definition of highly required guidelines for the molding procedures of stabilised soil specimens as used in QC/QA processes for Deep Mixing applications.

#### 5 ACKNOWLEDGEMENTS

The authors wish to thank Prof. Masaki Kitazume for his help and suggestions throughout the study. The Soil Stabilization Group of the Port and Airport Research Institute (JP) is also acknowledged for the helps during the tests and for providing part of the data.

# Analysis of Floating Pile Capacity in Improved Ground for Thi Vai Port, Vietnam

## Analyse de la capacité de pile flottante dans un sol amélioré du port Thi Vai, Vietnam

Hai N.M., Tuong N.K.

Faculty of Civil Engineering, Thu Dau Mot University, Vietnam

Long P.D., Nhon P.V.

Vietnamese Society of Soil Mechanics and Geotechnical Engineering, Vietnam

**ABSTRACT:** A static loading programme was performed to respond to total and effective stress analysis of floating pile capacity in improved ground at Thi Vai Port approximately 90 km southeast of Ho Chi Minh City, Vietnam. The soil profile consists of an about 15 to 23 m thick deposit of soft, normally consolidated, compressible clay deposited on dense to compact sand. Scheme of soil improvement was imposed, consisting of wick drains installed at a spacing of 1.5 m through the clay to the sand and placing to 4.7 m thick surcharge. After removal of the surcharge, two square precast concrete piles, 400 mm diameter, were driven to depths of 16 and 22 m and the static loading tests were performed reaching the pile capacities after piles driven about 14 and 23 days, respectively. The capacity of the 16 and 22 m pile measured are about 450 and 1,100 kN at maximum movements of about 5 and 6 mm, respectively. The tests indicate a good agreement between measurements and analysis of total stresses, and the correlation coefficient,  $N_{KT}$ , between CPTU pore pressure adjusted cone stress and vane shear stress is about 18 instead of 12 through 16 as used for the Project.

**RÉSUMÉ :** Un programme de chargement statique a été réalisé pour répondre à l'analyse des contraintes totale et effective de la capacité du pieu flottant dans un sol amélioré au port de Thi Vai à environ 90 km au sud-est de Ho Chi Minh-Ville, Vietnam. Le profil de sol est constitué d'un dépôt de 15 à 23 m d'épaisseur d'argile souple compressible normalement consolidé, déposé sur un sable dense et compact. Le schéma d'amélioration des sols a été imposé, composé de drains verticaux installés à une distance de 1,5 m à travers l'argile au sable et à la mise à 4,7 m d'épaisseur en supplément. Après l'élimination de la surcharge, deux piles carrées en béton préfabriqué de 400 mm de diamètre ont été installés à des profondeurs de 16 à 22 m et les essais de chargement statique ont été réalisés pour atteindre les capacités de pieux après ce que des pieux sont mis en place environ 14 et 23 jours, respectivement. La capacité de la pile 16 et 22 m mesurée est d'environ 450 et 1100 kN aux mouvements maximum d'environ 5 et 6 mm, respectivement. Les tests montrent un bon accord entre les mesures et l'analyse des contraintes totales, et que le coefficient de corrélation,  $N_{KT}$ , entre la pression interstitielle CPTU ajustée la contrainte cône et la contrainte de cisaillement est d'environ 18 au lieu de 12 à 16 comme utilisés pour le projet.

**KEYWORDS:** soil improvement, static loading test, total stress analysis, effective stress analysis.

## 1 INTRODUCTION

The Thi Vai Container Port is built on an improved ground over a 470 m by 600 m area along the Thi Vai River approximately 90 km southeast of Ho Chi Minh City. The soil profile consists of deltaic sediments of about 15 to 23 m of soft, normally consolidated, highly compressible clay on a thick layer of dense to compact sand. The highest water level is at Elev. +4.0 m, which requires raising the ground elevation by about 2 m to Elev. +5.0 m to avoid flooding. To reduce settlement after construction, wick drains were installed with a spacing of 1.5 m through the clay to the sand and a temporary surcharge was added raising the surface to Elev. +7.6 m, an additional 2.0 m of fill height. The surcharge was removed after 80 % to 90 % of the consolidation settlements had developed and the expected future ground settlement shall not exceed 200 mm over a period of 20 years, which included secondary compression. After removal of surcharge, two 400 mm square precast piles driven into 16 and 22 m depth to serve for test and design of building foundations.

This paper presents the methods used for analysis of the pile capacity based on total and effective stress approaches, details of the results from the tests on 16 and 22 m piles, and discusses the merits of each method.

## 2 SOIL PROFILE

The soil profile is indicated in Figures 1 and 2. Figure 1 shows the results of a typical CPTU sounding pushed at the site before driving test piles.

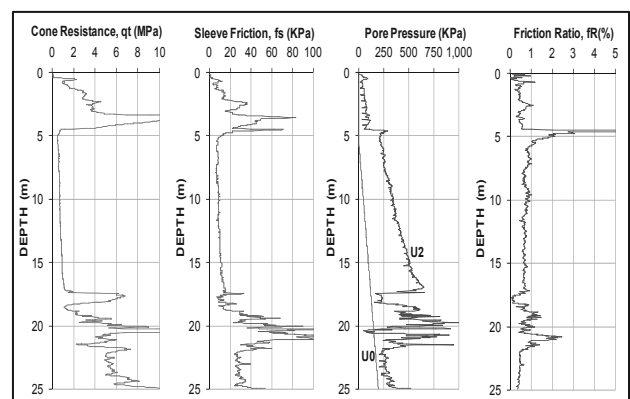

Figure 1. Diagram of CPTU sounding pushed before construction start

Figure 2 presents distribution of the grain size, water content, consistency limits, and the distribution of the undrained shear strength in the clay from a field vane. The field vane demonstrates the clay to be very soft above 10 m depth and soft below. Total saturated density is about  $1,600 \text{ kg/m}^3$  throughout the clay (from  $w_n = 61 \%$ ). The density of the sand above and below the clay is estimated to  $2,100 \text{ kg/m}^3$  (from  $w_n = 24 \%$ ) and  $1,800 \text{ kg/m}^3$  (from  $w_n = 22 \%$ ), respectively.

Figure 2. Water content and Atterberg Limits, grain size distribution, and field vane strength

### 3 SOIL IMPROVEMENT AND MEASUREMENTS

Figure 3 shows the location of SS8 settlement benchmark was installed on the original ground surface before the placing of the fill. Pore pressure measurement was performed by piezometer tips installed at depths of 6.5 m and 15.2 m. Settlement distribution with elevations was measured by means of extensometer gages placed at elevations of +5 m, -1.6 m, -5.9 m, -10.3 m and -17 m in the clay. Figure 4 also indicates location of field soil tests and test piles.

Figure 3. Locations of test piles, borehole, CPTU, VST, and field instrumentation

Figure 4 shows the settlements measured at SS8 plate near the tested piles. Day 0 is March 12, 2009 and the total settlement measured after completed removal of surcharge was about 2.15 m. Removal of surcharge at the 22 and 16 m pile was completed on August 22, 2011 and September 9, 2011, respectively. 15 and 60 days after removal of surcharge, the 22 and 16 m test pile was driven on September 6, 2011 and November 8, 2011, respectively, to serve for test and design of building foundation.

Figure 5 shows the settlement distribution with depth as measured at extensometer station, next to the SS8 at 4.6, 8.9, 13.3, and 20 m depths below the original ground surface from August 29 through June 30, 2011. The extensometer station had to be removed on June 30, 2011 before the test pile driven. The four settlements anchors were referenced to the presumed zero for the fifth anchor point placed at 20 m depth. The settlement distribution is almost linear from the fill surface to zero at 15 m depth.

Figure 4. Fill stress versus settlement

Figure 5. Distribution of settlement versus depth

Figure 6 shows the pore pressures measured at Elev. -1.5 m and -10.2 m from August 29, 2009, through September 23, 2011. The Piezometer had to be removed before driving the test piles. As shown in Figure 6, the pore water pressures seem to be equal to the hydrostatic pressures after removing the surcharge.

Figure 6. Pore water pressure versus fill stress

## 4 ANALYSIS OF PILE CAPACITY

### 4.1 Total stress approach ( $\alpha$ Method)

The so-called alpha method is a most common method to calculate shaft resistance in total stress approach, which correlates the shaft resistance,  $r_s$ , to the undrained shear strength of the clay,  $S_u$ , via an adhesion reduction coefficient,  $\alpha$ , as the undrained shear strength of the soil increased:

$$r_s = \alpha S_u \quad (1)$$

For field CPTU tests, Lunne et al. (1985) proposed a method to indirectly estimate the  $S_u$  versus corrected cone resistance ( $qt$ ) as:

$$S_u = (qt - \sigma_{v0})/Nkt \quad (2)$$

Where,  $Nkt$  is known as an empirical cone factor and  $\sigma_{v0}$  is the total overburden stress.

The records of undrained shear strength from the field vane test are substituted to Eq. (2) to determine  $Nkt$  as shown in Figure 7.

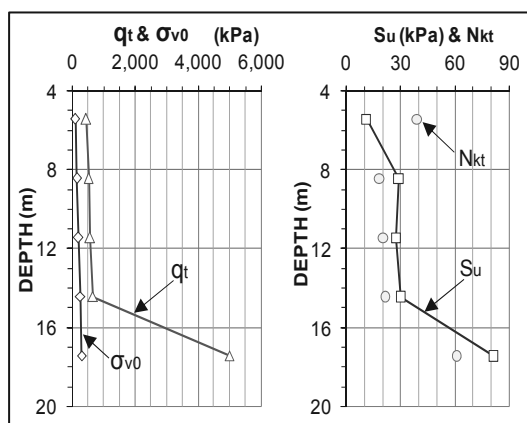

Figure 7. Correlation between cone stress and field vane strength

To improve total stress approach, Randolph and Murphy (1985) considered ratio of the undrained strength to the effective overburden stress,  $\sigma'_{v0}$  (stress history) and proposed a reduction coefficient incorporated into the API 1987 edition (excluding the effects of the pile length) as:

$$\alpha = 0.5(S_u/\sigma'_{v0})^{0.50} \text{ for } (S_u/\sigma'_{v0}) \leq 1 \quad (3a)$$

$$\alpha = 0.5(S_u/\sigma'_{v0})^{0.25} \text{ for } (S_u/\sigma'_{v0}) > 1 \quad (3b)$$

The effects of the pile slenderness (ratio of the embedment pile length,  $L$ , to the pile width,  $B$ ) also were considered by Murff (1980), Kraft et al. (1981), Semple and Rigden(1984), Randolph and Murphy (1985). The unit shaft resistance proposed from two alternative combinations of undrained shear strength and effective stress was refined in the API 1993 edition as shown in Eq. (4) and (5).

$$r_s = 0.5(S_u)^{0.50} (\sigma'_{v0})^{0.50} \quad (4)$$

$$r_s = 0.5(S_u)^{0.75} (\sigma'_{v0})^{0.25} \quad (5)$$

Kolk and van der Velde (1996) suggested an updated version incorporated directly length effects and the unit shaft resistance was determined in Eq. (6):

$$r_s = 0.55(S_u)^{0.7} (\sigma'_{v0})^{0.3} (40B/L)^{0.2} \quad (6)$$

The  $Nkt$  values in Figure 7 determined correlation between cone stresses and field vane strengths are used to determine the  $S_u$  of CPTU test and calculate the unit shaft resistance according to Eq. 1 and Eqs. 4 - 6.

The results are plotted in Figure 8 versus the accumulated unit shaft resistance for the full dissipation of excess pore pressures. For 5 m thick fill sand layer above the clay layer surface, the effective stress analysis is applied with a coefficient  $\beta$  of 0.3 and indicates the bearing capacity of this layer is about 97 KN.

Figure 8. The accumulated shaft resistances versus depth

### 1.1 Effective stress approach ( $\beta$ Method)

The effective stress approach for evaluating the pile capacity, Burland (1973) developed a simple equation written as:

$$r_s = K \tan \delta \sigma'_{v0} = \beta \sigma'_{v0} \quad (7)$$

Where,  $K$  is the lateral earth-pressure coefficient,  $\delta$  is the constant volume friction angle, and  $\beta = K \tan \delta$  is Bjerrum-Burland coefficient.

Two direct CPTU methods typical of effective stress approach are method of Eslami and Fellenius (1997) and Takesue et al. (1998). In the Eslami and Fellenius CPTU method, the cone stress is transferred to an apparent "effective" cone stress,  $q_E$ , by subtracting the measured pore pressure,  $U_2$ , from the measured total cone stress,  $q_t$ , the unit shaft and toe resistance is obtained from:

$$r_s = C_s q_E \quad (8)$$

Where,  $C_s$  is the side correlation coefficient determined from the soil profile chart which uses both cone stress and sleeve friction.

For method of Takesue et al. (1998), the unit pile shaft resistance,  $r_s$ , is estimated from the measured sleeve friction,  $f_s$ , which is scaled up or down depending on the magnitude of the measured excess porewater pressures during penetration,  $\Delta U$  ( $\Delta U = U_2 - U_0$ ). The data used to derive the correlation were obtained from both bored and driven pile foundations in clays, sands, and mixed ground conditions.

$$r_s = f_s (\Delta U / 1250 + 0.768) \text{ for } \Delta U < 300 \text{ kPa} \quad (9a)$$

$$r_s = f_s (\Delta U / 200 - 0.5) \text{ for } 300 < \Delta U < 1,250 \text{ kPa} \quad (9b)$$

The results of the effective stress analysis are presented in Figure 9. For fill layer above clay surface, the analysis is made the same as above total stress analysis.

Figure 9. The accumulated shaft resistances versus depth

### 1.2 Pile test results and evaluation of approaches

The static loading tests for the 22 and 16 m Pile were performed after piles driven about 23 and 14 days, respectively. The 22 and 16 m were tested on September 29, 2011 and November 22, 2011. The load-movement curves of the two tested piles in Figure 12 indicate the ultimate loads of the plunging failures at 1,100 and 459 kN, respectively.

Figure 10. Pile-head load-movement curves of two static loading tests performed on 22 and 16 m pile.

Normally, the plunging failures of the test piles are found when the pile toe is in soft clay as in the subject case and the pile toe resistance can be disregarded when evaluating the analysis methods. Performance of two approaches are evaluated basing on ratio of the estimated capacities,  $Q_p$ , to the measured capacities,  $Q_m$ . Table 1 shows the performance evaluation of two approaches for the measured pile capacities.

Table 1. Evaluation on performance of the total and effective approach for predicting the pile capacity.

	Pile 16 m ( $Q_p/Q_m$ )	Pile 22 m ( $Q_p/Q_m$ )
Total stress approach		
Eq. 1	0.967	0.949
Eq. 4	1.422	1.416
Eq. 5	1.048	1.280
Eq. 6	1.203	1.423
Effective stress approach		
Eq. 8	0.915	0.884
Eq. 9	0.624	0.688

## 5 SUMMARY AND CONCLUSION

The total and effective stress analysis on two tested piles driven in improved ground of Thi Vai Port is performed and summarized as:

- For total stress approach, the analysis indicates the alpha method with a reduction coefficient incorporated into the API 1987 edition gave the best agreement.
- For effective stress approach, the analysis shows the Eslami and Fellenius method (1997) is approximately the same as the measurements.
- For two approaches, the total stress approach is the better agreement.
- Correlation coefficient,  $N_{KT}$ , between CPTU pore pressure adjusted cone stress and vane shear stress is about 18.

# Carbonate Cementation via Plant Derived Urease

## Cimentation carbonatée par l'utilisation d'uréase issue de plantes

Hamdan N., Kavazanjian Jr. E., O'Donnell S.

*School of Sustainable Engineering and the Built Environment, Arizona State University, Tempe, AZ 85287-5306; PH: (480) 965-3997*

**ABSTRACT:** The use of plant-derived urease enzyme to induce calcium carbonate ( $\text{CaCO}_3$ ) cementation has been demonstrated through laboratory column tests. Benefits of the use of plant-derived urease over the use of microbially-generated urease to induce carbonate cementation include the small size of the enzyme, which permits penetration into finer grained soils and makes the process less sensitive to biopugging, and the availability of 100% of the carbon in the substrate for conversion to  $\text{CaCO}_3$ . The laboratory column tests employed both Ottawa 20-30 silica sand and finer-grained F-60 silica sand. The laboratory column specimens were prepared in a variety of manners and showed varying degrees of cementation and carbonate yield. Triaxial tests performed on cemented specimens showed significant strength increases over non-cemented specimens. These tests confirm the feasibility of using plant-derived urease to induce carbonate cementation in sand and provide valuable insight into the factors that must be considered in developing practical applications for ureolytic carbonate precipitation using plant-derived urease enzyme.

**RÉSUMÉ :** La cimentation de sable par du carbonate de calcium ( $\text{CaCO}_3$ ) produit par l'enzyme uréase obtenue à partir de plantes a été réalisée en laboratoire. Les avantages d'utiliser de l'uréase obtenue de plantes plutôt que de l'uréase produite microbilogiquement pour produire la cimentation carbonatée sont la petite taille de l'enzyme qui permet la pénétration dans les sols fins et rend le processus moins sujet au colmatage biologique et la disponibilité à 100% du carbone présent dans le substratum pour conversion en  $\text{CaCO}_3$ . Des essais en colonnes ont été réalisés sur deux sables de silice dits Ottawa 20-30 et F-60 (plus fin). Les échantillons ont été préparés de différentes manières et ont atteint des degrés de cimentation variés et des productions de carbonate différentes. Les résultats des essais de compression triaxiale sur des échantillons cimentés et des échantillons non-cimentés indiquent que les premiers sont beaucoup plus résistants. Ces essais confirment que l'uréase obtenue à partir de plantes peut être utilisée pour induire une cimentation carbonatée dans les sables. De plus ces essais ont permis de d'identifier les facteurs à considérer pour développer des applications pratiques pour l'utilisation de la précipitation carbonatée « uréolytique » en utilisant l'uréase issue de plantes.

**KEYWORDS:** carbonate, cementation, urease, calcite, soil improvement

## 1. INTRODUCTION

### 1.1 Background

The potential for using plant-derived urease enzyme to cement sands by inducing calcium carbonate ( $\text{CaCO}_3$ ) precipitation has been demonstrated through a series of laboratory column tests on two different gradations of silica sand. The use of microbially induced carbonate precipitation (MICP) to cement cohesionless soils has recently received substantial attention from geotechnical researchers (Burbank et al. 2012, Chou et al. 2011, Dejong et al. 2010, Harkes et al. 2010, van Paassen et al. 2010). The MICP mechanism most often discussed in the literature and most advanced in terms of field application is hydrolysis of urea (ureolytic hydrolysis). MICP via ureolytic hydrolysis relies on microbes to generate urease enzyme, which then serves as a catalyst for the precipitation reaction. The use of plant-derived urease (enzymatic ureolytic hydrolysis) to induce  $\text{CaCO}_3$  precipitation eliminates the need for microbes in the  $\text{CaCO}_3$  precipitation process.

Besides eliminating the need to nurture urease-producing microbes, enzymatic ureolytic hydrolysis offers several other advantages over ureolytic MICP. Applications of ureolytic MICP on clean sands in laboratory column tests and limited field tests have encountered significant practical difficulties, including biopugging (permeability reduction accompanying induced mineral precipitation) and generation of a toxic waste product (ammonium salt) (Harkes et al. 2010, van Paassen et al. 2008). Biopugging not only limits the distribution of

precipitation agents within the soil but also makes flushing of the waste product from the soil a difficult, energy intensive task. Due to these limitations, mass stabilization of soil using ureolytic MICP remains problematic. Furthermore, the microbes that produce the urease enzyme cannot readily penetrate the pores of soils smaller than medium to fine sand, limiting the minimum grains size of soils amenable to ureolytic MICP to clean fine sands or coarser graded soils. The small size (on the order of 12 nm) of the urease enzyme suggests that  $\text{CaCO}_3$  precipitation by enzymatic ureolytic hydrolysis will be less susceptible to bio-pugging and will be able to penetrate finer grained soils, perhaps into the silt-sized particle range, compared to MICP processes.

### 1.2 Sustainability of Ground Improvement Practices

Finding effective solutions to ground improvement challenges is becoming increasingly complex due to sustainability considerations. Established materials and methods often need to be either replaced or supplemented by innovative materials and environmentally-friendly practices to address sustainability considerations. One example of a common building material that poses significant sustainability concerns is Portland cement. Portland cement is widely used in ground improvement applications. Unfortunately, Portland cement production is extremely energy intensive and a major source of emissions of carbon dioxide ( $\text{CO}_2$ ), as well as of sulfur and nitrogen oxides. MICP has been explored recently as an alternative to Portland cement for ground improvement. Reductions in the use of

Portland cement through either direct substitution or complementary use of MICP could contribute considerably towards reduction in CO<sub>2</sub> emissions. Research suggests that cementation using MICP can address a number of important geotechnical problems in granular soils, including slope stability, erosion and scour, under-seepage of levees, the bearing capacity of shallow foundations, tunneling, and seismic settlement and liquefaction (DeJong et al. 2010, Harkes et al. 2010, Kavazanjian and Karatas 2008, van Paassen et al. 2010).

### 1.3 Ureolytic MICP

MICP attempts to create a cemented soil mass by precipitating calcium carbonate from the pore fluid such to form cementation bonds at the interparticle contacts (van Paassen et al. 2010, DeJong et al. 2006). Karatas et al. (2008) have identified several mechanisms for MICP. The MICP mechanism that has garnered the most attention and is most advanced in terms of development is ureolytic hydrolysis, or ureolysis (Chou et al. 2011, DeJong et al. 2006, van Paassen et al. 2010, Whiffin et al. 2007). Ureolytic MICP has typically been accomplished using a technique best described as biogrouting (Harkes et al. 2010, van Paassen et al. 2010), wherein bacteria and nutrients are mixed in a tank ex-situ and then injected into the soil followed by a fixation fluid to foster microbial attachment to soil particles and, finally, by a calcium-laden cementation fluid. Ureolytic MICP by stimulation of indigenous bacteria has also been reported in the literature (Burbank et al. 2012).

### 1.4 Agricultural Urease

Urease is a widely occurring hexameric protein found in many microorganisms, higher order plants, and some invertebrates. The enzyme is approximately 12 nm in dimension (Blakely & Zerner 1984). The small size of a solubilized urease enzyme affords it a distinct advantage over carbonate cementation methods that employ ureolytic microbes in cases that require penetration into very small pore spaces as nearly all known bacteria are greater than 300 nm in diameter, with the majority in the range of 500-5000 nm. Several families of common plants are very rich in urease, including some varieties of beans, melons and squash, and the pine family (Das et al. 2002). Extraction of urease enzyme from most urease containing plants has been shown to be very simple (Srivastava et al. 2001) and the enzyme is readily available from laboratory suppliers.

It is well-established that urease can occur as both an intra- and extra-cellular enzyme (Ciurli et al. 1996, Marzadori et al. 1998). Free soil urease (i.e. urease not bound to any living organism), generally derived from dead and decaying microorganisms and possibly from plant sources, readily occurs apart from the host microorganism and, upon absorptive association with soil particles, can persist for long periods of time without degradation or loss of function (Pettit et al. 1976). By contrast, exogenously added urease (i.e. urease added as a free enzyme) has a limited lifespan and its activity and function decrease with time (Marzadori et al. 1998, Pettit et al. 1976). This limited lifespan is potentially advantageous in some engineering applications as the enzyme can naturally degrade thereby eliminating long term impacts to the ecosystem.

## 2. METHODS

### 2.1 Ottawa 20-30 Sand

Laboratory column tests were conducted using plant derived urease to induce CaCO<sub>3</sub> precipitation in Ottawa 20-30 sand. These tests were carried out in 6"x 2" (152 mm x 51 mm) acrylic tubes and membrane-lined 2.8" x 6" (71 mm x 152 mm) split molds (for creating specimens for triaxial testing). Three acrylic tubes and two columns for triaxial testing were filled with 20-30 Ottawa silica sand (mean grain size 0.6 mm,

coefficient of uniformity 1.1) and treated as follows: tube #1: the sand was dry pluviated via funnel at ≈3" (76 mm) drop height and then received 5 applications of a cementation solution containing urea and calcium chloride mixed with 1.4g/L enzyme (total solution volume ≈ 300 ml); tube #2: sand was added in same manner as tube #1 and then received 2 applications (≈ 150 ml total) of the same cementation solution mixed with 1.4g/L enzyme; tube #3: the lower-third of tube was filled with sand and dry enzyme (≈ 3g), the remainder of the tube contained dry pluviated sand without enzyme, and the tube then received 2 applications (≈ 150 ml) of the cementation fluid with no enzyme added. The cementation fluid composition was based upon stoichiometry and experience with microbial urease cementation, e.g. DeJong et al. (2007), Whiffin et al. (2008).

Approximately 100 mL of a pH=7.8 solution containing 383 mM urea (reagent grade, Sigma-Aldrich), 272 mM CaCl<sub>2</sub>-2H<sub>2</sub>O (laboratory grade, Alfa Aesar) was used for the first application in each acrylic tube. Subsequent applications employed approximately 50 mL of a pH=7.6 solution containing 416 mM urea and 289 mM CaCl<sub>2</sub>-2H<sub>2</sub>O. Solution concentrations, while variable, were formulated within a reasonably similar range as a matter of convenience. In each application, the cementation fluid was poured into the top of the acrylic tube with the bottom closed off. The cementation fluid was allowed to stand, loosely covered, in the acrylic tube for at least 24 hours and then drained out the bottom of the cylinder. The next application followed immediately after drainage was complete. Drainage was accomplished by puncturing the base of the cylinder with a 20-gauge needle. When drainage was complete, the needle was removed and the puncture was plugged with a dab of silicone. Occasionally, the needle became plugged and an additional needle was inserted through the base. The triaxial columns were filled with sand in the same manner as tube 1 and then received 2 applications (each application ≈ 250 ml) of cementation solution with 1.4g/L enzyme.

In each application of cementation fluid, the fluid was added until it rose to approximately ½-inch (12-mm) above the soil line. After 2 applications, tubes #2 and #3 were allowed to air dry for several days and then analyzed. Experimentation with tube #1 was continued for several more days as three more batches of cementation fluid were applied. The last 2 applications of cementation fluid were allowed to slowly drain through the needle in the base immediately after application rather than sit for 24 hours (drainage rate ≈10-25ml/hour). The triaxial columns were allowed to stand for at least a week after the second cementation fluid application and then drained.

After drainage was complete, the triaxial columns were moved to a triaxial testing device. After draining the specimens from the acrylic tubes and after the completion of the triaxial tests, all samples were triple washed with de-ionized water. Tubes #2 and #3 were separated in 3 layers, while tube #1 was separated into six layers (for better resolution). Each layer from the specimens in the acrylic tubes and the entire mass of the triaxial specimens were acid washed to determine CaCO<sub>3</sub> content by oven drying for 48 hours, weighing, digesting with warm 1M HCl, washing, drying, and reweighing to determine carbonate mineral content.

Several of the cemented specimens were analyzed for mineral identification using X-Ray Diffraction (XRD). Samples were ground in an agate mortar and pestle and powdered onto a standard glass slide for analysis. Scanning electron microscopy (SEM) imaging was performed on intact cemented chunks of material with an Agilent 8500 Low-Voltage SEM (LV-SEM). A LV-SEM is a field emission scanning electron microscope capable of imaging insulating materials, such as organic and biological substances without the need for a metal coating and without causing radiation damage to samples.

### 2.2 Ottawa F-60 Sand

A triaxial column was prepared using Ottawa F-60 silica sand (mean grain size 0.275 mm, coefficient of uniformity 1.74) to

investigate enzymatic ureolytic  $\text{CaCO}_3$  precipitation in a finer grained material. The specimen was prepared in the same manner as described for the triaxial columns for the Ottawa 20-30 sand. The cementation fluid for the first of the two applications contained approximately 2.0 g/L enzyme, 400 mM urea (reagent grade, Sigma-Aldrich), 300 mM  $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$  (laboratory grade, BDH) at  $\text{pH}=7.7$ . The fluid for the second application contained 1 M urea- $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$  solution at  $\text{pH}=7.8$  without any enzyme. After the test, the triaxial specimen was washed and subject to acid digestion in the same manner as the Ottawa 20-30 triaxial specimens.

### 3. RESULTS

#### 3.1 Acrylic Tubes

Approximately 100 ml of cementation solution was delivered per application for the first application in each acrylic tube. However, the amount of solution the tube would accept was notably reduced in subsequent applications, when less than 75 ml was typically required to fill the tubes to  $\approx \frac{1}{2}$  inch (12 mm) above soil line. At the conclusion of the experiment, precipitation was visible along the entire length of tubes 1 and 2. Internally the cementation was variable, with some highly cemented zones and other zones with little to no cementation.

Tube 1 yielded mostly small, loose chunks of sand with strong effervescence upon digestion. Most of this column appeared un-cemented and exhibited unusually viscous behavior when wet. A fairly large (compared to column diameter) piece of strongly cemented sand (not breakable without tools) formed in the deepest layer of tube 1. Tube 2 had many small chunks of weakly cemented sand with strong effervescence upon digestion. Tube 3 had little to no precipitation in the top layer (i.e. this layer did not show any indication of carbonate upon acid digestion.) The deepest layer of tube 3 contained many pieces of weakly cemented sand that effervesced strongly upon digestion. The middle layer of tube 3 contained a few pieces of cemented sand that effervesced moderately upon digestion. The results from the acid washing are presented in Table 1.

Table 1. Results from *Experiment Set 1* using 20-30 Ottawa silica sand

Summary of Results					
Tube #	Layer	Weight Change via Digestion	Amt. of $\text{CaCO}_3$ (g)	Total Amt. $\text{CaCO}_3$ (g)	Theor. Max $\text{CaCO}_3$ (g)
1	1	11%	3.57	11.8	$\approx 14.5$
	2	3.8%	1.67		
	3	2.7%	1.73		
	4	2.1%	1.40		
	5	2.3%	1.74		
	6	2.0%	1.64		
2	1	0.76%	0.63	2.07	$\approx 4.35$
	2	0.65%	0.69		
	3	0.49%	0.75		
3	1	0.23%	0.31	3.57	$\approx 4.35$
	2	0.58%	0.63		
	3	1.7%	2.63		

The theoretical maximum  $\text{CaCO}_3$  content is the stoichiometric maximum balanced on initial concentrations. The primary experimental differences between the tests are (1) the number of applications of cementation fluid and (2) the manner in which the urease was delivered. The results indicate that there is greater carbonate precipitation with increasing number of applications, as expected. The data show more precipitation in (or on) the top layer of tubes 1 and 2 but not in tube 3, as the enzyme was physically confined to the lower-third layer in tube

3 during sample preparation. In the top layer of tube 3, where no urease was mixed with the sand, carbonate precipitation was nearly undetectable. There was no visual evidence of precipitation and practically no measurable change in weight of this layer after acidification (weight change = 0.23%). In the bottom layer of tube 3, where 3 g of dry enzyme was mixed with the soil, there was a weight change of 1.7% following acid washing. The middle layer of this specimen had a minor change in weight (0.58%), possibly due to uneven distribution of the layers during preparation or splitting of the specimen or to upward migration of urease from the bottom layer.

XRD analysis, presented in Figure 1, confirms that calcite is the mineral phase present in the cemented soil chunks. LV-SEM images, presented in Figure 2, show silica (quartz) sand particles cemented with calcium carbonate and various morphological features associated with the cementation process on the silica surface.

Figure 1. XRD results from cemented sand sample (top plot). Quartz & calcite standards (middle & bottom plot, respectively).

Figure 2. LV-SEM images a.) Well-grown and cementing calcite crystals; b.) Cementing calcite crystals at inter-particle contact; c.) Indentation of quartz surface (blue arrows) and nucleation of calcite crystals (red arrows); d.) Calcite crystal growing on quartz surface.

#### 3.2 Triaxial Columns

The three triaxial sand columns (2 Ottawa 20-30 sand columns and 1 Ottawa F-60 sand column) were tested in drained triaxial compression prior to acid digestion. All three columns were able to stand upright after removal of the split mold. The results

of the triaxial compression tests performed on the 20-30 Ottawa sand are presented in Figure 3 and the results for the F-60 Ottawa sand are presented in Figure 4. The carbonate cement content for one of the 20-30 silica sand columns was 2.0% CaCO<sub>3</sub> (by weight). The carbonate content of the other 20-30 Ottawa sand column could not be quantified due to unintended sample loss. The carbonate cement content for the finer grained F-60 Ottawa sand was 1.6% CaCO<sub>3</sub> (by weight). The results show substantial strength increase for all 3 sand columns tested.

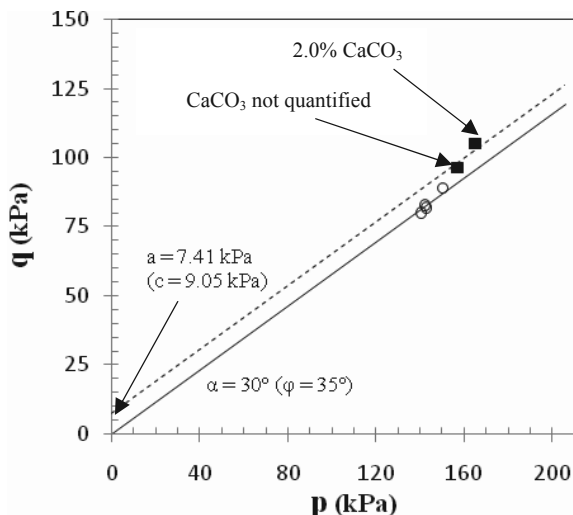

Figure 3. p-q plot failure envelopes for 20-30 silica sand: ■ Cemented ( $D_r = 60\%$ ); ○ Uncemented ( $D_r = 60\%$ )

Figure 4. p-q plot failure envelopes for F-60 silica sand: ■ Cemented ( $D_r = 35\%$ ); ○ Uncemented ( $D_r = 37\%$ );

#### 4. CONCLUSION

Sand column tests at Arizona State University have shown that agriculturally-derived urease can be used to induce calcium carbonate precipitation in sand. Sand columns were developed using Ottawa 20-30 and F-60 sand and three different preparation methods: dry pluviation followed by percolation of a calcium-urease-urea cementation solution, pluviation into a calcium-urease-urea cementation solution, and mixing the sand with urease prior to pluviation with a calcium-urea solution. Cementation was observed in all of the columns. XRD and SEM testing confirmed that calcium carbonate (specifically calcite) was the cementing agent. Acid digestion showed that increased applications yielded correspondingly greater

carbonate precipitation. The quality of cementation, as determined by the effort needed to break apart cemented chunks of sand, varied depending on the sampling location within the column. Triaxial test results on cemented columns showed substantial strength increase over non-cemented columns at the same relative density.

# Experimental investigation on bearing capacity of geosynthetic encapsulated stone columns

## Étude expérimentale sur la capacité portante des colonnes de pierre géosynthétiques encapsulées

Hataf N., Nabipour N.

*Department of Civil and Environmental Engineering, Shiraz University, Shiraz, Iran*

**ABSTRACT:** Civil engineers have developed different soil improvement techniques in recent decades to improve the bearing capacity of soft soils loaded by foundations and reduce soil settlement. A method for increasing the bearing capacity of foundation soil is the use of stone columns. However, one of the major weaknesses in use of stone columns in loose soils is lack of confinement. Using geosynthetic reinforcement to compensate low confinement pressure in these soils, is a solution to this problem. This paper presents the results of an experimental study on the improvement of the bearing capacity of stone columns reinforced by geosynthetics. In this study the influences of three variables have been investigated, including: surrounding soil types (i.e. clay and sand), stone column aggregate size and length of reinforcement. Having mentioned these variables, the results showed that encapsulating stone column with geosynthetic is more effective in cohesive soil compared to granular soil. The results of the experiments revealed that the coarser the aggregate the better behavior is expected for the stone column. The results also showed that, reinforcing half height of stone columns is the optimal encapsulating length.

**RÉSUMÉ:** Ces dernières décennies, les ingénieurs civils ont développé différentes techniques pour l'amélioration de la capacité portante du sol mou ainsi que celles des fondations. Une des techniques couramment utilisée permettant l'augmentation de la capacité portante des sols et des fondations est l'utilisation des colonnes de pierre. Cependant, l'une des grandes faiblesses de l'utilisation de colonnes de pierre dans les sols mous est le manque de confinement. L'utilisation de renforts géosynthétiques permet de compenser pour la faible pression de confinement. Cet article présente les résultats d'une étude expérimentale sur l'amélioration de la capacité portante des colonnes de pierre renforcées par des méthodes géosynthétiques. Dans cette étude, l'influence de trois variables ont été étudiées, notamment: le type de sol environnant (i.e. argile et sable) ainsi que la longueur de l'armature de renforcement. Les résultats démontrent que l'emploi de la colonne en pierre avec encapsulation géosynthétique est plus efficace dans un sol consistant comparé aux sols granulaires. De plus, les résultats de ces expériences ont révélé que plus la rugosité de l'agrégat augmente, plus le comportement des colonnes de pierres est amélioré. Finalement, les résultats indiquent que la longueur d'encapsulation optimale est atteinte en renforçant la hauteur médiane des colonnes de pierre.

**KEYWORDS:** stone column, bearing capacity, geosynthetic, reinforcement.

### 1 INTRODUCTION.

In recent years with increasing in population density in specific locations, the value of land has increased significantly. This has made the use of areas with soft soils inevitable.

Due to the lack of bearing resistance in these soils, different methods of soil improvement techniques, including stone columns as a method of strengthening the loose soil are used.

Stone columns behavior has been studied experimentally, theoretically and numerically by many researchers (Bergado and Teerawattanasuk 2008, Guetif et al. 2007, Castro and Sagasetta 2011)

However, one of the major weaknesses in use of stone columns in loose soils is lack of confinement. This leads researchers and practitioners to use geosynthetics to increase confinement of column, compensating the scarcity of studding around reinforced stone columns (Malarvizhi and Ilamparuthi 2007, Gniel and Bouazza 2009, Gniel and Bouazza 2010). In this study the parameters affecting the behavior of reinforced stone columns have been investigated. These parameters are reinforced length, column material and surrounding soil type.

### 2 LABORATORY SETTINGS

Since the focus of this research was on the laboratory results, the physical model, is described, firstly.

#### 2.1 Test apparatus

A cylindrical tank (height=1.0 m and dia.=1.0m) filled with soil was used as the soil environment. Stone column run in the middle of the tank. The static loading system consists of a loading arm and weights were used (Razavi and Hataf, 2003) to determine the bearing capacity of a circular foundations resting on stone column, Figure 1.

#### 2.2 Soil tested

To test and evaluate the behavior of reinforced stone columns in loose soil, two soil types were used, a clay soil as cohesive soil and a sandy soil as granular soil.

Physical properties of the soils are listed in Table 1.

#### 2.3 Specimens preparation

To prepare the soil and column, first two 10 cm soil layers has been poured in the tank and compacted using 20 strokes caused by dropping a 50 N weight attached to a wooden handle from a distance of 40 cm as the substrate layer. The next layers were compacted with 10 strokes from 10cm distance to provide loose soil.

To prepare the stone column an open ended hollow cylindrical pipe with a diameter of a little more than the diameter of the stone column was used. After that the cylinder was placed at its position and the surrounding was filled slowly with soil.

Figure 1. Laboratory setting for model testing.

Table 1. Physical properties of the soils tested.

Parameter	Clay	Sand
Friction Angle	26.0	35.0
Cohesion (KN/m <sup>2</sup> )	5.0	0.0
Unit weight(KN/m <sup>3</sup> )	15.0	16.0
Liquid Limit(%)	44.5	-
Plasticity Index (%)	20.0	-

Then until reaching up to the surface level the stone column filled with stone aggregates in 10 cm layers. After filling each layer the cylinder pulled out about 10 cm and aggregates were poured in and compacted with 40cm length rod.

Three types of aggregates were used to fill the stone columns. These are shown in Figure 2.

Stone columns with no reinforcement, half-length reinforcement and full-length reinforcement were prepared for testing. A commercially available geogrid was used for reinforcement.

Figure 2. Different aggregates used as stone columns materials.

### 3 TEST RESULTS

Test results as load settlement curves for stone columns embedded in cohesive and granular soils are illustrated in Figures 3 and 4. In this figures f-Ri, h-Ri and no-Ri stand for full-length, half-length and no reinforced column, respectively.

Loads were normalized to maximum load obtained for unreinforced column in each case and settlements were normalized to radius of stone column.

As it can be seen from these figures it is obvious that reinforcement improve the bearing capacity of stone columns in both cohesive and granular soils. The reinforcement however is more effective in cohesive soil than in granular soil.

Further numerical studies (not presented here) showed that the effect of viscosity is reduced with the increase in cohesion of soil which in turn caused increase in the confining pressure of surrounding soil. Therefore this results in decrease in stone column material to spread out within the surrounding soil.

The most important variable in this study was to experimentally and practically examine the optimal length of

reinforcement for optimal strength. This was achieved by changing the length of reinforcement compared to the column length as full-length, half-length and non-reinforced.

Test results indicated that in both types of surrounding soils and for all sizes of column aggregate materials, it is enough to reinforce only half length of the column to achieve desired bearing improvement. However the Improvement rate in cohesive soils is more noticeable. This can be related to the fact that the confining pressure in the bottom of the column is higher than that in the upper parts of the column due to higher overburden pressure. By increasing the confining pressure in the upper parts of the column by installing reinforcement, the radial strain reduces and as the result, it reduces the side contact pressure between the soil and stone column. This in turn causes just vertical distribution of the stresses to the layer below the column and not distributing of stresses to the surrounding soil. This obviously causes more vertical deflections in the below layers of soil and less in the upper layers.

In the half-length reinforced column by increasing in stresses, a small amount of inflation on the side layers are observed which results in increase in lateral soil friction and so the stresses spreads over a larger surface of the soil and it results the deflection not to increase below the column but spread in larger area homogeneously.

Figure 3. Test results for stone columns embedded in cohesive soil.

4-a fine aggregate material

4-b medium aggregate material

3-c coarse aggregate material

Figure 4. Test results for stone columns embedded in granular soil.

As it was mentioned earlier one of the variables in this study was the size of the column aggregate materials. The results of tests on the same stone column conditions but with different size of stone column materials are illustrated in Figure 5 and 6 for cohesive and granular surrounding soils, respectively. It can be seen that keeping all conditions constant, there was an increase in bearing resistance of the column with increasing grain size dimension of column material. However the improvement due to the use of geosynthetic reinforcement was the same for all column material sizes.

#### 4 CONCLUSION

One of the recent methods for increasing the bearing capacity of foundation soil is the use of vertical stone columns. Stone columns consist of a stiffer material or aggregates, compared to the surrounding soils, which are usually vibrocompacted into the soil. These columns increase the bearing capacity of the soil significantly. Compared to concrete or steel piles inclusion, for soil improvement, this technique is more economical and needs to be studied further. However, one of the major weaknesses in use of stone columns in loose soils is lack of confinement. This leads to use reinforcement to compensate low confinement pressure in these soils. Because of the lack of experimental studies on the behavior of reinforced stone columns, an experimental study has been performed. It was shown that the use of stone columns improves the soil bearing capacity, significantly. The results showed that encapsulating stone column with geosynthetic is more effective in cohesive soils compared to granular soils. Three types of stone column materials were used with different aggregate dimensions. The results of the experiments revealed that the coarser the aggregate the better behavior is expected for the stone column. Although the increase in grain size should not be more than two percent of stone column diameter. On the other hand, the

behavior of stone column encapsulated by geosynthetic in its entire length was compared to partially encapsulated stone column behavior. The results showed that, reinforcing half height of stone columns in both types of soils, especially in clay, is the optimal encapsulating length. This finding is significant regarding the economical and efficiency of use of stone columns as a soil improvement technique.

Ameratunga J.

*Coffey Geotechnics, 47 Doggett Street, Newstead, QLD. 4006, Australia*

**ABSTRACT:** Due to a projected increase in trade activities at the Port of Brisbane, new berths on Fisherman Islands at the mouth of the Brisbane River will be constructed in the outer area (235ha) close to the existing port facilities via land reclamation. A vacuum assisted surcharge load in conjunction with prefabricated vertical drains was chosen to reduce the required consolidation time. The features of the combined vacuum and surcharge fill system and the construction of the embankment are described in this paper. A comparison of the performance of the vacuum combined surcharge loading system with a standard surcharge fill emphasizes the obvious advantages of vacuum consolidation. Field data is presented to show how the embankment performed during construction. An analytical solution for radial consolidation incorporating both time-dependent surcharge loading and vacuum pressure is employed to calculate the settlements and associated excess pore pressures of the soft Holocene clay deposits.

**RÉSUMÉ :** L'augmentation des activités de commerce au port de Brisbane nécessite la construction, à proximité des terminaux existants, de nouveaux postes de quais dans les îles Fisherman à l'embouchure de la rivière de Brisbane sur une superficie de 235 Ha gagnée sur la mer. Un chargement sous vide contrôlé, associé à des drains préfabriqués, a été appliqué pour réduire le temps de consolidation. L'article décrit les caractéristiques de la technique de consolidation sous vide associée au chargement par remblaiement et la construction du remblai. Une comparaison entre la consolidation sous vide associée au remblaiement et le pré chargement classique montre clairement les avantages en faveur de la consolidation sous vide. Les données enregistrées sur le site illustrent le comportement du remblai durant la consolidation. Une solution de consolidation horizontale tenant compte du chargement et de la pression sous vide est présentée en vue de prédire le tassement et l'excès de la surpression interstitielle du dépôt d'argile molle de l'Holocène.

**KEYWORDS:** consolidation, soil improvement, vertical drains, vacuum.

## 1 INTRODUCTION

The Port of Brisbane is one of the Australia's largest commercial ports located at the entrance of the Brisbane River at Fisherman Islands. With demand in commercial activities, a new outer area (235ha) is being reclaimed for major expansion to maximise the available land, and to provide the maximum number of berths suitable for container handling for servicing regional importers and exporters. In this area, the soil profile mainly consists of compressible clay deposits over 30m in thickness with very low undrained shear strength (<15 kPa at shallow depth). The strength of dredged mud had a much lower strength depending on the placement time and the thickness of capping material. Without surcharge preloading, it is estimated that the consolidation time could be more than 50 years with overall settlements of 2.5-4.0m. Therefore, vacuum consolidation with prefabricated vertical drains (PVDs) was suggested to accelerate the consolidation process and to minimise lateral deformation adjacent to the Moreton Bay Marine Park (Indraratna et al. 2011).

The effectiveness of the vacuum preloading assisted by PVDs has been illustrated by Chu et al. (2000) and Chai et al. (2005). In this technique, vacuum pressure can propagate to a greater depth of the subsoil via PVD length. Also, extended consolidation time due to stage construction can be minimized (Indraratna et al. 2005). The surcharge fill height can be reduced by several metres, if a vacuum pressure (at least 70 kPa) is applied and sustained (Rujikiatkamjorn et al. 2008). The embankment construction rate can be increased and the number of construction stages can be reduced (Yan and Chu 2003). Once the soil has increased its stiffness and shear strength due to consolidation, the post-construction settlement will be significantly less, thereby eliminating any risk of differential settlement of the overlying infrastructure (Shang et al. 1998). To the authors' knowledge, there is no comprehensively

reported case history where both the conventional surcharge preloading and vacuum technique have been applied in the same area with distinct variation of drain types and spacing.

In this paper, the performance between the vacuum and non-vacuum areas has been compared based on the measured settlements, excess pore pressures and lateral displacements. The influences of drain spacing, drain types and type of soil improvement are discussed based on the observed degree of consolidation. The analytical solutions for radial consolidation considering both time dependent surcharge loading and vacuum pressure are proposed to predict the settlement and associated excess pore pressure.

## 2 GENERAL DESCRIPTION OF EMBANKMENT CHARACTERISTICS AND SITE CONDITIONS

At the Port of Brisbane, to evaluate the performance of the vacuum consolidation system with the non-vacuum system (PVD and surcharge load), a trial area (S3A) shown in Fig. 1 was partitioned into WD1-WD5 (Non-vacuum areas) and VC1-VC2 (Vacuum areas). After placing the dredged fill, the mud was capped off with a 2-3m layer of dredged sand, which acted as a working platform for PVD installation machine, whilst serving as a drainage layer.

The upper Holocene sand beneath the reclaimed dredged mud was about 2m thick, followed by the Holocene clay layer with different in thickness from 6m to 25m. A Pleistocene deposit containing highly over-consolidated clay underlies the softer Holocene clay layer. Site investigation techniques including cone penetration/piezcone tests, dissipation tests, boreholes, field vane shear tests and oedometer tests were carried out to assess the relevant consolidation and stability design parameters. The water contents of the soil layers were similar to or exceed their liquid limits. The vane tests show that the undrained shear strength of the reclaimed dredged mud and

the Holocene clays were from 5 to 60 kPa. The compression index changed from 0.1 to 1.0. The coefficient of consolidation in vertical direction is similar to that in horizontal direction ( $c_h$ ) for the remoulded dredged mud layer, while  $c_v/c_h$  is about 2 for the Holocene clay layer.

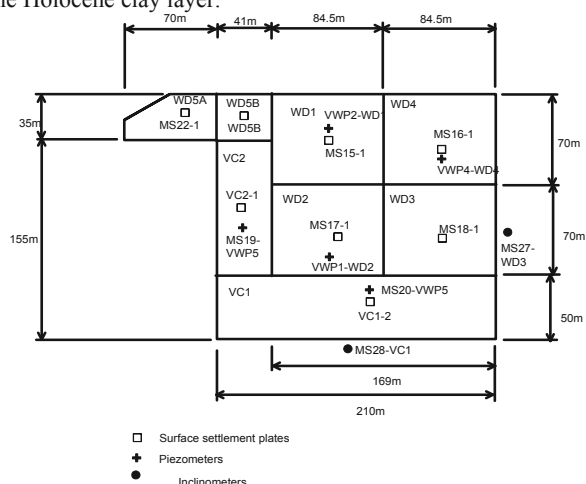

Figure 1. Site layout for S3A with instrumentation plan

The surcharge preloading system was adopted for the inner areas (WD1-WD5) while, in the outer area (VC1 and VC2) close to the Marine Park, the technique of vacuum combined preloading was selected to control lateral displacement in order to minimise disturbance of the nearby marine habitats. Stringent design criteria were adopted for the design and construction of embankment over the soft Holocene deposits: (a) Service load of 15-25 kPa, (b) maximum residual settlement less than 250 mm over 20 years after treatment. The surcharge embankment heights varied from 3.0m to 9.0m. Based on the design criteria, Table 1 presents the PVD characteristics and treatment types applied to each section. In the non-vacuum areas, both circular and band shape drains were established in a square pattern at a spacing in the range of 1.1-1.3m. The length of PVDs changed from 6m to 27.5m across the site as shown in the Table 1. Table 1. PVD characteristics and improvement scheme

	Drain type	Drain spacing	Fill height (m)	Treatment scheme
WD1	Circular drains	1.1	5.2	Surcharge
WD2	Circular drains	1.3	7-7.2	Surcharge
WD3	Band drain Type -A	1.1	4.3-4.6	Surcharge
WD4	Band drains Type -A	1.3	6.1	Surcharge
WD5A	Band drains Type -B	1.2	3.3	Surcharge
WD5B	Band drains Type -B	1.1	5.5	Surcharge
VC1	Circular drains	1.2	3.2	Surcharge+ vacuum
VC2	Circular drains	1.2	2.8	Surcharge+ vacuum

The inevitable variation in drain lengths was attributed to the non-uniform clay thickness. Wick drains (Band Drain Type-A and Band Drain Type-B) had dimensions of 100mm x 4mm, and the circular drains had an internal diameter of 34mm. The Authors have deliberately omitted the commercial brand names of all PVDs used. To monitor the ground behaviour, comprehensive instruments were installed e.g. settlement plates, vibrating wire piezometers, magnetic extensometers, and inclinometers. In the vacuum area, only circular drains were employed at a spacing of 1.2m in conjunction with a High Density Polyethylene (HDP) membrane, horizontal perforated

pipes and the pumps that represent the vacuum system. The horizontally pipes offered the desired uniform distribution of suction beneath the membrane. The measured suction varied from 60 kPa to 75 kPa, and no air leaks were observed during vacuum application that ensured the intact seal provided by the membrane. A vacuum pressure of 70kPa was applied after 40 days.

### 3 INTERPRETATION OF FIELD RESULTS

The embankment performances including settlements and excess pore pressures together with the staged construction of the embankments are depicted in Fig. 2. It would be observed that the trends are very comparable where the settlement occurred more quickly at the early stage of consolidation. The amount of final settlement depends on the clay thickness and embankment height. The highest settlement was measured in the WD4 area having the greatest clay thickness (19-26m), whereas the lowest settlement was in the WD5A area in which the clay layer was relatively thin (8-12m).

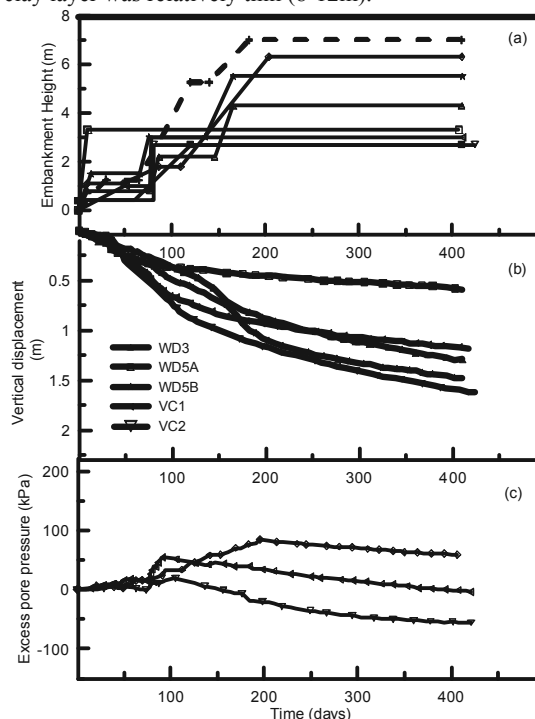

Figure 2. Embankment responses (a) staged construction, (b) settlements and (c) excess pore pressures

The measured lateral displacement normalized to total change in applied stress (vacuum plus surcharge load) for two inclinometer locations is shown in Fig. 3. For WD3 area, the total surcharge height was 90 kPa, whereas for VC1 area the reduced surcharge pressure of 40 kPa was complemented with a vacuum pressure of 65 kPa. The lateral displacements clearly lessen in the Holocene sand due to its greater stiffness. Fig. 3 indicates that the lateral movements are effectively controlled to minimise the disturbance in the adjacent Moreton Bay Marine Park, due to the isotropic consolidation by vacuum pressure.

### 4 SETTLEMENT AND EXCESS PORE PRESSURE PREDICTIONS

In order to analyse the radial consolidation caused by vertical drains, the unit cell theory has been employed to predict the settlement and excess pore pressure. A unit cell theory was introduced by Barron (1948) and Richart (1957) for surcharge preloading alone. Lekha et al. (1998) further extended the radial consolidation by including time-dependent surcharge loading. Indraratna et al. (2005) introduced the unit cell analysis for vacuum preloading under instantaneous loading while Geng et al. (2012) proposed analytical solutions under time-dependent

surcharge preloading. During embankment construction, the surcharge fill is increased at a prescribed rate to reach the desired height. Therefore, the time-dependent loading due to the filling would be more realistic than an instantaneous loading, especially during the stages of embankment construction. In this section, the embankment load is assumed to be a ramp loading: i.e., the embankment load ( $\sigma_t$ ) increases linearly with time up to a maximum value ( $\sigma_1$ ) within time  $t_0$  and is constant thereafter (Fig. 4a). The vacuum is applied at  $t=t_{vac}$ . Figure 4b shows the unit cell adopted for analytical solutions with boundary conditions (Fig. 4c).

Figure 3. Comparison of lateral displacements at the embankment toe in vacuum and non-vacuum area after 400 days (Indraratna et al. 2011)

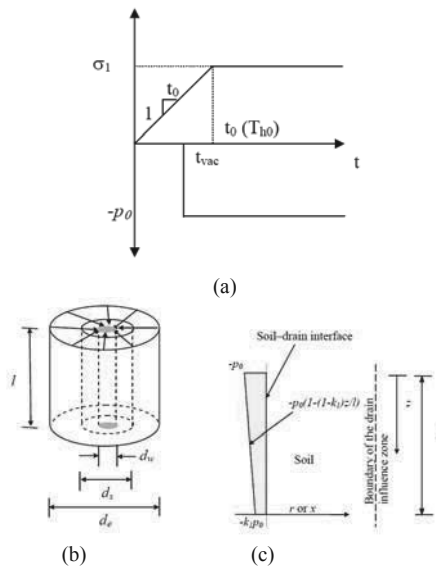

Figure 4. (a) time-dependent surcharge loading, (b) unit cell including smear zone, and (c) boundary conditions with vacuum distribution (after Indraratna et al. 2011)

The excess pore pressure due to radial consolidation considering smear effect under time-dependent surcharge can be expressed by (Indraratna et al. 2011):

$$\bar{u}_L = \frac{\mu d_e^2}{8c_h t_0} \left( 1 - \exp\left(\frac{-8c_h t}{\mu d_e^2}\right) \right) \sigma_1 \quad \text{for} \quad 0 \leq t \leq t_0 \quad (1)$$

$$\bar{u}_L = \frac{\mu d_e^2}{8c_h t_0} \left( 1 - \exp\left(\frac{-8c_h t_0}{\mu d_e^2}\right) \exp\left(\frac{-8c_h (t - t_0)}{\mu d_e^2}\right) \right) \sigma_1 \quad \text{for} \quad t > t_0 \quad (2)$$

Recently, Indraratna et al. (2005) proposed that the excess pore pressure dissipation due to vacuum pressure alone could be determined from:

$$u_{vac} = 0, \quad t < t_{vac} \quad (3)$$

$$u_{vac} = p_0 \exp\left(\frac{-8c_h (t - t_{vac})}{\mu d_e^2}\right) - p_0, \quad t \geq t_{vac} \quad (4)$$

$$\mu = \left[ \ln\left(\frac{n}{s}\right) + \frac{k_h}{k_s} \ln(s) - \frac{3}{4} + \pi \frac{2k_h}{3q_w} l^2 \right] \quad (5)$$

$$n = d_e / d_w \quad (6)$$

$$s = d_s / d_w \quad (7)$$

where,  $d_e$  = the diameter of soil cylinder dewatered by a drain,  $d_s$  = the diameter of the smear zone,  $d_w$  = the equivalent diameter of the drain,  $k_s$  = horizontal soil permeability in the smear zone and  $q_w$  = drain discharge capacity.

The excess pore pressure at a given time  $t$  can be calculated based on the Equations (2) to (7). For normally consolidated clay, the settlement ( $\rho$ ) can now be determined by the following equation:

$$\rho = \frac{HC_c}{1 + e_0} \log\left(\frac{\sigma'}{\sigma'_i}\right) \quad (8)$$

where,  $\rho$  = settlement at a given time,  $C_c$  = compression index, and  $H$  = compressible soil thickness.

In order to calculate excess pore pressures and associated settlements, Equations (1)-(8) are employed using parameters in Table 2. For the completely remoulded dredged mud that was reclaimed from the seabed and the Upper Holocene Sand the ratio  $k_h/k_s$  was assumed to be unity. For the upper and lower Holocene clay, the ratios of  $k_h/k_s$  and  $d_s/d_w$  were 2 and 3, respectively, in accordance with the laboratory observation described by Indraratna and Redana (1998).

The embankment load was applied according to a staged construction (unit weight of  $20 \text{ kN/m}^3$ ). Settlement and associated excess pore pressure predictions were calculated at the embankment centreline using Eqs. 1-8. It is noted that, at the beginning of each subsequent stage, the initial in-situ effective stress was calculated based on the final degree of consolidation of the previous stage. In vacuum areas, a suction pressure of 65 kPa was employed.

Figures 5 and 6 present the predicted settlement and associated excess pore pressure with the measured data in Areas WD1 and VC1, where the total applied load (vacuum and surcharge = 120-130kPa) and clay thickness (20-23m) are comparable. Overall, the comparisons between prediction and field observation show that the settlement and associated pore water pressure can be predicted very well. In vacuum areas, the degree of consolidation was more than 90% after 13 months, whereas that in the non-vacuum area was less than 85%. This confirms that, at a given time, the vacuum combined preloading would speed up consolidation compared to a surcharge preloading alone. This is because in non-vacuum areas, a staged embankment construction had to be adopted to avoid any undrained failure in the remoulded dredged layer.

Table 2. Soil properties for each layer

Soil layer	Soil type	$C_c/(1+e_0)$	$c_h$ (m <sup>2</sup> /yr)	$k_h/k_s$	$s=d_s/d_w$
1	Dredged Mud	0.235	1	1	1
2	Upper Holocene Sand	0.01	5	1	1
3	Upper Holocene Clay	0.18	2	2	3
4	Lower Holocene Clay	0.2	1.9	2	3

5 CONCLUSIONS

A system of vertical drains with vacuum preloading is an effective method for speeding up soil consolidation. The performance of 2 treatment schemes at the Port of Brisbane was

analysed and discussed. The dredged materials from the seabed were placed in the reclaimed area. A total of 8 areas were selected to examine the performance of vacuum consolidation, and the vertical drain spacing varied from 1-1.3m for 3 different drain types. The vacuum application induces an inward lateral movement, whereas the conventional surcharge fill creates outward movement. When the vacuum pressure combined with surcharge fill is employed, the overall lateral movement is decreased due to the isotropic consolidation induced by vacuum pressure. From a stability point of view, vacuum pressure reduces the ratio of lateral displacement to surcharge fill height at any given time.

The unit cell theory considering time-dependent surcharge load and vacuum application was employed to predict the settlement and associated excess pore pressure, which provided a good agreement with the field measurements. After 1 year, the degree of consolidation in the vacuum areas was much higher than the non-vacuum areas for the same total stress.

# Improvement of a Clay Deposit using Prefabricated Vertical Drains and Pre-loading. A Case Study

Amélioration d'un massif d'argile à l'aide de drains verticaux préfabriqués et de pré-chargement. Une étude de cas

Islam M.S., Yasin S.J.M.

Bangladesh University of Engineering and Technology, Dhaka, Bangladesh

**ABSTRACT:** Construction of a Container Terminal covering an area of 153,000 m<sup>2</sup> is underway at Chittagong sea port in Bangladesh, situated on the right bank of the Karnaphuli river at its confluence with the Bay of Bengal. The sub-soil at the site consisted of a 4 to 6 m thick clay layer with random zones of soft to stiff clay (CL). This was underlain by a 10 m thick loose to medium dense silt/fine sand (SM) layer below which a loose clayey silt layer existed beyond 30 m depth. The unconfined compressive strength, void ratio and compression index of the soft clay zones varied in the ranges of 12~16 kPa, 0.8~1.2 and 0.2~0.3, respectively. The targeted use of the land required improvement of the sub-soil. This paper presents the design considerations, comparison of required time and cost of alternative options, effectiveness of the adopted measure and the achieved improvement of the engineering properties. Actual consolidation settlements were up to 600 mm over a period of about 30 days with PVD and pre-load. The effectiveness of the available theories of consolidation settlement under vertical and radial drainage, in the design of the ground improvement measures, has been demonstrated.

**RÉSUMÉ :** La construction d'un terminal à conteneurs d'une superficie de 153.000 m<sup>2</sup> est en cours en ville portuaire de Chittagong au Bangladesh, située sur la rive droite de la rivière Karnaphuli à sa confluence avec le golfe du Bengale. Le sous-sol sur le site se composait d'une couche de 4 à 6 m d'épaisseur d'argile avec des zones aléatoires d'argile molle à raide (CL). Cela a été superposée à une épaisseur de 10 m limon / sable fin (SM) lâche à dense, une couche en dessous de laquelle une couche limon argileux lâche existait au-delà de 30 m de profondeur. La résistance à la compression, l'indice des vides et l'indice de compression des zones d'argile molle varient dans les plages de 12 à 16 kPa, 0.8 ~ 1.2 ~ 0.3 et 0.2, respectivement. L'utilisation obligatoire de ces terres requiert l'amélioration du sous-sol. Cet article présente la conception, la comparaison du temps nécessaire et le coût des options alternatives, l'efficacité de la mesure adoptée et de l'amélioration obtenue des propriétés mécaniques. Les tassements de consolidation réels ont été de 600 mm sur une période d'environ 30 jours avec PVD et pré-chargement. Dans la conception de l'amélioration des sols, l'efficacité des théories existantes de tassement de consolidation en vertu de drainage vertical et radial a été démontré.

## 1 INTRODUCTION

Chittagong sea port, the largest sea port of Bangladesh is situated on the right bank of the Karnaphuli river at its confluence with the Bay of Bengal. The port, that once handled mostly bulk cargo is gradually shifting its operational mode to handle increasing volume of container traffic. In this regard, Chittagong Port Authority (CPA) is implementing a project for construction of backup facilities at New Mooring behind berths 4 and 5. The site is locally known as 'NCT' (New-Mooring Container Terminal). The project area is about 153,000 m<sup>2</sup> which is planned to accommodate stacking yard for containers, passage for truck and trailer movement, tracks for Gantry Crane, electrical substation etc.

A comprehensive geotechnical investigation was carried out at the site to assess the sub-soil condition, decide on the necessity of improvement and determine relevant design parameters for the envisaged improvement methodology. The soil profile in the project area, consisted of a 4 to 6 m thick soft to medium stiff clay layer, underlain by a 10 m thick loose to medium dense silt/fine sand layer below which a loose clayey silt layer existed to more than 30 m depth.

To keep conformity with the earlier constructed adjacent yard, it is considered that the area will be paved with interlocking block (ILB) except the RMG (Rail Mounted Gantry) and RTG (Rubber Tyred Gantry) tracks which will be pile founded. On the basis of design requirements and geotechnical characteristics, improvement of the upper soft clay layer was considered essential to eliminate the possibility of differential settlement within the yard as well as between pile founded structures (i.e. jetty and RMG, RTG tracks) and yard.

From an study of several alternatives, Prefabricated Vertical Drain (PVD) with pre-loading was adopted as the ground improvement measure for the site. Improvement measures have been completed on a part of the project area. The settlement under preloading with PVD has been monitored using settlement plates. Field and laboratory tests have also been conducted to evaluate the effectiveness of the adopted measures in terms of change of soil properties. This paper presents the geotechnical characteristics of the sub-soil in the area, the design considerations and a comparison of cost of several alternative improvement methods. From the limited data, that has so far been available, comparison of some engineering properties before and after preloading has also been made.

## 2 SITE LOCATION AND TOPOGRAPHY

The site for the container yard is in a tidal plain at a narrow strip between Chittagong hilly uplands and the Bay of Bengal. Geologically it is a recent alluvium formed by the material carried by the river Karnaphuli and its tributaries from the upper tertiary hills. Figure 1 shows the site map with grid lines. About half of the land, the eastern side (segments marked 1, 2, 3 and 4) had been used as jetty yard for more than 50 years and housed storage sheds for general cargo, road and railway tracks. The other half (western part, segments marked 1A, 2A, 3A and 4A) contained a city road, a residential area of CPA containing one/two storey building, ponds, play ground, open land, village dwellings etc. Different parts of this western side had different elevations with 1~3 m ditches. Because of earlier diverse use of the land, there was little possibility of homogeneity of the upper soil layer in the area.

### 3 SUB-SOIL CHARACTERISTICS

A total of 67 exploratory boreholes were drilled in the area to gather information about sub-soil type and characteristics. The borehole locations were carefully decided to make them distributed over the entire area as well as to cover zones of different land use (i.e. pond, road, houses etc.). The borehole that are referred here are marked by grid points as shown in Figure 1. The boreholes, approximately 100 mm in diameter, were drilled using water flush aided by chiselling. Twelve boreholes were of 30.5 m depth and the rest were of 15.0 m depth below the existing ground level. Standard Penetration Tests (SPT) were made at 1.5 m interval. Undisturbed samples were retrieved from cohesive layers by pushing conventional 76 mm external diameter thin-walled Shelby tubes. Disturbed samples were also collected from the SPT spoon (conventional split spoon) from cohesive and cohesionless soil layers at different depths for visual-manual identification of the layers as well as for laboratory testing.

Figure 1 Site map showing grids and loading blocks.

In general, the sub-soil at the site is found to consist of a layer of 'soft to medium stiff silty clay' extending from the ground surface to about 4 to 6 m depth. This layer is underlain by a 10 m thick 'loose to medium dense fine sand/silt' layer. A 'clayey silt' layer is encountered below the fine sand/silt layer which extend beyond the maximum depth of investigation (i.e., about 30 m from surface). Thus, up to a depth of 30 m the sub-soil at the site is idealized to have three distinct layers (top silty clay layer, intermediate fine sand/silt layer and bottom clayey silt layer). In a small number of boreholes medium dense sand was encountered near the ground surface instead of the clay layer, which was probably a fill during past use of the land. Figure 2 presents the field SPT-N values at different depths for the explored borehole locations and the stratigraphy.

silt', the field SPT-N values ranged between 5 and 27 except in one borehole where a 'sandy silt' layer existed.

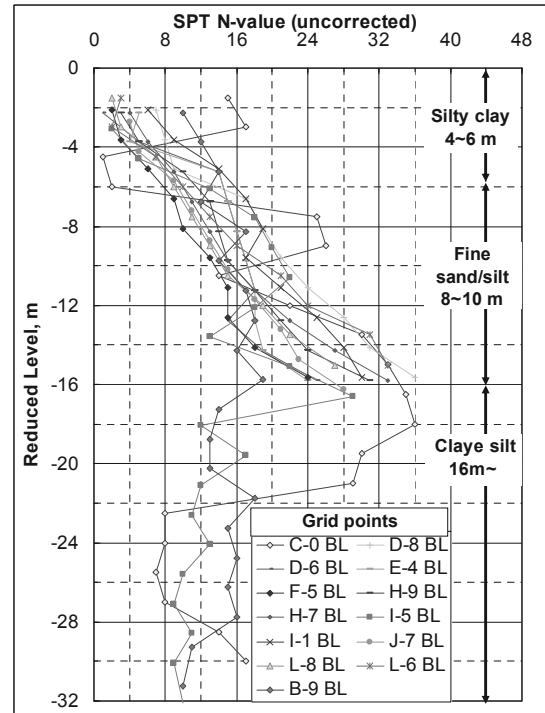

Figure 2 General ground profile and variation of SPT with depth.

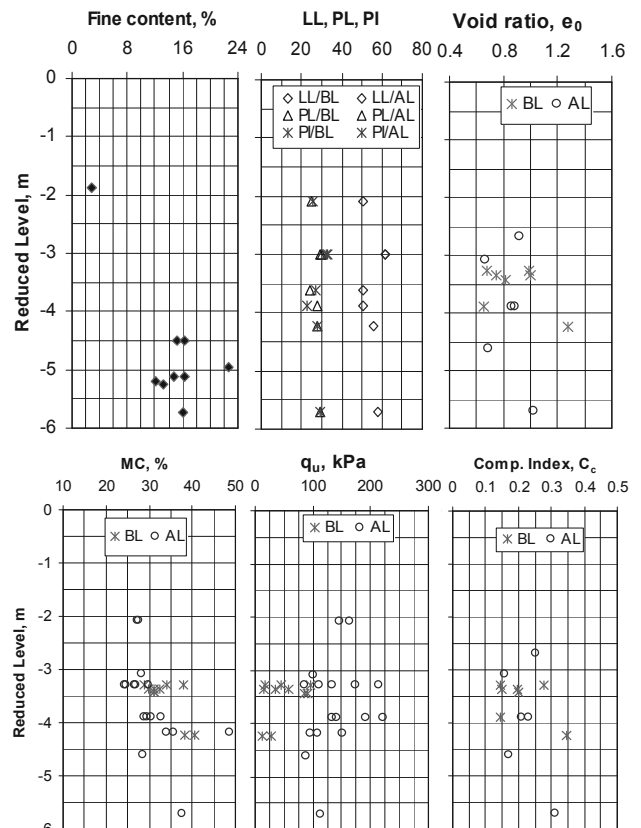

Figure 3 Variation of index, strength and deformation properties of the upper clay deposit with RL (BL=Before loading, AL=After loading).

Extensive laboratory tests have been conducted on samples of top silty clay layer (BRTC, BUET Report, 2009) and some of the results are presented in Figure 3. The layer may be

characterized as having  $LL=50\sim60$ ,  $PL=20\sim30$ ,  $PI=20\sim30$ ,  $NMC=20\sim35\%$ . According to Unified Soil Classification System (USCS), the soil in this layer is mostly plastic-silty clay of low plasticity (CL), though a few samples were found to be clay of high plasticity (CH). On the USCS chart, the data points lie just above A-line. The dry unit weight varied in the range of  $13\sim15 \text{ kN/m}^3$  and the range of void ratio was  $0.80\sim1.20$ . The variation of these properties can be seen from Figure 3. The layer also has some organic content is about  $1.4\sim4.0\%$ . The values of the coefficient of consolidation in the vertical direction,  $C_v$  were mostly within  $3.1$  to  $25.2 \text{ m}^2/\text{year}$  and at some location as low as  $0.79 \text{ m}^2/\text{year}$ .

#### 4 DESIGN OF GROUND IMPROVEMENT METHOD

It was decided by CPA, that the project will be carried out by local contractors. Therefore, capacity, experience, equipments etc. of local contractors were to be considered in the design of the yard. Furthermore, ground improvement was to be completed for the entire project site within one year. Hence, the area was divided into four blocks and time for improvement for each block was 3 months. An area adjacent to the north boundary of the site was earlier developed for similar purpose, by a foreign contractor, where dynamic temping was used for ground improvement and interlocking block pavement was made. To keep similarity with the earlier part, interlocking block pavement was decided for this yard too.

The presence of very soft to medium stiff silty clay at various locations within the site indicated strong possibility of substantial total and differential settlement unless effective measures for improvement of sub-soil are undertaken before the construction of pavement for the Container Yard. Therefore, effective measures for improvement of sub-soil before the construction of pavement were considered essential in order to avoid/minimize future problems.

The necessity and extent of the ground improvement measures are judged with an objective to reduce the differential settlement and maintenance operations considering the maximum load from stacking of containers on the entire area (i.e.  $p=52 \text{ kN/m}^2$ ). It should be understood that a solution, for which there will be no future settlement, will lead to high cost and time for completion and thus may not be practical. The load on the RTG tracks from the gantry is estimated to be  $77.5 \text{ kN/m}^2$ . The extent of improvement and design of pavement system at the site is targeted to keep maintenance option with minimal disruption. For RTG and RMG tracks and other facilities, suitable deep/shallow foundations will be considered so that they do not undergo relative settlement with respect to jetty top.

Five alternatives, that appeared to be feasible for local contractors, were assessed. These are- (i) preloading (ii) sand drain with surcharge (iii) PVD with surcharge and (iv) dynamic

Figure 4 Details of the ground improvement work. temping and (v) soft pocket identification, removal and

compacted backfilling. Table 1 presents the comparison of cost and completion time for different methods. Both time and cost depends to some extent on the number of equipments mobilized and source of material, particularly the surcharge (max. 5 m of soil considered). Considering the capacity of local contractors minimal engagement of equipments and dredge sand from the Karnaphuli river were considered. Though dynamic temping/compaction appeared to be very prospective in terms of time and cost, it posed the risk of damaging the adjacent yard and structures. Finally, PVD with surcharge was adopted as the ground improvement measures, mainly because of reduced time in PVD driving compared to sand drain installation, though PVD is an imported material. Also this method was considered advantageous over other methods in bringing the clay layer to a state where differential settlement potential will be reduced as it will automatically take care of soft zones and bring the soft and stiff zones to closer soil properties in terms of deformation and strength.

Since, from  $e\text{-log}(p)$  curves, most of the samples of the upper clay layer was found to be normally consolidated, the total consolidation settlement under the working loads ( $52 \text{ kPa}$ ) without improvement was calculated using  $S_c = \sum \Delta e \cdot H$ ,  $\Delta e = C_c / (1 + e_0) \log(\Delta p + p'_0) / p'_0$  and  $p'_0 = \sum \gamma H$  where,  $e_0$  = initial void ratio,  $p'_0$  = effective past maximum overburden pressure,  $\gamma$  = effective unit weight of soil,  $H$  = thickness of the compressible layer. The estimated settlement for different borehole locations varied from about  $140 \text{ mm}$  to  $570 \text{ mm}$ . This variation is due to difference in  $e_0$ ,  $C_c$  and layer thickness. In these estimations,  $\Delta p$  is calculated as  $\Delta p = \sigma_0 [1 - \{1 + (r/z)^2\}^{-1.5}]$  where  $\sigma_0$  = Intensity of stress applied on the surface,  $r$  = radius of the loaded area,  $\Delta p$  = increase in stress at depth  $z$  from the centre of the loaded area. This expression for  $\Delta p$  is obtained by integration of Boussinesque's equation that gives the stress at a point within a semi-infinite, homogeneous, isotropic, weightless, elastic half-space for a point load on the surface (Bowels, 1988). Estimated time to achieve this consolidation ( $U_{av} \approx 99\%$ ) varied from about 50 days to more than 700 days for different borehole locations. The time was determined using Terzaghi's one dimensional consolidation theory with double drainage and constant initial pore pressure distribution using the equations (Das, 1983):

$$U_{av} = 1 - \sum_{m=0}^{\infty} \frac{2}{M^2} e^{-M^2 T_v}, \quad T_v = \frac{C_v t}{H^2} \quad \text{and} \quad M = \frac{\pi}{2}(2m+1)$$

It was intended to apply a surcharge with PVD such that a maximum of  $25 \text{ mm}$  of total settlement remains to occur in future under the working loads expecting a differential settlement of not more than  $12 \text{ mm}$ . Estimation of required time to achieve this level of consolidation was made considering both vertical and radial drainage (Carillo, 1942) as  $U = 1 - (1 - U_v)(1 - U_r)$  where  $U_v$  and  $U_r$  are the average degree of consolidation respectively for vertical and radial drainage. The average degree of consolidation for radial drainage was calculated using the following as

$$U_r = 1 - e^{-\frac{8T_r}{m}} \quad \text{where} \quad T_r = \frac{C_{vr} t}{d_e^2}$$

$$m = \frac{n^2}{n^2 - S^2} \ln\left(\frac{n}{S}\right) - \frac{3}{4} + \frac{S^2}{4n^2} + \frac{k_h}{k_s} \left(\frac{n^2 - S^2}{n^2}\right) \ln(S)$$

$$n = \frac{d_e}{d_w} \quad \text{and} \quad S = \frac{d_s}{d_w}$$

The equivalent diameter of PVD was calculated following Hansbo (1979) as

$$d_w = \frac{2(b+t)}{\pi}$$

where,  $b$  is the width and  $t$  is the thickness of PVD. Considering smear effect  $S$  was chosen between  $1.0$  and  $1.2$ . The effective diameter of soil column around the PVD was taken as  $d_e = 1.06s$ ,  $s$  = PVD spacing in triangular pattern.

For all the calculations horizontal permeability is taken as

the same as the vertical permeability. From the calculations it appeared that for 5 m surcharge and PVD the target settlement would occur within 10 to 50 days in different locations.

Table 1 Comparison of estimated cost and completion time for different ground improvement methods.

Method	Time (month)	Cost (million USD)	Comments
Preloading	36	1.96	Reliable Better assessment of improvement Long time required for improvement
Sand drain with surcharge	20	3.29	Relatively less reliable Installation of drains takes long time
PVD with surcharge	14	3.24	Reliable Good control of field operation Vibration may damage adjacent facilities
Dynamic compaction	11	2.04	High noise pollution Assessment of improvement needs lot of field tests
Soft pocket identification, removal and improvement, compacted backfilling	12	7.25	Relatively less reliable Assessment of improvement is difficult Highly dependent on field monitoring and control

The PVD used were of 100 mm width, 3 mm thick placed 1m c/c in triangular pattern. Other properties - Drain: Water discharge capacity  $90 \times 10^{-6}$  m<sup>3</sup>/s, and  $60 \times 10^{-6}$  m<sup>3</sup>/s respectively at 10 and 350 kPa ( $i=0.5$ ); Core: Tensile strength 700 N; Filter jacket: Apparent Opening size (AOS) 90  $\mu$ m, Grab tensile strength 400 N, Elongation at break 50%, Puncture resistance 130 N, Burst strength 800 kN/m<sup>2</sup>, Permeability  $2 \times 10^{-4}$  m/s. Details of the ground improvement work is shown in Figure 4.

5 ASSESSMENT OF GROUND IMPROVEMENT

Monitoring of settlement has been made using settlement plates placed at 25 m grid as shown in Figure 1. After preloading exploratory boreholes were made at selected locations with field SPT and laboratory tests were conducted on collected undisturbed samples.

Figure 5. Variation of SPT-N value before and after loading.

Figure 5. compares the Field SPT-N values at several spots before and after preloading. It can be observed that in the upper silty clay layer the SPT-N values has become twice or more up to about 3m depth. At about 4~5m, which is the boundary between the clay and sand/silt layer the SPT-N values have not

changed. The field SPT-N values are found to increase significantly in the 'fine sand/silt' layer up to about 12 m.

Figure 6 Comparison of (a) unconfined compressive strength and (b) observed and estimated settlement .

The unconfined compressive strength of the upper clay layer before and after preloading can be seen on Figure 6(a) for different locations and depths. In general the unconfined compression strength has increased at most of the spots. However, the magnitude of increase is not same. A few data points lie below the 45 degree line, that apparently shows to have reduction in strength but quite unlikely. The reason for these discrepancies may be the variation of non-plastic silt content in the layer.

In Figure 6(b) the recorded settlements are plotted against the estimated settlement for some of the grid points. Out of the six locations (for which estimates were made) four appear to match reasonably well. For one location the observed settlement is about five times the estimated value, which may be due to presence of localized sand lenses. On the other hand for another location the observed settlement is one-fifth of the estimated value, which may be due to clogging or disturbance of the clay during drain installation. Conclusive comments regarding the variation may be made when data from the remaining project work become available.

6 CONCLUSIONS

The following conclusions can be made based on the design and field monitoring of the ground improvement work:

- 1) Due to the application of the surcharge with PVD the consolidation settlement could be achieved within the stipulated time.
- 2) Both the SPT-N value and unconfined compressive strength were found to increase satisfactorily due to application of preload with PVD.
- 3) The available theories of 1-D consolidation and combined vertical and radial consolidation used in the design of ground improvement for the project site using PVD and preload appeared to have been fairly applicable. Predicted and observed settlement matched reasonably.

7 ACKNOWLEDGEMENTS

This research work was carried out in connection with the consultancy services provided to CPA through BRTC, BUET. The authors would like to express their sincere thanks to CPA and Contractor's personnel involved in the project.

# Importance et applications des inclusions de grande inertie

## Importance and practical examples of inertial soil improvement

Jeanty J.M., Mathieu F., Benhamou L.  
*Soletanche-Bachy, RUEIL-MALMAISON, France.*

Berthelot P.  
*Bureau Veritas, Paris, France.*

**RÉSUMÉ :** Les techniques traditionnelles d'amélioration des sols par inclusions visent le plus souvent à renforcer l'aptitude du massif à reprendre les charges verticales auxquelles il est soumis, moyennant des déformations acceptables par les ouvrages. Elles peuvent également avoir pour objectif d'améliorer la résistance aux efforts horizontaux, et plus généralement aux sollicitations à dominante déviatorique, dans le cadre de problématiques liées aux séismes (traitements anti-liquéfaction), à la stabilité générale (remblais sur sols compressibles), à la réduction des poussées sur des ouvrages de soutènement, au poinçonnement du sol sous de fortes surcharges (effets de bord), ... La réalisation d'inclusions à forte inertie, sous forme de tranchées parallèles ou de réseaux de tranchées, est une réponse particulièrement bien adaptée à ces problématiques d'amélioration des sols. Une manière élégante de construire ces inclusions sans perturber les structures existantes consiste à traiter le sol en place en y incorporant un liant hydraulique, par application des techniques de soil mixing les plus récentes. Après une présentation de ces méthodes, la communication proposée met en évidence le rôle fondamental joué par l'inertie des inclusions, par des considérations fonctionnelles et par divers exemples d'application.

**ABSTRACT:** Conventional soil reinforcement techniques as rigid inclusions mainly report vertical loadings to the substratum layer with an induced settlement. They can also improve soil resistance regarding lateral forces as those related to earthquakes (liquefaction hazard), or slope stability for embankments on soft soil foundation. They can reduce active pressure on retaining walls. The appropriate design answer to those issues is to create strong inertia inclusions based on a trench geometry with either a parallel or a crossed frame arrangement. Last but not least, an even better technique to build those inclusions with a reduced environment impact consists in treating in situ soil by adding cement. This article presents different soil mixing projects and explains how strong inertia trenches are relevant.

**MOTS-CLÉS:** amélioration de sols, sol-mixing, sol-ciment, inclusions rigides, inertie, liquéfaction, soutènement, poussée des terres, tassement, tranchées de sol-mixing.

**KEYWORDS :** soil reinforcement, soil mixing, rigid inclusions, slope stability, retaining wall, liquefaction, seismic, active pressure, Bouassida approach, settlement, soil mixing caissons, soil mixing trench, crosswalls.

### 1 INTRODUCTION

Le soil mixing profond est une technique développée dans les années 1970 en Europe du Nord et au Japon, initialement pour résoudre des problématiques liées au comportement des sols compressibles. Cette technique consiste à améliorer les caractéristiques d'un sol en le mélangeant en place avec un liant hydraulique.

La déstructuration des terrains et l'incorporation du liant s'effectue par des moyens mécaniques, en utilisant un outil dont la géométrie et le mouvement dans le terrain définissent les dimensions des éléments de sol traité.

La mise en œuvre de cette technique a longtemps fait appel à l'utilisation d'outillages simples ou multiples, rotatifs à axe vertical, munis de pales latérales de géométries très variées. Des outils de type tarière simple ou tarières multiples avec inversion des sens de rotation entre forage descendant et malaxage / compactage en remontant sont aussi utilisés. Des colonnes réalisées par jet-grouting peuvent aussi être apparentées au sol-mixing.

Plus récemment, durant la dernière décennie, de nouveaux procédés de soil mixing avec des outils à axe horizontal ont fait leur apparition : haveuses et trancheuses. Ces procédés ont permis de repousser les limites du soil mixing en élargissant la méthode au traitement d'une plus large gamme de sols et présentant des atouts en termes de caractéristiques et d'homogénéité.

Le soil mixing se distingue depuis l'origine des autres procédés d'améliorations des sols en ce sens qu'il permet de réaliser, à l'extrême, des réseaux d'inclusions isolées (pour l'exécution desquelles des outillages de type tarière peuvent être suffisants) ou des traitements dans la masse (utilisation d'outillages de type multitarière ou haveuse pour réaliser des "pavés" de sol traité), mais c'est dans la réalisation d'éléments linéaires de grande inertie, de type refend ou écran continu (susceptible à la fois de jouer un rôle porteur et d'assurer une fonction soutènement moyennant l'incorporation d'armatures métalliques), voire de réseaux orthogonaux, permettant de confiner le sol en place, que le soil mixing trouve sa véritable originalité et ses développements les plus prometteurs.

Généralement apparenté aux réseaux d'inclusions plutôt qu'aux traitements dans la masse, il s'en distingue pourtant de façon fondamentale, non seulement par les aspects géométriques précédemment évoqués, mais encore par ses propriétés mécaniques. Cela ne permet de le classer ni dans la catégorie des inclusions souples (colonnes ballastées, dont la résistance en compression est nulle en l'absence d'étreinte latérale de la part du sol avoisinant), ni dans la catégorie des inclusions rigides, dont la résistance en compression, qu'il s'agisse de métal, de béton ou de mortier, est au contraire indépendante de l'étreinte exercée par le sol et pour lesquelles la résistance en compression simple est par conséquent le paramètre déterminant pour le dimensionnement.

Au contraire, les propriétés du soil mixing sont bel et bien celles d'un sol amélioré, même s'il ne s'agit généralement pas d'un

traitement uniforme de l'ensemble du massif de fondation, dont le critère de rupture n'est autre que le critère de Coulomb, qui lui permet de bénéficier à la fois :

- .d'une résistance intrinsèque indépendante de l'étreinte (terme de cohésion) ;
- .d'une augmentation de résistance avec la profondeur en fonction de l'étreinte latérale du sol (terme de frottement).

En termes de déformations, ses propriétés sont également intermédiaires entre celles généralement attribuées aux inclusions rigides et souples ce qui conduit naturellement à le ranger dans la catégorie inédite des "inclusions semi-rigides".

Le tableau qui suit résume les ordres de grandeurs usuels de la résistance à la compression  $F_c$  et du module de déformation  $E_y$ .

Renforcement	Inclusion rigide	Inclusion semi-rigide	Inclusion souple
$F_c$ (MPa)	5 à 500	0.5 à 5	0
$E_y$ (GPa)	3 à 200	0.2 à 3	0.04 à 0.08

### 1.1 Mélange par haveuse

Le procédé met en œuvre un outillage appelé « Cutter Soil Mixing » (CSM), dérivé de la technologie utilisées sur des machines de type haveuse ou hydrofraise. Deux tambours spécialement conçus pour cette application et entraînés en rotation par des moteurs hydrauliques de fort couple, sont utilisés pour déstructurer et mélanger le sol en place. Une buse d'injection située entre ces moteurs permet l'incorporation d'un fluide. Le mélange ainsi réalisé est ensuite déplacé soit au dessus des tambours dans le sens descente ; soit au dessous dans le sens remontée.

Les inclusions construites avec cet outillage jusqu'à des profondeurs de quelques dizaines de mètres, sont de section rectangulaire (longueur courante 2,80 m ; épaisseurs 500 à 1000 mm). Elles peuvent être utilisées unitairement (on parle alors de barrettes) ou disposées de manière contiguës afin de constituer des parois continues (Figure 1).

Certains outillages plus perfectionnés sont munis d'un dispositif de mesure inclinométrique, permettant de mesurer et de corriger en temps réel la position de l'outil lors de la construction d'une inclusion.

Le fluide injecté peut être de différents types : il peut s'agir d'un fluide facilitant le forage, remplacé en phase remontée par un mélange eau-ciment (appelé aussi coulis de ciment). Il est également possible d'injecter directement un coulis pendant le forage, la phase de remontée étant alors utilisée pour parfaire le mélange.

Le type et la quantité de liant utilisée permettent d'atteindre une large gamme de caractéristiques (résistance, perméabilité, cohésion, module de déformation), en fonction de la nature des sols en place.

Pour les outillages les plus perfectionnés, les volumes injectés ainsi que les énergies de malaxage sont contrôlés et ajustés en temps réel grâce à un système informatique embarqué dans la cabine de la machine. Tous les paramètres opératoires sont enregistrés afin d'être restitués sous forme de rapports.

Figure 1 : Principe de construction de parois avec le procédé CSM.

Enfin, divers types d'armatures peuvent être mis en place dans le matériau encore frais, permettant ainsi de réaliser des ouvrages de soutènement provisoire ou à caractère permanent.

### 1.2 Mélange par trancheuse

Les machines de type trancheuse mettent en œuvre une chaîne avec outils de coupe et de malaxage. La chaîne est guidée par une lame travaillant dans un plan vertical dans le sol. L'ensemble de l'outillage présente une certaine similitude visuelle avec une tronçonneuse. L'action de cette lame, combinée à l'incorporation d'un fluide, permet de construire des tranchées de sol traité en place (Figure 2).

Suivant les cas, le liant hydraulique peut être injecté sous la forme d'un coulis ou incorporé au mélange sous forme pulvérulente, auquel cas une adjonction d'eau est généralement réalisée afin de faciliter l'action des outils.

Les tranchées construites de cette manière sont continues, et toutes les couches de sol sont uniformément mélangées. L'épaisseur de l'inclusion est de l'ordre de 0.3 à 0.5 m pour une profondeur maximale d'environ 10 mètres.

De manière analogue au procédé par havage, le procédé par trancheuse s'accompagne d'un dispositif de contrôle-qualité embarqué, permettant le pilotage de la machine, le respect des paramètres de traitement ainsi que les enregistrements nécessaires pour l'émission de rapports.

Figure 2. Principe de construction d'une tranchée.

## 2 DOMAINES D'APPLICATION

Les tranchées de sol traité en place peuvent être parallèles à une seule direction ou constituer une trame selon deux directions en général perpendiculaires. Le premier cas correspond à une problématique avec une direction privilégiée de sollicitation, le second avec deux directions de sollicitation d'égales probabilités.

Différents domaines d'application selon le type de renforcement recherché méritent d'être distingués.

.Domaine 1 : Reprise de charges surfaciques, permettant un traitement plus réparti qu'avec des inclusions rigides (ce qui permet de limiter fortement l'effet de "point dur" qui conditionne sinon le ferrailage du dallage ou du radier sus-jacent et l'épaisseur du matelas de répartition).

A noter que le caractère "2D" du procédé permet en outre de procéder à des calculs plus rigoureux que les approches traditionnelles, utilisant par exemple les coefficients de capacité portante de Bouassida (Bouassida, 2002) (qui permettent de traiter le cas d'une semelle de fondation sur sol renforcé par une tranchée), ainsi que des modèles de calcul numérique en déformation plane pour le calcul du tassement (ce qui ne serait pas acceptable pour un réseau d'inclusions isolées).

Un exemple d'application récent est donné par le chantier de Saint-Roch (06), consistant à renforcer le sol sous un remblai SNCF par un réseau de tranchées longitudinales.

Figure 3. Coupe type SNCF St Roch (06).

.Domaine 2 : Renforcement du sol dans les zones où le champ de contraintes est à dominante déviatorique.

La justification des réseaux d'inclusions repose en général sur des justifications de portance effectuées en partie courante de la surface chargée, là où le risque de rupture du massif de sol est insignifiant dans la mesure où le champ de contraintes est généralement de type plutôt oedométrique. Le plus souvent, aucune justification particulière n'est demandée dans les zones soumises à de fortes contraintes déviatoires mobilisant de façon significative la résistance au cisaillement du sol (périphérie des zones de stockage par exemple), et corrélativement susceptibles de mobiliser les inclusions en flexion.

Un exemple de ce type est donné par les zones latérales des remblais de forte hauteur reposant sur des sols compressibles. Alors, une combinaison judicieuse d'inclusions isolées en partie centrale et de refends sous la partie latérale a pu être préconisée et mise en œuvre par différents auteurs (réf. Filz G. & Al, Kitazume M.).

Figure 4. Diagramme de grand glissement.

.Domaine 3 : Réduction des poussées exercées sur les écrans de soutènement.

Les inclusions isolées agissent par limitation du tassement derrière le soutènement et allègement des contraintes verticales dans le massif de sol par transfert partiel sur les inclusions, tandis que les inclusions de forte inertie ajoutent à cet effet celui d'une diminution "directe" des contraintes de poussée par mobilisation du frottement sur les refends autostables.

Un exemple d'application significatif est celui du rempiètement du quai poste 7 du Transmanche (Calais), pour lequel le premier mode de comportement s'avérait inefficace en raison d'un contraste de rigidités verticales insuffisant entre le sol en place et les inclusions, et où seul l'effet inertiel permettait donc de réduire la poussée de façon significative (cf chapitre 3.1).

.Domaine 4 : Traitement anti-liquéfaction des sols sous sollicitation sismiques.

Il a été montré (réf. Seed) que certaines méthodes de justification des réseaux d'inclusions disjointes reposaient à tort sur un effet de transfert sur ces dernières des contraintes de cisaillement induites par le séisme.

Ces méthodes reliaient en effet l'efficacité des inclusions à leur module de cisaillement, en ignorant le fait que leur élancement induit en général un mode de déformation en flexion largement prépondérant par rapport au mode de déformation par cisaillement, à l'instar des poutres sur appuis élastiques de la résistance des matériaux.

C'est donc bien l'inertie et non la rigidité qui constitue le facteur clé dans l'efficacité de ce type de traitement, ce qui conduit là encore à privilégier les réseaux d'inclusions de forte inertie. Le traitement de type "quadrillage" est souvent qualifié à tort de "confinement", alors que c'est bien l'effet "inertiel" qui est recherché, le double réseau d'écrans orthogonaux permettant avant tout de réaliser un traitement isotrope dont l'efficacité est ainsi rendue indépendante de la direction des ondes sismiques.

Un exemple particulièrement représentatif est donné par le chantier de l'extension de la préfecture de Fort-de-France, pour lequel s'ajoutait, à la problématique du traitement de terrains fortement liquéfiables sur une grande hauteur, celle de l'écoulement post-liquéfaction induit par le pendage significatif du substratum, ce qui rendait nécessaire la mise en œuvre d'un réseau autostable (cf chapitre 3.2).

Figure 5. Stabilité. Principaux efforts dans le plan d'un refend.

## 3 EXEMPLES D'APPLICATION

### 3.1 Renforcement de sol derrière un soutènement

La mise en place de tranchées de soil-mixing de grande inertie à l'arrière d'un écran de soutènement permet la réduction des poussées du terrain sur l'écran lui-même.

Une optimisation de la reprise des efforts de poussée conduit à installer des éléments d'inertie maximale (concentration des efforts pour des déplacements limités). Des éléments isolés sont bien moins efficaces en terme d'inertie globale.

C'est ce principe qui a été proposé et retenu pour les travaux de reconstruction du poste transmanche n°7 à Calais.

La mise en place de refends de Geomix (Méthode par havage spécifique à l'entreprise) perpendiculairement à l'axe du quai (figure 6) a permis de réduire la section des palplanches à mettre en œuvre dans le cadre des travaux d'approfondissement du quai.

Figure 6. Vue 3D du renforcement derrière le rideau du quai existant.

Le massif de sol traité reprend la poussée des terres et les palplanches à l'avant ne reprennent plus que la poussée d'eau. La stabilité du massif renforcé par les éperons de sol mixing est vérifiée vis-à-vis du non-basculement, du non-glisement, et de la non extrusion entre tranchées.

L'autre partie des vérifications a consisté à établir la cohésion homogénéisée du massif de sol, variable de 45 à 85 kPa pour ce projet.

La solution de base en barrettes isolées apportait une cohésion homogénéisée moyenne de l'ordre de 24 kPa, attestant la bien moindre performance des renforcements disjoints par rapport à la disposition en refends de grande inertie.

### 3.2 Traitement anti-liquéfaction

Les dégâts engendrés par le dernier séisme significatif de novembre 2007 en Martinique ont nécessité la reconstruction de la préfecture de Fort de France (bâtiments type R+4).

Le contexte géotechnique du site montre un fort potentiel de liquéfaction des alluvions à dominante sablo-limoneuse de faible caractéristique ( $PI^* \sim 0,3$  MPa,  $Em \sim 2,2$  MPa), sur une épaisseur variable de 9 à 18 m correspondant à la pente du substratum.

En réponse à l'appel d'offres, l'entreprise a proposé une solution variante pour répondre à la fois aux problématiques de liquéfaction et d'écoulement post-liquéfaction des sols sur la pente du substratum.

Un nouveau type de fondations basé sur un quadrillage en sol mixing sous l'emprise totale des bâtiments (environ 36 m x 40 m) a été conçu (figure 7).

Les tranchées Geomix, d'épaisseur 0,50 m, sont espacées d'environ 4.5 m entre axes. Par leur forte inertie (par comparaison aux inclusions rigides) et à leur géométrie, les déformations des panneaux sont limitées pendant l'épisode sismique. Le cisaillement additionnel du sol et les efforts horizontaux provenant de la structure se concentrent sur les bandes Geomix. Le traitement de confinement permet ainsi de limiter le cisaillement et le développement de pressions interstitielles dans le sol confiné non traité. Le risque de liquéfaction est évité.

Les caissons anti-liquéfaction servent également en phase service de fondation aux bâtiments par l'intermédiaire d'une dalle de transfert. Ils ont donc aussi le rôle de réduction des tassements sous la structure en situation statique.

Le phénomène d'écoulement post-liquéfaction a provoqué de nombreux dégâts lors du séisme de Kobé au Japon en 1995. Sur le site de la préfecture de Fort-de-France, ce risque est accru par une pente importante du substratum (dénivelé de 9 m sur une

longueur de seulement 40 m). Les inclusions isolées de faible inertie ne peuvent résister à ce phénomène.

Cette première technique, mise en œuvre entre octobre 2010 et janvier 2011 représente un vrai pas en avant dans l'approche des fondations pour les Départements d'Outre Mer.

Plus largement, il s'agit d'une solution technique innovante, reposant sur un procédé propre à Solétanche Bachy et qui répond efficacement aux problématiques des clients en sites sismiques.

Figure 7. Vue en 3D des fondations en caisson.

## 4 CONCLUSION

Les quelques exemples présentés dans l'article, représentatifs de différents domaines d'application, ont permis de mettre en évidence la nécessité de privilégier non pas tant la rigidité que l'inertie des réseaux d'inclusions : la mise en œuvre de refends, de parois continues ou de caissons "semi-rigides", réalisés au moyen de techniques récemment développées pour étendre le domaine d'application du procédé "soil mixing", permet ainsi dans bien des cas d'apporter à des problèmes complexes une réponse particulièrement pertinente.

# Assessment of Carillo's Theory for Improved Tunis Soft Soil by Geodrains

## Évaluation de la théorie de Carillo pour les sols mous de Tunis améliorés par géodrains

Jebali H., Prikha W., Bouassida M.

Université Tunis El Manar, Geotechnical Engineering Research Team, École nationale d'ingénieurs de Tunis (ENIT)

**ABSTRACT:** This paper presents an experimental study carried out on undisturbed cored samples of Tunis soft soil extracted at 17.25 m depth at the lagoon of Séjoui. Three types of oedometer tests had been performed: first type was a standard test on Tunis soft soil, the second was an oedometer test on the same soil improved by a prefabricated vertical drain MebraDrain 88 (Mb88) type and the third test is similar to the second test in which vertical drainage was prevented. Then, the assessment of Carrillo's theory is studied by quantifying the effect of radial and vertical consolidation from the observed global degree of consolidation of improved Tunis soft soil specimens by geodrains.

**Résumé:** Ce papier présente une étude expérimentale réalisée sur des échantillons intacts du sol mou de Tunis prélevés à 17,25 m de profondeur de la marécage de Séjoui. Trois types d'essais oedométriques ont été effectués : le premier est un test standard sur le sol mou de Tunis, le second était un essai oedométrique sur le même sol amélioré par un drain vertical de type MebraDrain 88 (MB88); le troisième test est similaire au deuxième test dans lequel seulement le drainage radial a été favorisé. Ensuite, l'évaluation de la théorie de Carrillo est étudiée en quantifiant l'effet de la consolidation radiale et verticale sur le degré de consolidation global.

### 1. INTRODUCTION

Considerable attention has been recently devoted worldwide to the problem of building structures on highly compressible saturated soils and to the development of soil improvement techniques for increasing stability, reducing settlements, and accelerating consolidation of soft soils.

Prefabricated vertical drains (PVD) with preloading method was considered the most used improvement technique to accelerate the consolidation of soft soils and, consequently, to increase their bearing capacity.

The commonly used consolidation theory for designing PVD's is the unit cell model, e.g., Barron (1948), Hansbo (1981) and Terzaghi (1943). Because the solutions considering both vertical and radial drainage are complicated, those most used in practice ignore the effect of vertical drainage, such as Barron's theory. Barron (1948) developed solutions for two types of boundary conditions at the surface of improved soil such as: (i) "free vertical strain," resulting from a uniform distribution of vertical load, and (ii) "equal vertical strain", which results from imposing the same vertical deformation. However, in some cases, the vertical drainage by PDV has a considerable effect on the degree of consolidation of improved soil; Terzaghi (1943) suggested the well known simple method for one-dimensional (1D) vertical consolidation condition.

Furthermore, for most cases in practice, the soil is not homogeneous, and the deformation of PVD improved soil

does not occur in 1D condition. Carrillo's theoretical solution (1942) is used to combine the vertical and radial drainage effects to predict the global degree of consolidation  $U$ :

$$(1 - U) = (1 - U_r)(1 - U_v) \quad (1)$$

$U_r$  and  $U_v$  are respectively the radial and the vertical average degree of consolidation.

Theoretically speaking, Carillo's formula (Eq 1) is only valid for instantaneously applied loading.

The consolidation of soft soil is related to the dissipation of excess pore pressure generated by the surcharge load. For radial consolidation problem with centered vertical drain in oedometer cell, the governing differential equation of excess pore pressure is (Parakash et al, 1996):

$$\frac{\partial(\Delta u^r)}{\partial t} = C_r \left( \frac{\partial^2(\Delta u^r)}{\partial r^2} + \frac{1}{r} \frac{\partial(\Delta u^r)}{\partial r} \right) \quad (2)$$

$C_r$  is the coefficient of radial consolidation of soft soil and  $\Delta(u^r) = \Delta u(r, t)$  is the excess of pore pressure at radius  $r$  and time  $t$ .

Solution of equation (2) that uses the condition of equal vertical strain without smear effect is given by (Barron, 1948):

$$U_r = 1 - \exp\left(-\frac{8T_r}{F(n)}\right) \quad (3)$$

The smear zone is defined as the remolded zone of soil immediately adjacent to the drain.  $F(n)$  is a Barron's function given by :

$$F(n) = \left( \frac{n^2}{n^2 - 1} \right) \ln(n) - \left( \frac{3n^2 - 1}{4n^2} \right) \quad (4)$$

"n" is the drain spacing ratio given by:

$$n = \frac{D}{d_w} \quad (5)$$

D and  $d_w$  denote the equivalent diameters of unit cell and of PVD, respectively.

$T_r$  is the dimensionless time factor of consolidation due to radial drainage is written in function of time t:

$$T_r = \frac{C_r \times t}{D^2} \quad (6)$$

For vertical consolidation problem, the differential equation of one-dimensional consolidation for the excess pore pressure is written (Terzaghi, 1943):

$$\frac{\partial(\Delta u^z)}{\partial t} = C_v \left( \frac{\partial^2(\Delta u^z)}{\partial z^2} \right) \quad (7)$$

$\Delta(u^z) = \Delta u(z, t)$  is the excess of pore pressure depending of the depth z and time t;

$C_v$  is the coefficient of vertical consolidation.

Solution of the differential equation (7) is the vertical degree of consolidation  $U_v$  as follows:

-  $U_v < 50\%$ :

$$U_v = 2\sqrt{\frac{T_v}{\pi}} \quad (8)$$

-  $U_v > 50\%$ :

$$U_v = 1 - \frac{8}{\pi^2} \exp\left(-\frac{T_v \pi^2}{4}\right) \quad (9)$$

$T_v$  denotes the time factor of vertical drainage:

$$T_r = \frac{C_v \times t}{H^2} \quad (10)$$

H is the drainage distance that is equal half of the thickness of specimen.

## 2. STUDIED SOIL

Tunis soft soil specimens used in this study were obtained from the Sejoumi's lagoon at depth of 17.25 m. The extracted sample is grey coloured, it has a characteristic smell and contains shell debris. From grain size analysis performed by hydrometer and sieving in accordance with standards NFP 94-056 and NFP 94-057, (AFNOR, 1995), it was found that Tunis soft soil presents 85 % of particles

with dimension less than 80  $\mu\text{m}$ , it also includes a high fraction of silt.

Figure 1. Gradation curve of Tunis soft soil

## 3. CONSOLIDATION TESTS

Three series of consolidation tests were carried out on the Tunis soft soil in oedometer cells. These tests involved applied increments of vertical load to the specimen and measurements of the settlement. For each increment of loading, the decrease of the thickness of the sample versus time is recorded. Duration of the applied increment of load depends on the soil and its consolidation characteristics.

The range of applied stress depends on the range of effective stress which is needed in the consolidation analysis of the studied. When the primary consolidation at prescribed load level is completed (200 kPa) the sample is unloaded in one or several steps until the increment of load of 25 kPa is dismantled and the swelling of specimen can be measured. The applied vertical load is doubled at each increment until reaching the maximum required load (50, 100, 200,400,800 kPa). The specimen is again unloaded. At the end of the test, the sample is careful removed and its thickness and water content are measured. Series 1 (VD): It corresponds to a standard oedometer test performed according to NF P94-90-1 standard (French Standard, 1997). This test is carried out on a cylindrical sample of saturated soil with 70 mm diameter and 19 mm thickness. The soil sample is enclosed in a metal ring and is placed on a porous stone. The loading cap has also a porous stone, so the sample is sandwiched between two porous stones at the top and bottom of the sample to allow vertical drainage (VD).When preparing the sample, filter papers are placed between the soil and the porous stones. The sample is then placed in the consolidation cell and the unit cell. Water is added into the cell around the sample, so the sample remains saturated during the test.

Series 2 (RD): It corresponds to an oedometer test performed on Tunis soft soil improved by a single geodrain (Mebradrain 88) of sizes (thickness = 0.5 cm, width = 1cm and length= 19 mm). In these tests only

radial drainage (RD) is allowed, vertical drainage is prevented by mean of an impervious membrane which covers the porous stone at the top and the bottom levels of the specimen.

Series 3 (V&RD): It corresponds to an oedometer test performed on Tunis soft soil improved by a single of geodrain (Mebradrain 88) type sized as that used in series 2. In these tests the vertical drainage radial drainage are allowed.

Results of the three series of tests presented in Figure 2 show the variation of void ratio  $e$  in function of the effective stress plotted in the logarithmic scale for loading-unloading – reloading sequences for three series of tests.

Figure 2. Oedometer curves obtained from three experimental series

Compression  $C_c$  and the swelling  $C_s$  indices, obtained from the three series of tests (VD, RD and VR&D) were determined from oedometer curves and summarized in table 1. Notice that the compression index obtained from series 3 (VR&D) is roughly the double of that recorded in series 1 (VD) and 2 (RD). This can be explained by the allowed vertical and radial drainage paths from which follows enhanced consolidation of the compressible soil. From Table 1, it is understood the swelling is only attributed to vertical infiltration of water with sample unloaded.

Table 1: Values of compression and swelling indices

Serie of tests	1 : VD	2 : RD	3 : V&RD
$C_c$	0.16	0.16	0.30
$C_s$	0.022	0.022	0.023

#### 4. STUDY OF THREE DIMENSIONAL CONSOLIDATION:

##### 4.1 Coefficients of consolidation:

Coefficients of vertical and radial consolidation  $C_v$  and  $C_r$  are determined from the evolution in time of settlement for each increment of loading (from 50 to 800 kPa). From the results obtained for series 1 and 2:  $C_v$  and  $C_r$  were determined by the logarithmic method; which use the plot of thickness of sample versus the logarithmic of time:  $\log(t)$  (Casagrande, 1938).

##### 4.2 Coefficient of permeability

Vertical and radial hydraulic conductivities (permeability coefficients  $k_v$  and  $k_r$ ) are determined by the variable head permeability test. In fact, oedometer apparatus (in series 1 and 2) is equipped with a conventional measuring device (tubes connected to the base of the specimen). The measurements are performed for different levels of applied load from 100 kPa to 800 kPa (100, 200, 400 and 800 kPa).

Figure 9 shows opposite variations of the ratios  $C_r/C_v$  and  $k_r/k_v$  when the consolidation stress varies from 100 to 800 kPa. In this range, ratio  $C_r/C_v$  varies from 36 to 12 and ratio  $k_r/k_v$  varies from 4 to 12. Obtained results show that the assumption made e.g.  $C_r/C_v = k_r/k_v$  is only valid at high levels of consolidation stress (Jia and Chai, 2010).

Figure 3. Ratios  $k_r/k_v$  and  $C_r/C_v$  versus consolidation stress

##### 4.3 Degree of consolidation:

In this paper, the global degree of consolidation  $U(t)$  is predicted by two methods. The first one uses the measured settlement at different levels of applied load in series 3 (case of vertical and radial drainage, VR&D):

$$U(t) = \frac{s(t)}{s_{\infty}} \quad (11)$$

$s(t)$  and  $s_{\infty}$  denote respectively the settlements at given time and at the end of consolidation.

The second method consists in calculating  $U$  by the Carillo's equation (1). The radial degree of consolidation  $U_r$  is estimated from the experimental results of series 2 (case of radial consolidation RC) and equations (7) and (9). The vertical consolidation  $U_v$  is obtained from recorded results in series 1 (case of vertical consolidation VC) by using equation (2).

Figures 4a and 4b illustrate the variation of global degree of consolidation  $U$  in function of time for vertical consolidation stress of 400kPa and 800 kPa.

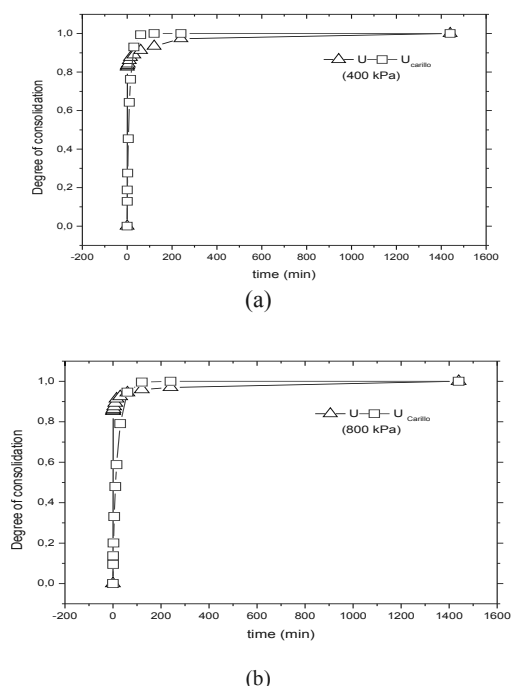

Figure 4. Variation of global degree of consolidation

For applied loads (100, 200, 400 and 800 kPa), it is noted that the degree of consolidation as predicted by the Carillo's theory reaches 100% for a time less than 24 hours, while the degree of consolidation  $U$ , estimated from equation (11) by using measurements of serie 3 results, reaches 100% in 24 hours.

One can also remarks that by using the Carillo's theory a lower degree of consolidation which starts from 10% is obtained, however when using measurements of in series 3 simple approximate methods, higher degrees of consolidation starting from 70% are obtained. Comparing between recorded and predicted global degree of consolidation  $U$ , it follows that the evolution of  $U$  predicted by the Carrillo's theory are overestimated with respect to that deduced from recorded settlement from series 3. The final global consolidation degree  $U$  is identical by using the two methods.

## CONCLUSION

This paper presented an experimental study conducted on Tunis soft clay, in which three types of oedometer tests were executed: a standard oedometer test; an oedometer test on specimen soil improved by an element of geodrain and test a similar test to the second one by preventing the vertical drainage. From measurements coefficients of permeability  $k_v$  and  $k_r$  were determined by the variable head permeability test. In addition, coefficients of vertical and radial consolidation  $C_v$  and  $C_r$  were determined from the evolution in time of settlement at different levels of consolidation stress. Comparison between the ratios  $k_r/k_v$  and  $C_r/C_v$  demonstrated that equality between the two ratios only happens at high level of stress consolidation, contrarily to the common assumption made in previous studies. Predictions of the global degree of consolidation showed that the Carillo's theory leads to overestimated results with respect to predictions from recorded settlements. Further, the effect of vertical and radial consolidations

from the observed global consolidation of improved Tunis soft soils was discussed.

# Improvement of soft fat clay using rigid inclusions and vertical drains

## Amélioration d'une argile plastique molle par inclusions rigides et drains verticaux

Kirstein J.F.

BVT DYNIV GmbH; Germany

Wittorf N.

Ingenieurbüro Dr. Lehnert und Wittorf; Germany

**ABSTRACT:** In the case of a new road crossing in Germany with 1.5 to 7.0 m high embankments nearby the Danish border particularly soft clays were found 13 to 20 m deep below sea level. The undrained shear strength of the clay varied between 7 and 20 kN/m<sup>2</sup>. The water content was almost 100 % and the organic matter below 6 %. The consolidation coefficient  $C_v < 0.3$  m<sup>2</sup>/year is characteristics of a fat clay which requires a long time or tight spacing of vertical drains to consolidate. Due to stability risks, vertical wick drains were installed at a 0.5 m spacing in the part of the highest embankments, which were built in three load steps, each time waiting for 60 to 80 % consolidation degree before loading the next step. Even using 600 kN/m woven geotextiles, a total vertical settlement of around 1.5 m and up to 27 cm horizontal deformation were measured throughout one year of monitoring. These deformations were too high for the existing and running highway in the middle of the new projects. Therefore, full displacement concrete columns (rigid inclusions system CMC) were installed up to 22 m deep with load transfer platforms installed on top the inclusions. In order to improve the installation process of the rigid inclusions, additional vertical drains were installed in the soft soil before the inclusions. Within the first two years, the area supported by the rigid inclusion experienced less than 2 cm of deformation, a proportionally small amount compared to the deformations recorded in the wick drain consolidation parts of the project.

**RÉSUMÉ :** Pour un projet d'une nouvelle route sur des remblais de 1,5 à 7,0 m de hauteur en Allemagne près de la frontière danoise, des argiles particulièrement molles ont été trouvés de 13 à 20 m de profondeur sous le niveau de la mer. La résistance au cisaillement de l'argile varie entre 7 et 20 kN / m<sup>2</sup>. La teneur en eau est proche de 100% et la matière organique inférieure à 6%. Le coefficient de consolidation  $C_v < 0,3$  m<sup>2</sup> / an montre une argile plastique qui nécessite un long temps ou un réseau de drains verticaux très serrés pour la consolidation. En raison de calculs de stabilité, les drains verticaux ont été installés avec un espacement de 50 cm dans la partie des remblais les plus hauts, qui ont été construits en trois étapes de chargement, avec pour chaque étape des périodes d'attente de 60 à 80% degré de consolidation avant de la prochaine étape de chargement. Même avec l'utilisation de géotextiles de 600 kN/m, des tassements verticaux de 1.5 m et des déformations horizontales jusqu'à 27 cm ont été mesurés pendant une année de surveillance. Ces déformations sont trop importantes pour l'autoroute existante en exploitation près du nouveau projet. Des inclusions rigides (système CMC) ont été installées jusqu'à 22 m de profondeur avec différents matelas de répartition placés au dessus des colonnes. Afin d'améliorer le processus d'installation des inclusions rigides supplémentaires, des drains verticaux ont été installés dans le sol mou avant l'installation des colonnes. Au cours des deux premières années de construction, la zone supportée par les inclusions rigides a eu moins de 2 cm de déformation, une déformation relativement petite comparé avec celles enregistrées dans des zones du projet consolidées par des drains verticaux.

**KEYWORDS:** soil improvement, Controlled modulus columns (CMC), vertical drains

### 1 INTRODUCTION AND DESCRIPTION OF THE PROJECT

Large areas nearby the northern sea are nearly flat with elevations slightly above or under the sea level. Soft soil of silt, clay, mud and peat reach between five and twenty meters from the surface, before glacial sands are encountered.

The existing west coast highway B5 near the German city of Husum will be widened from two to three lanes in the future in order to improve traffic. The crossing between B5 and B202 was designed as a bridge project with high embankments located on the unconsolidated soft soils, typical at the flat coastal region near the North Sea.

All traffic constructions bring new loads in form of dead- and live-loads to these soft soils. Without soil improvement methods large long-time settlements will occur, which often causes damages to the road during the construction or later on.

The traffic on the highways B5 and B202 in the site had to be maintained during the construction period and the existing road could not tolerate additional stability risks or settlements, especially when the 1.5 to 7 m high embankments are built directly beside the traffic. There are different stages to look at, but we will focus only on the western part with the highest dam nearby the bridge.

Figure 1. detail of the highest embankment west with the bridge abutment over the highway B5 (CMC close to bridge and coloured areas with vertical drains and preloading)

Due to stability and settlement calculations the foundation works took place according to the following sequence of works and according to the figure 2 below:

1. Installation of vertical drains in different spacings from a one meter thick sand working platform.
2. Preloading with three load steps with a distance of 30 m security and working space from the bridge and existing highway B5. (A)
3. The measured consolidation settlements shown in figure 8 fit with the given predictions according to figure 7. An additional strong woven geotextile layer of 600 kN/m tensile strength between the embankment and vertical drains had very little influence on the vertical inclinometer results with 27 cm of deformation as shown in figure 9.
4. After waiting for 1.3 m settlement (figure 8) a part of the embankment and preload was temporarily rebuilt in order to install the controlled modulus Columns CMC. (B)
5. The preload was brought back to the edge of the foundation systems between CMC and vertical drains in order to optimize the settlement behaviour.(C)
6. Installation of deep foundations for the bridge took place on driven concrete piles with additional sleeves sockets in the soft soils.
7. The CMC were installed between the driven piles afterwards, free of vibrations.

Figure 2. steps of consolidation and construction

The working sequence with different steps was necessary because of stability calculations and the wide influence of the settlements during the consolidation. The CMC brought the following advantages:

- short installation period to complete the project on time
- the vibration free technique allows to work close to the piles of the bridge
- The settlements of the embankment support on CMC with a stiff load transfer platform are compatible with the bridge abutment

## 2 SOIL-PARAMETERS

After the first part of the soil investigations with several borings (BS) and cone penetration tests (CPT) it was clear that there was a problem of stability and consolidation time due to the presence of fat clay in the upper soft soil layer. The project can be modelled with two layers of soft soils divided by a loose sand layer in between. This reaches 13 m up to 22 m in the deepest parts from the surface.

The undrained shear strength  $c_u$  in the soft soil from the results of shear vane tests multiplied with factors of 0.5 to 0.65 are linked to the plasticity according to Bjerum standard DIN

4094-4, Part 4 (Deutsche Institut für Normung 2002). In addition to borings, several laboratory testing ( water content, organic matter and plasticity index ) as well as several load-settlement tests were performed.

figure 3. boring, cone penetration test and shear vane test in the detail area bridge west

The vane tests showed an undrained shear strength of  $c_u = 6$  to  $8 \text{ kN/m}^2$  near the bridge and an undrained shear strength of  $c_u = 12$  to  $20 \text{ kN/m}^2$  in other parts of the project. This was one more reason to select a CMC foundation nearby the bridge in the area of the lowest undrained shear strength.

Following this decision and the results of soil investigation and laboratory the geotechnical engineers assumed an undrained shear strength of  $c_u = 12 \text{ kN/m}^2$  in vertical drain areas. The representative soil parameters for the calculation of consolidation and stability in the project are given in the following table.

Table 1 . soil parameters for the calculation of consolidation and stability in the coloured drain areas

soil properties / soil	density $\gamma_k/\gamma_k'$ [ $\text{kN/m}^3$ ]	shear strength $\phi'_k$ [grade]	Cohesion $C'_k$ $C_{u,k}$ [ $\text{kN/m}^2$ ]	Modulus $E_{s,k}$ [ $\text{MN/m}^2$ ]	Consolidation coefficient $c_v$ [ $\text{m}^2/\text{s}$ ]
fill sand	18/10	30,0	---	60	$6,0 \cdot 10^{-1}$
soft soil, clay [top level]	14/4	17,5	15 12	0,8	$8,0 \cdot 10^{-9}$
soft soil, silt top level	15/5	20,0	10 12	0,8	$2,0 \cdot 10^{-8}$
sand	18/10	27,5	---	25	$2,5 \cdot 10^{-3}$
soft soil, silt (Bottom level)	16/6	20,0	10 20	2,0	$1,0 \cdot 10^{-7}$

## 3 SOILIMPROVEMENT TECHNIQUES

### 3.1 Vertical drains

Prefabricated vertical drains were installed in different spacings with lengths between 15 m (corresponding to the conditions in figure 3) and 22 m in other parts of the project. It was necessary

to pass the intermediate sandlayer in order to place the vertical drains in the glacial sand below the second layer of soft soil. The small spacings in this project were justified by the step loading and the presence of fat clay in the upper layer of soft soil with special low permeability and corresponding primary consolidation coefficient.

### 3.2 *Controlled Modulus Columns CMC*

The controlled modulus columns CMC are well adapted to installation in soft soils. The full displacement auger acts as a casing and maintain the right borehole diameter over more than two meter length. Concrete pressure and adequate volume are monitored and maintained throughout the concreting phase, which is very critical in very soft soils. The typical piling standards give a minimum limit of 15 kN/m<sup>2</sup> undrained shear strength to use for cast-in-place-concrete.

By the standard DIN EN 12699 (Deutsche Institut für Normung 2001) above  $c_u = 15 \text{ kN/m}^2$  the minimal distance between full displacing elements is linked to the undrained shear strength of the soils. Critical distance is only relevant during the concrete curing period.

Compared to vibrating techniques, CMC are usually faster to install and can be performed in softer soils with lower undrained shear strength. There are several references with CMC-installation directly adjacent to freshly grouted CMC under  $c_u < 15 \text{ kN/m}^2$  conditions. In this project the CMC have been first successfully checked under conditions with the lowest  $c_u$ -values by integrity tests and dynamic pile tests. Loads larger than 500 kN could be tested with a factor of safety larger than 2 FOS on the CMC, drilled into the glacial sand layer.

On part of the project, the process of installing additional CMCs close to nearby fresh CMC was improved through the installation of vertical drains in-between the CMC. Immediately after the CMC installation the water starts to flow out of the vertical drain even at the top of the sandy working platform. A continuous flow for several hours up to one day and the volume of water collected show an efficient fast additional consolidation.

Compared with other CMC areas the heave of the working platform and the excessive over-consumption of concrete, normally increasing with the thickness of softsoil, could be reduced by the additional intermediate vertical drains.

Figure 4. installation of CMC combined with vertical drains and pore-water on the platform

## 4 CALCULATIONS AND PREDICTIONS

### 4.1 *Consolidation and stability calculations in the areas receiving vertical drains*

Initially, a total settlement of 1.29 m was calculated in the area west of the bridge. The time-settlement curves for both primary and secondary consolidation are shown below on figure 5.

Figure 5. 129 cm of settlements within ½ year of primary consolidation with vertical drains spacing of 0.75 m

The stability calculations are based on undrained shear strength  $c_u$  and required to build the embankment in three steps of loading with berms and twice waiting for the sufficient degree of consolidation necessary. According to (Chaumeny, Kirstein and Varaksin 2008) the shear strength was calculated using the following relation to the degree of consolidation:

$$\tau = U (\sigma \tan \phi' + c) + (1-U) c_u \quad (1)$$

- U: degree of consolidation
- $\sigma$ : total load at a given depth
- $\phi'$ : internal friction angle
- c: final drained cohesion
- $c_u$ : undrained shear strength

Figure 6. stability calculation of three loading steps and control calculation of the final situation

For this project  $c = c_u$  in formula (1) as improvement  $\Delta c_u$  was added to the basic  $c_u$  value in the stability calculations.

$$\Delta c_u = U \sigma \tan \phi' \quad (2)$$

Figure 7. settlement calculations with the three load steps

Field measurements and the stability analysis in final configuration based on  $\phi'$ , c and porewater pressure were in good agreement with the calculations using the improved undrained shear strength.

### 4.2 *Controlled Modulus Columns CMC*

Due to the presence of very soft soils, the CMC are designed to take the full load of the embankment, neglecting the small load bearing capacity of the soil in between the inclusions. With 500 kN characteristic load per CMC, the calculated settlement at the top of each CMC is very similar to the settlement of the piles under the bridge.

Nevertheless, below the embankment, there is no concrete slab or rigid structure like for the foundation of the bridge. Reinforced earth with galvanized steel was designed to hold the large horizontal forces of active earth pressure. Because of the large geotextile deformations during the consolidation period, as shown in the following monitoring results, the decision was made to use a stronger more rigid construction with nearly no deformation. Compared with plastic geotextiles, the steel grid material has only very small elastic deformations, and as a result limiting the horizontal deformations of the embankment. Through the addition of some gravel in parts of the sandy load transfer platform LTP, the friction between LTP and CMC was greatly increase and nearly no deformation was necessary to mobilize the friction of the LTP.

## 5 MONITORING RESULTS

### 5.1 Wick drains

Figure 8. measurement at the settlement plates SP 9 und SP10.

Figure 9. vertical inclinometer results at the 7 m high damm with drains and 600 kN/m woven geotextile

The measured settlements during the consolidation process in figure 8 follow very closely the predictions shown in figure 7. An additional strong geotextile layer of 600 kN/m tensile strength between the embankment and the vertical drains had 27 cm of deformation measured with vertical inclinometers.

### 5.2 Controlled Modulus Columns CMC

Several measurement systems were installed between the CMC and the reinforced earth in the load transfer platform. The instruments show an almost perfect full stress concentration of the load on the CMC and less than one centimetre of horizontal deformation. Figure 10 shows the cross section and the 5 vertical deformation measurements over a period of 2 years. The horizontal inclinometer was laid across six marked CMC-columns (figure 1 and figure 9). A settlement of one centimetre of the top of the CMCs and two centimetres in-between CMC in the reinforced earth steel construction were measured. There was a good agreement between the calculated values of the settlement and the results of the monitoring.

Figure 10. horizontal inclinometer results with around 1 cm of CMC settlements and 2 cm of reinforced earth settlements

## 6 SUMMARY AND CONCLUSIONS

Soft and fat clay were found at the B5 / B202 road crossing. Additional soil investigations and laboratory tests were performed to be able to complete a proper design, regarding stability and consolidation time.

Oedometer consolidation tests allowed to precisely predict the movements during the consolidation processes that were accelerated by the use of vertical drains at different spacings. Large deformations of up to 1.5 m of settlements and 27 cm of horizontal displacement were experience and closely match the calculations and show that it was the right decision not to place the highest embankment directly on the softest soil beside the bridge over the running traffic on the highway B5.

Vibration free CMC in combination with reinforced earth allowed to construct this high embankment with less than two centimetre differential settlements to the piled bridge.

With a careful planning of the work within the overall construction schedule, detailed design combined with an extensive monitoring program, economic soil improvement techniques can be combined with deep foundations in one project even on very soft soil can be treated successfully.

*AUTH, MSc DIC*

**ABSTRACT:** This work deals with a simulation of a construction sequence of a stone column in two distinct stages: a) a one stage excavation and b) a multi-stage backfilling of the column stone excavation with crushed gravel at ascending steps of 1m. Simulation of this procedure is attempted using a 3D model which represents the stone column and the surrounding soil. Analysis is carried out using a numerical code, called FLAC3D, based on finite differences. The mathematical model incorporates geometry and boundary conditions of the problem, profile of soil layers with their physical, deformational and mechanical properties and their constitutive laws, as well as, initial conditions of stresses and deformations of subsoil stratum of the examined area. Special emphasis is given to simulation of an harmonically imposed vertical loading of the vibrating column, into an equivalent static vertical loading and subsequently into an equivalent radial pressure against internal wall of the cylindrical excavation of the constructed stone column. Results clearly denote that there is a strong interaction of the complex system in the kinematical and stress field, which satisfactorily justifies modification of the final diameter of the constructed stone column compared to the theoretical proposed diameter.

**RÉSUMÉ :** Ce travail se réfère à une simulation numérique de la séquence de construction d'une colonne ballastée, en deux étapes séparées : a) une étape unique d'excavation, et b) plusieurs pas successifs de remblayage de l'excavation cylindrique de la colonne ballastée, avec du matériau granulaire écrasé, à des pas montants de 1m. La simulation est effectuée à l'aide d'un modèle 3D qui représente la colonne ballastée et le sol environnant. Le code numérique utilisé est FLAC3D et il est basé sur le modèle des différences finies. Le modèle mathématique intègre la géométrie et les conditions limites du problème, le profil du sol avec leurs propriétés physiques, mécaniques et de déformation, ainsi que leurs lois de comportement et les conditions initiales de la région examinée. Une attention particulière est donnée à la simulation d'un chargement harmonique vertical imposé à la colonne vibrante, à un chargement équivalent vertical statique, et par la suite, à une pression équivalente radiale exercée sur l'intérieur de l'excavation cylindrique de la colonne ballastée construite. Les résultats démontrent clairement l'interaction prononcée du système complexe, qui justifie aisément le grossissement du diamètre construit par rapport au diamètre théorique conçu lors du dimensionnement du projet.

## 5 INTRODUCTION – SCOPE OF THE WORK

The present work focuses on the investigation of kinematic and strain interaction of a complex system consisting of a single column stone and the surrounding soil, during the excavation stage and the backfilling stage with crushed gravel.

The scope of this work is the investigation and a possible explanation of the problem concerning modification of the constructed stone column diameter, versus the theoretical (design) one, taking into account the procedure of the stone column construction, its geometrical characteristics and the geotechnical model representing the surrounding soil and its physical, deformational and mechanical properties.

In the framework of this work, a summary of geological, geophysical, geotechnical and seismological data are presented in a succinct way in the following chapters, for the examined area, based on a number of corresponding projects performed in the recent past. After a short technical description of the stone column constructing procedure adopted for this project, the numerical model is determined and numerical analyses results are presented, in an attempt to explain the deduced discrepancy between “constructed” and “designed” stone column diameter. The examined area is located in the wide bed of a river in northern Greece, prone to liquefy, where a bridge is founded.

## 2. GEOLOGICAL AND SEISMOLOGICAL DESCRIPTION OF THE SITE

According to geological and geotechnical data, resulting from preceding investigation projects on this area, the surface is

covered by deposits that belong to the Quaternary and is subdivided into: a) river deposits (RD) consisting of silty sands, clay-silty sands, gravels and locally cobbles of gneiss or marble, and b) alluvial deposits (AL), consisting mainly of sands with a largely fluctuating percentage of clays, silts and gravels, of a thickness ranging from 12 to almost 55m.

The geological bedrock of the examined site consists of rocks of the alpic age and belongs to the Rodopic Mass, consisting mainly of biotitic gneisses (gn) interpolated by amphibolites and marbles green-gray coloured. The upper part of the gneissic rockmass appears intensively weathered to totally weathered, consisting thus the weathering zone of 2 to 4m of thickness. The permeability of different geological formations is quite heterogeneous: the riverbed deposits, mainly gravel consisting (RDg) are a rather permeable soil formation ( $k \geq 10^{-3} m/sec$ ), whilst alluvial deposits present a rather low permeability ( $10^{-7} \leq k \leq 10^{-5} m/sec$ ).

As for the seismological data, the examined site belongs to zone I of low seismic hazard, with a horizontal free-field peak ground acceleration value:  $a_{max}=0.16g$ , according to the most recent Hellenic map of seismic zones, valid from 1/1/2004.

## 3. GEOTECHNICAL CHARACTERIZATION

According to the entity of the geotechnical and geophysical investigation programs performed on the broad area (geotechnical boreholes, CPTs and Cross-Hole tests), it results that the prevailing soil formation are alluvial deposits consisting

of sands to silty sands, with a high degree of heterogeneity, characterized by USCS as SP, SW, SM, SM-SP, SM-SW. In some cases they appear as clayey sand (SC) to sandy clay (CL), whereas in other cases, they turn out to be gravel layers, such as: GP, GW, GM, GP-GM. According to the almost 200 SPTs performed, the mean value of blows was calculated about 23, with a standard deviation of  $\pm 11$ . The whole area, where the bridge is founded, has been initially divided into three sub-regions represented each by a different geotechnical design section (ITSAK & Gazetas 2003), and finally a design geotechnical section has been attributed to each bridge pier (Edafomichaniki 2007) used for dynamic analyses purposes.

From various simplified design geotechnical sections, each per bridge pier, it has been chosen one, for the needs of the present project, corresponding to a precise pier of the bridge, as being the most representative of the area, but not the most conservative one. The soil profile used in the present work, can be described as follows:

Layer S<sub>1A</sub> (0 to 2m): loose to medium dense gravels with sand and sand or silty sand with local presence of gravels (GP, SW-SM, SP):  $N_{SPT} \cong 22$ ,  $\gamma=20.5\text{kN/m}^3$ ,  $\phi^{\circ}=36^{\circ}$ ,  $c^{\circ}=3\text{kPa}$ ,  $E_s=10\text{MPa}$ ,  $\nu=0.33$

Layer S<sub>1B</sub> (2 to 5m): medium dense gravels with sand and sand to silty sand with local presence of gravels (GP, SW-SM, SP):  $N_{SPT} \cong 23$ ,  $\gamma=20.5\text{kN/m}^3$ ,  $\phi^{\circ}=37^{\circ}$ ,  $c^{\circ}=5\text{kPa}$ ,  $E_s=12\text{MPa}$ ,  $\nu=0.32$

Layer S<sub>2A</sub> (5 to 12m): medium dense gravels with silt and sand to silty sand with presence of gravels (GM-GP, SP-SM, SM):  $N_{SPT} \cong 25$ ,  $\gamma=21.0\text{kN/m}^3$ ,  $\phi^{\circ}=39^{\circ}$ ,  $c^{\circ}=6\text{kPa}$ ,  $E_s=16\text{MPa}$ ,  $\nu=0.31$

Layer S<sub>2B</sub> (12 to 19m): medium dense silty gravels, silty sand with presence of gravels to silty sand (GM-GP, SP-SM, SM):  $N_{SPT} \cong 28$ ,  $\gamma=21.0\text{kN/m}^3$ ,  $\phi^{\circ}=40^{\circ}$ ,  $c^{\circ}=8\text{kPa}$ ,  $E_s=20\text{MPa}$ ,  $\nu=0.30$

Layer S<sub>3A</sub> (19 to 23m) and layer S<sub>3B</sub> (23 to 35m): medium dense clayey sand-gravels mixture to sandy clay with gravels, or silty sand-gravels mixture (GC-GM, SM, CL):  $N_{SPT} \cong 26$ ,  $\gamma=21.2\text{kN/m}^3$ ,  $\phi^{\circ}=37^{\circ}$ ,  $c^{\circ}=12\text{kPa}$ ,  $E_s=15\text{MPa}$ ,  $\nu=0.31$ .

From 35 to almost 48m the weathering zone of the gneissic bedrock or highly weathered gneiss is met.

#### 4. METHODOLOGICAL APPROACH

The analysis was carried out with FLAC 3D numerical code of finite differences.

##### 4.1 Modeling Procedure

By considering the construction of a stone column in the above soil profile, simulation of two distinct stages of the construction of a stone column is attempted using a three-dimensional (3D) model which represents the stone column and the surrounding soil. Simulation of soil materials is realized by a 3-dimensional polyhedral grid with use of the finite difference method. The mathematical model adopted, incorporates geometry and boundary conditions of the problem, the profile of soil layers, physical, deformational and mechanical properties, constitutive laws for the geomaterials, as well as, initial conditions of stresses and deformations of the subsoil stratum of the area under study.

Geometry of the problem is simplified to axial symmetry. A vertical plane through stone column axis is a plane of symmetry for the analysis. Model grid is shown in figure (1). Coordinate axes are located with origin at the base of the grid, whereas y-axis is oriented along vertical column axis and upward. The initial grid is assigned by 5.0m and 50 units in x-direction, by 5.0m and 50 units in z-direction and by 28.0m and 56 units of in y-direction. A Mohr-Coulomb constitutive model elastoplastic behavior is assigned to all zones of soil surrounding stone column, whilst linear elastic one is assigned to stone column backfilling crushed material. Boundary conditions consist of roller boundaries along the external grid sides of column axis and a fixed base. Equilibrium conditions for initial stresses are

based on earth pressure coefficient at rest  $K_0=v/(1-v)$ , where  $\nu$ : Poisson's ratio.

The modeling sequence consists of the following stages:

Stage I : Initial stresses

Establish equilibrium conditions to initialize stresses

Stage II : Excavation

Stone column excavation at full penetration depth was decided to be numerically simulated in one and only stage, since in reality, excavation was accomplished in about 30 min for a typical stone column of the project, and also, because no steps of excavation during its construction, could be discretized.

Stage III : Stone Column Construction

In reality, construction of cylindrical stone columns of the project with a theoretical diameter  $D=0.8\text{m}$  and a length  $L=23.0\text{m}$ , is realized by ascending steps of 0.5m; at each step, the crushed geomaterials are driven through the top of the stone column downwards (top feed method), and then, the vibrational torpedo is sunk into the excavated cyclic area, reaches the top of the crushed material and starts vibrating harmonically at a frequency of 30Hz, in order to achieve an harmonically applied normal stress of 30 to 35MPa. However, our choice of computational ascending steps to simulate stone column construction was of 1.0m, since an initial comparative study between 0.5m and 1.0m ascending steps, revealed no significant differences, whereas computational time difference was important. Therefore, Stage III is sub-divided in two distinct calculation steps, ever after named as "Sub-stage IIIa and IIIb"

Sub-stage IIIa : Simulation of Vibration and Compaction

Based on the construction procedure concerning the one stage of excavation of the stone column to be realized, which affects significantly the mechanical properties of the surrounding zone, a weak zone boundary has been created, by reducing  $\phi^{\circ}$  &  $c^{\circ}$ , in a distance of 0.60m surrounding column lateral sides, in order to simulate relaxation due to excavation. The width of the weak zone, the reduced values of the mechanical parameters and the elastic deformation modulus, resulted from a "trial and error" back calculating procedure, based on the quantity of the crushed material measured in situ, during the construction of a stone column of the project. Namely, we tried to match the increase of the "as built" diameter of the examined stone column, in agreement with the quantity of the crushed material used for the construction of the stone column, by adjusting the values of mechanical and deformational parameters of the disturbed zone. Vertical normal stress, harmonically applied on top of filling crushed material in order to compact the crushed fill material, per numerical ascending step of the stone column construction, is transferred as a lateral pressure "p" to simulate subjected compressive lateral loads of material due to gravel compaction, in terms of an "equivalent static" lateral (radial) pressure, as explained in the following paragraph.

Sub-stage IIIb : Simulation of Crushed Stone Material filling

This sub-stage simulates filling of the stone column crushed material taking under consideration the preceding compaction procedure. In order to maintain the shape of the "deformed diameter" per constructed step of the stone column, crushed fill material, considered as a linear elastic one, it has been attributed a very high modulus of elasticity, avoiding thus a rebound of the plastic lateral displacements obtained from sub-stage IIIa.

##### 4.2 Assessment of equivalent lateral static loading

It is widely known in Mechanics, that a dynamic system responds to an harmonic external loading, according to the following equation:

$$u(f) = u_{st} \frac{1}{\sqrt{[1 - (f/f_1)^2]^2 + 4\zeta^2}} \quad (1)$$

where,  $u(f)$ : dynamic displacement,  $u_{st}$  : equivalent static displacement ( $=P/K$ ),  $\omega$ : frequency of the input motion,  $\omega_1$ :

predominant frequency of the system (herein: the soil column overlying gneissic bedrock), and  $\zeta$ : damping ratio of the system.

Figure 1. Model grid used for 3D numerical analyses.

From equation (1), it results that ratio  $u(f)/u_{st}$  is greater than 1.0 when  $f/f_1 < 1.0$ , and vice versa, when  $f/f_1 \gg 1.0$ . In this last case, it results:

$$u(f)/u_{st} \cong \frac{1}{(f/f_1)^2} < 1 \quad (2)$$

Based on the aforementioned, in order to use an “equivalent static” loading instead of a dynamic or harmonic one, we need to use a coefficient  $b(f)$ , defined as in equation 2. As  $b(f)$  is proportional to  $u(f)/u_{st}$ , it is evident that it will be inversely proportional to loadings, i.e. the ratio  $P_{st}/P(f)$ . Therefore:

$$b(f) \cong \frac{P(f)}{P_{st}} = \frac{1}{\sqrt{[1 - (f/f_1)^2]^2 + 4\zeta^2}} \quad (3)$$

In the present problem, it can be assumed approximatively, that:

$$f_1 \cong \frac{V_{La}}{4H} \cong \frac{3V_s}{8H} \quad (4)$$

where,  $V_{La}$ : wave velocity according to Lysmer ( $V_{La} \approx 1.5V_s$ ),  $V_s$ : shear wave velocity, and  $H$ : depth of the soil column overlying the gneissic bedrock.

Consequently, for the examined case, where a mean depth of the soil column is admitted as:  $H=30\text{m}$  and  $V_{S30} \approx 250\text{m/sec}$ , the predominant frequency of the system for vertically induced harmonic external loading, can be roughly approximated, as:

$$f_1 \approx \frac{3 \times 250\text{m/s}}{8 \times 30\text{m}} = 3\text{ Hz} \quad (5)$$

For input motion frequencies ranging from 20 to 35Hz (mean estimated value of 30Hz) and mean estimated value of damping ratio  $\zeta=20\%$  (Mylonakis et al 2006), equation (3) results  $b \approx 0.15$ , which represents a reductional coefficient due to the frequency of the input motion. It is estimated that due to a large number of uncertainties of the system, and also because the examined system is not a single degree freedom oscillator, it would be wiser to impose a factor of safety of 2.0, resulting thus to a design coefficient  $b_{design} = b \times 2 = 0.3$ . Accordingly, it results that  $P_{st} \approx 30\%P_{cyclic}$ .

Based on the above, vertical harmonic loading imposed by a hydraulic vibrating torpedo, can be calculated via cyclic normal stress (30 to 35MPa) applied through the edge of the vibrating

column of a diameter  $d=0.40\text{m}$ . The vertical harmonic loading, is calculated, as follows:

$$P_{cyclic} = q_{cyclic} \frac{\pi d^2}{4} = 30 \times \frac{3.14 \times 0.4^2}{4} = 3.768\text{MN} \quad (6)$$

providing thus an equivalent static vertical loading  $P_{st} \approx 30\%P_{cyclic} = 0.3 \times 3.768 \approx 1.13\text{MN}$ , and an equivalent vertical normal stress that is estimated to compact vertically the crushed fill material of the stone column at every step of construction:

$$\sigma_{z,st} = \frac{1130 \times 4}{3.14 \times 0.8^2} \cong 1777\text{kPa} \quad (7)$$

According to linear elastic theory, earth pressure coefficient at rest, equals to:  $k_0 = \nu/(1-\nu) = 0.3/(1.0-0.3) \approx 0.429$ , and then the equivalent radial (horizontal) static normal stress is estimated  $\sigma_h = 0.429 \times 1777 \approx 762\text{kPa}$ .

For the numerical analyses performed, for the deeper part of the stone column it was adopted a radial pressure of 750 to 800kPa, whereas, it has been progressively reduced as ascending steps of stone column construction were getting close to the head of the stone column at free surface until it has almost been nullified in the last step.

## 5. NUMERICAL ANALYSIS IMPLEMENTATION & RESULTS

Developing a step by step simulation of a stone column construction (excavation, filling & compaction), analysis results are mainly concentrated to the plasticity limits of soil strength and to the outwards lateral displacement of the stone column excavated sides due to gravel compaction. Plasticity indicators for shear or tension are divided at a present plastic yield indicator with symbol (-n) or a past plastic yield indicator with symbol (-p). Outwards lateral displacement are being recorded at every depth level of the stone column, in different grid points with distance of 0, 30cm, 60cm and 100cm of the excavated sides of the stone column.

Figure (2) shows plasticity indicators generated due to the excavation at full penetration depth. It can be seen that one step column excavation, has no remarkable effect at inwards horizontal displacements. At this case, plasticity limits of soil strength developed in a distance of 0.20-0.40m surrounded excavated sides. Inwards horizontal displacements of the excavation are limited in a range of 4-5mm with maximum values appearing at deeper levels of excavation.

Sub-stages IIIa & IIIb simulate the compaction/filling of crushed stone material and interaction of the above to surrounding soil. Figures (3) and (4) exhibit plasticity indicators for two different construction depths from 16m to 15m and from 1m up to the head of the stone column (free soil surface) respectively. Although, most of plastic indicators, reveal a past plastic yield (indicator -p) in shear or tension, plasticity disturbance of the soil is generated in a remarkable distance of 1.0 to 1.2m surrounding column sides for the first example and in almost the entire surface area of the surrounding soil at the second one. Low initial stress state at free soil surface, leads to a remarkable plastic yield over limit close to the stone column head, even though equivalent static normal radial stress is very low. Concerning lateral outwards displacement of stone column excavated sides, due to gravel compaction/filling, shows that values between 10 and 20cm keep well at a distance of 100cm of the excavated sides. Indicatively, outwards radial displacement values (at excavated sides) for depths at 22.5m, 11.0m and 1.0m are in a size of 23cm, 12cm and 20cm respectively. In general terms, outwards horizontal displacements are eliminated at distances more than 60cm of excavated sides.

Figure 2. Plasticity zones during the one stage excavation of the examined stone column

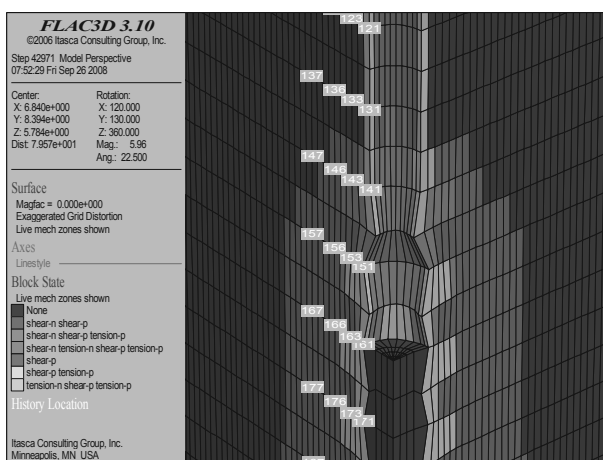

Figure 3. Plasticity zones during multi-stage filling of the stone column with crushed geomaterial at depth of 16 to 15m simulated by an equivalent static radial pressure (sub-stage IIIa, 8<sup>th</sup> ascending step of construction of the examined stone column)

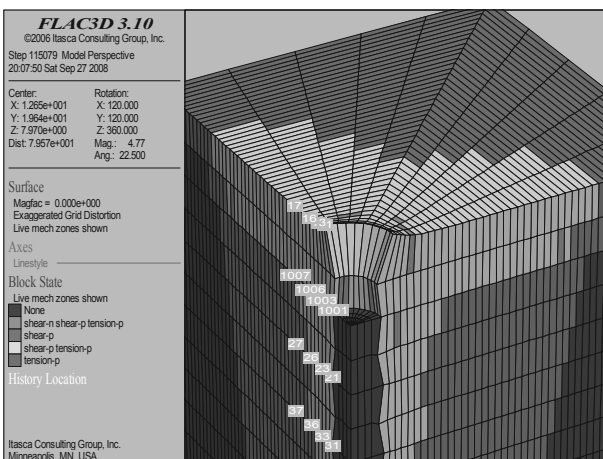

Figure 4. Plasticity zones during multi-stage filling of the stone column with crushed geomaterial at depth of 1m to head of the stone column, simulated by an equivalent static radial pressure (sub-stage IIIa, 23<sup>rd</sup> final ascending step of construction of the examined stone column)

## 6. CONCLUDING REMARKS

For the needs of the present project it has been decided to adopt a rather simple, yet representative, soil profile corresponding to a bridge pier, where typical stone columns of 0.8m diameter and 23m length are constructed, in order to improve foundation soil behaviour. The complex system consisting of a stone column

and the surrounding soil is numerically analyzed with FLAC3D numerical code based on finite differences.

The numerical code used considered the procedure of construction, as well as, its effects on the surrounding soil, and simulated at its best, the physical procedure of the stone column construction, in a rational and well documented way.

Excavation stage is simulated in one and unique stage, whereas, construction of a stone column is simulated by a multi-stage complex procedure divided in two distinct calculating steps. Those are identified as two sub-stages per ascending step of construction: a) vibration and compaction, materialized by application of an equivalent radial pressure against the internal wall of the cylindrical excavation and b) stone column filling with a linear elastic geomaterial assigned a high elastic modulus of compressibility, due to the compaction procedure, preventing a rebound of the induced radial displacements of the first sub-stage.

Commenting the outcome of numerical analyses performed, the following points can be outlined:

1. after completion of excavation stage, the plastic zones developed around the cylindrical excavation are limited, same as horizontal displacements, ranging from some millimeters to only a few centimeters,
2. once excavation procedure is completed, it has been documented via a “trial and error” back calculating procedure, that a zone of about 60cm is seriously disturbed, affecting notably the mechanical and deformational parameters of the surrounding soil,
3. the stage of construction of the stone column has been simulated by a multi-stage procedure of ascending steps of 1m and application of an equivalent static radial pressure, as defined in §4.2, progressively reduced as ascending construction steps approached the head of the stone column at the free surface,
4. horizontal inelastic displacements in the limit of the side wall of the cylindrical excavation range between 10 and 20cm, resulting thus in an expansion of the constructed diameter, compared to the theoretical one as designed.

# Laboratory tests and numerical modeling for embankment foundation on soft chalky silt using deep-mixing

Essais au laboratoire et modélisation numérique de la fondation d'un remblai sur un limon crayeux mou des sols améliorés par malaxage en profondeur

Koch E., Szepesházi R.

*Széchenyi István University, Győr, Hungary*

**ABSTRACT:** The deep-mixing is nowadays world-wide accepted method as a ground treatment technology to improve the permeability, strength and deformation properties of soils. Binders, such as lime or cement are mixed in-situ with the soil by rotating mixing tools. The method is undergoing rapid development, particularly with regard to its range of applicability, cost effectiveness and environmental advantages. The paper describes the results of laboratory tests on chalky silt samples mixed with cement of different content. The influence of the different mixing parameters on the unconfined compression strength and deformation modulus is shown and evaluated. Typical results of the laboratory tests were used in numerical modeling with PLAXIS 3D as input parameters to study the behavior of a 4 m high embankment constructed on this soil improved by deep mixed columns with different spacing and diameters. The parameters of the soil improvement technique were analyzed to study their influence on the settlement and the stability of the embankment. The trends of the calculation outputs are shown and evaluated.

**RÉSUMÉ :** Pour l'amélioration de la perméabilité, de la résistance et des caractéristiques de déformation des sols mous la malaxage est considéré comme une technique courante, préconisée partout. La procédure consiste à malaxer, par rotation, les liants: la chaux ou/et le ciment et le sol in-situ à l'aide de l'outil de malaxage par rotation. Grâce à la diversité technique et aux possibilités d'application de l'appareillage, ainsi que ses avantages économiques, tout en respectant les intérêts de l'environnement, cette technologie approuve un développement continu même dans nos jours. L'étude a pour but de faire connaître les résultats des essais au laboratoire réalisés sur des éprouvettes prélevées du sol traité avec les liants: la chaux et le ciment, dont la teneur par éprouvettes était variable. L'analyse des résultats de ces essais a mis à l'évidence l'influence des divers paramètres de malaxage sur la résistance à la compression simple et sur le modul de déformation du sol traité. Ces résultats nous ont rendu possible d'appliquer le programme d'éléments finis PLAXIS 3D, en vue d'étudier une digue de 4m de hauteur, reposant sur des colonnes de sol traité, ayant une disposition variable et des diamètres différents. Le but de cette étude était de fournir un moyen de calcul qui permet le suivi des tassements et la stabilité de la digue, en fonction de la variation des paramètres de malaxage.

**KEYWORDS:** deep mixing, laboratory test, numerical modeling

## 1 INTRODUCTION

Road and railway embankments have often been constructed on soft, saturated, organic subsoil. In the future this type of construction is suspected to increase, due to environmental and land management considerations. The low strength and the high compressibility together with the low permeability and the high creep potential result in stability problems, extremely large settlements with prolonged consolidation times, and long term secondary compression. One of the solutions to avoid these problems is deep-mixing stabilization of the subsoil.

The development of deep-mixing was started in Sweden and Japan in the late 1960's with the application of a single mixing tool to produce column-type elements (Figure 1.). Since then, new technologies using different mixing tools or binder types have been introduced. Lately, another technology; mass stabilization, based on Finnish research is gaining acceptance, where the whole soil mass is treated normally to a depths of 2 to 4 m (Figure 2.).

The goal of deep-mixing is to improve the soil characteristics, e.g. increase the shear strength and/or reduce the compressibility, by mixing the soil with some type of chemical additives that react with the soil. The improvement occurs due to ion exchange at the clay surface, bonding of soil particles and/or filling of voids by chemical reaction products.

Mass stabilization is preferred if the subsoil is very poor e.g. peat, organic clay or soft clay deposits, and the thickness of the mass to treat is less than 5 m, the height of the embankment is low, and the main purpose of the treatment is to increase stability (Allu Stabilisation System). If the main purpose is to reduce settlements and the weak soil is thicker than 5 m;

approximately 60 cm diameter single columns are used. With this technology the treated depths can be increased up to 40 m (Moseley and Kirsch, 2004, Logar, 2012).

Recently, the use of deep-mixing technology has been planned on several Hungarian railway projects. The „Sárrét” railway line rehabilitation is one of these projects; the railroad crosses an area where the subsoil is soft chalky silt. Both deep-mixing technologies could be applied on this site. This paper describes the preparation of their use at this project. Firstly, the mechanical properties of the improved soil were investigated in the laboratory, then, the effectiveness of the technology as embankment foundation was evaluated with the PLAXIS 3D finite element program using the laboratory test results.

## 2 LABORATORY TEST RESULTS

### 2.1 Parameters of deep-mixing technologies

The quality of the mixed depends on the applied binder type and quantity as well as the ratio of water to binder in the mixture. These quantities can be expressed by volume or weight. It is essential that the water content of the original soil is considered when calculating the water content of the slurry.

The binder quantity is described with the cement factor ( $\alpha$ ), and the in-place cement factor ( $\alpha_{inpl}$ ):

- $\alpha = m_{cement} / V_{soil} = \text{binder weight} / \text{soil volume} [\text{kg}/\text{m}^3]$ ,
- $\alpha_{inpl} = m_{cement} / V_{mix} = \text{binder weight} / \text{mixture volume} [\text{kg}/\text{m}^3]$ .

The water content of the soil is described with

- $w_T / c = m_{w,mix} / m_{cement} = \text{the total water-cement ratio} [-]$ .

The quality of the mixture is generally described with two parameters:

- $q_u = \text{the unconfined compressive strength} [\text{MPa}]$ ,
- $E = \text{the Young's modulus} [\text{MPa}]$ .

These mechanical properties are generally measured at 7, 14, 28, 42 and 90 days after mixing, because the strengthening of the improved soft fine grained soils is a long process, but the qualifying parameter is generally the 28 day unconfined compression strength [Filz et. al., 2003].

### 2.2 Properties of the chalky silt soil before treatment

Based on the laboratory tests, the main parameters of the original chalky silt are listed in Table 1.

The soil changes its color if its water content changes: the in-situ moist soil is pale yellow, while it turns light grey when drying. It has high lime content; the texture has small roots and organic threads, and high sensitivity. Based on laboratory tests, it is classified as highly plastic silt (MH).

Table 1. Soil properties of the chalky silt soil in „Sárrét”

$w_L$	$w_p$	$I_p$	$w$	$e$	$E_s$	$E_{s,ur}$	$c_\alpha$	$\lambda^*$
%	%	%	%	-	MPa	MPa	-	-
72.1	54.4	17.7	71.1	2.08	2.1	15	0.0015	0.038

### 2.3 Data of chalky silt mixtures

In the testing program the use of both deep-mixing technologies was investigated. Thirteen different mixtures were prepared by varying  $\alpha$  and  $w_T / c$  parameters (Table 2). Mixtures P1-P3 were made with low water contents and with slightly-varying cement contents. Mixtures 1-5 were prepared with lower water contents but highly varying cement contents. The mixtures 6-10 were made with a little bit greater water contents and with cement contents varied in the similar range. Since the water content of the original soil was high the addition of water was less significant in comparison to cement. The cement content dominated the behavior of the mixture.

### 2.4 Evaluation of stabilized soil parameters

In Figure 3, the increase of unconfined compressive strength with time is shown. As expected, the strength increases with time, but the hardening/strengthening rate is different from that of the concrete. The strength is less than 2.0 MPa for cement content of 50-300 kg/m<sup>3</sup>. Generally, 0.5-2.0 MPa 28-day unconfined compressive strength is required for column-type deep-mixing, and somewhat lower strength for mass stabilization (Moseley and Kirsch, 2004). The data presented in figure three indicate that:

- 4 tested mixtures (P2, 1, 6 and 7) which have a cement content of 125 kg/m<sup>3</sup> or less did not reach 200 kPa unconfined compressive strength, but 3 of them would be acceptable for a mass stabilization, only P2 with a cement content of 50 kg/m<sup>3</sup> should be considered as too weak,

- the 28-day unconfined compressive strength of mixtures 2, 3 and 8 (cement content = 150-175 kg/m<sup>3</sup>) was about 330 kPa, and for 90 days it increased to 500 kPa (50 %). These mixtures could be accepted for mass stabilization,
- the 28-day unconfined compressive strength of the rest of the samples with cement contents of 200-300 kg/m<sup>3</sup> were 500-2000 kPa with a 90-day to 1000-3000 kPa (50-100 %). These would be acceptable for column-type deep-mixing.

Table 2. Parameters of the mixtures

mix-ture	$w_T/c$	$\alpha$	$\alpha_{inpl}$	$q_u$ kPa				
				7	14	28	42	90
	-	kg/m <sup>3</sup>	kg/m <sup>3</sup>	day				
P1	6.8	102	96	70	80	70	93	104
P2	13.5	51	49	12	17	11	18	17
P3	3.4	204	187	303	418	567	727	980
1	5.3	127	120	58	69	92	88	93

3	3.8	178	166	301	297	312	380	598
4	2.7	254	231	655	878	1351	1384	1900
5	2.2	305	274	1037	1487	2125	2853	2991
6	6.8	108	97	81	71	94	82	117
7	5.5	134	120	81	92	165	174	246
8	4.5	162	144	196	231	334	424	508
9	3.4	214	188	370	542	910	1024	1559
10	2.7	268	231	508	670	1162	1458	1952

Figure 3. Measured hardening/strengthening of chalky silt mixtures

Figure 4 shows the relationship between the 28-day unconfined compressive strength ( $q_u$ ) and in-place cement factor ( $\alpha_{inpl}$ ). The exponential trendline fits the points well with  $R^2=0.97$ . The chalky silt responded well to cement addition.

Figure 4. Measured relationship between  $q_u - \alpha_{inpl}$

Figure 5 shows how the 28-day unconfined strength depends on total water-cement ratio. Samples with high water content

show very low strength, and improvement of soil with  $w_T/c > 8$  is not possible. When  $w_T/c < 4$  the strength increased rapidly with decreasing water-cement ratio, but this also means the soil is very sensitive to changes in its properties. Since the total water-cement ratio hardly changes, it is clear that the role of cement factor is significant.

Figure 5. Measured relationship between  $q_u - w_T/c$

Figure 6 shows the relationship between the unconfined strength and the Young's modulus. It can be seen that the trend-line fits very well. In this respect, the chalky silt of „Sárrét” behaves as expected: the modulus is proportional to unconfined strength. The equation from the figure can be simplified to

$$E_u = 70 \cdot q_u \quad (1)$$

where the units are both in kPa.

Figure 6. Measured relationship between  $q_u - E$

### 3 MODELING OF DEEP-MIXING TECHNOLOGIES

#### 3.1 Site evaluation

The second part of our research program was to apply a calculation method and give some guidelines for design. Both technologies (column-type and mass stabilization) were studied for expected design conditions at the Sárrét site. Variation in soil layering, soil strength and compression parameters, and embankment height will dictate the choice of technology. The PLAXIS 3D program was used to assess the effect of stabilization on stability and settlement.

The geometry of the embankment and the parameters of the untreated soil are shown in figure 7. Groundwater level was assumed to be even with the ground surface. Sandy-gravel, suitable for structural fill, was used for embankment material. A 3-m wide, 52.5 kPa distributed load was placed on top of the ballast during the stability analysis.

Column diameters were 60 cm, with a 5.0-m uniform length extending into the gravel layer. The columns were placed in  $2.0 \times 2.0$ -m and  $3.0 \times 3.0$ -m square grids (Figure 8). In order to

model partial mass stabilization, 1.8-m diameter equivalent columns were placed in  $2.4 \times 2.4$ -m,  $3.6 \times 3.6$ -m and  $5.4 \times 5.4$ -m square grids (Figure 9.). Total mass stabilization has been analyzed by modeling the treated soil as a homogeneous composite of mixed and in-situ soils with averaged strength properties.

Figure 7. The model geometry and soil properties

Figure 8. Column-type deep-mixing

Figure 9. Partial mass stabilization

The unconfined compressive strength of the 5 mixtures was used for modeling as base parameters (Table 2). Strength assigned to the column material in the analysis was assumed to be half of the unconfined compressive strength measured in the laboratory. In PLAXIS, this strength is represented by the cohesion ( $c_{ref}$ ). Based on laboratory tests, Young's modulus for the columns was 70 times the unconfined compressive strength. The value of Poisson's ratio was  $\nu = 0.2$ .

Table 2. Mechanical parameters of the mixtures

Mohr-Coulomb	mixture				
	1.	2.	3.	4.	5.
$E_{ref}$ kN/m <sup>2</sup>	7000	1500	20000	40000	70000
$q_u$ kN/m <sup>2</sup>	100	200	300	600	1000
$c_{ref}$ kN/m <sup>2</sup>	50	100	150	300	500

The analysis modeled the construction and load stages in five steps:

- placement of deep-mixing soil material,
- construction of initial 2-m high embankment in 30 days,
- construction of final embankment height in 30 days,
- final state (consolidation up to 5 kPa pore pressure).
- stability analysis considering traffic load.

#### 3.2 Analysis of settlement reduction

The results were evaluated by plotting the calculated settlements versus the unconfined strength of improved soil elements (Figure 10.). The following conclusions can be drawn:

- with increasing strength all technologies reduce settlement, but the effectiveness depends significantly on column diameter and spacing,
- there is a relation between column spacing and  $q_u$ . If  $q_u$  is too small, the column spacing is no longer effective, no matter how close. At a higher  $q_u$ , the column spacing scheme is efficient,
- for partial and total mass stabilization settlements reduce rapidly as  $q_u$  increases, up to 0.4 MPa. Beyond this value, the improvement is much less significant,

- 60-cm diameter column-type improvements reduce the settlements linearly with increasing unconfined strength, but not very markedly,
- 60-cm diameter columns are more effective in 2.0×2.0-m grid spacing than in 3.0×3.0-m, although the settlements are halved at  $q_u = 1$  MPa for the larger grid as well,
- there is little difference between the reduction curves of the 60-cm diameter columns in 2.0×2.0-m grid spacing and of the 1,8-m diameter equivalent columns made in 5.4×5.4-m grid spacing,
- the improvement with 1,8 m diameter equivalent columns in 3.6×3.6 m grid spacing is dramatic, the settlements are halved at about  $q_u = 0,2$  MPa,
- total mass stabilization can be the most effective technology. Even for very small unconfined strengths ( $q_u = 0.1$  MPa) the settlements are reduced to one-fourth.

Figure 10. Calculated relationship between  $s - q_u$

### 3.3 Stability analysis

The influence on sliding stability was evaluated by plotting safety factor as a function of unconfined strength (Figure 11.). For untreated soil,  $SF = 1.18$  and it could be significantly increased with even a slight amount of treatment.

Figure 11. Calculated relationship between  $SF - q_u$

The results can be summarized in the following:

- the lines for different diameters and grid spacing are very similar (except for mass stabilization),
- the four lines show that for  $q_u > 0.5$  MPa, improvement is not necessary,
- the 0.6-m diameter columns with 3-m grid spacing is the least effective just reaching  $SF = 1.4$  value with the maximum strength investigated,
- the most effective technology to insure stability is the partial mass stabilization. With 1.8-m diameter equivalent columns and 3.6-m grid spacing, the required  $SF = 1.35$  value can be achieved with even small unconfined strength,
- the line for total mass stabilization shows a very different behavior. It generates a high safety factor even for small

strength values, but quickly reaches a plateau. Beyond this point the mechanics of the stability failure changes with the failure surface travelling through the embankment slope only.

## 4 CONCLUSIONS

For road and rail embankment foundations, soil improvement is a frequently-used technique. Column-type deep-mixing and mass stabilization are effective soil improvement technologies to reduce settlements increase safety against slope failure. To prepare new railway rehabilitation projects the usability of both methods was investigated on a special soil type: chalky silt in Sárret (Hungary).

While the underlying chemistry may be complex, the performance of the mixed material can be evaluated by standard laboratory and field tests. Laboratory tests have clearly demonstrated that the Sárret chalky silt is suitable for improvement by cement. While it cures relatively slowly, an adequate strength is reached in about 40 days. Unconfined strengths up to 1,0 MPa can be reached by adding relatively small amounts of cement. Its uniform and predictable response to treatment allows the engineer to design the field improvement. For example, the relationship between unconfined strength and total water-cement ratio can be described with simple equations. The Young's modulus of the chalky silt can be calculated as 70 times the unconfined strength.

Finite element modeling was used to study the effectiveness of the mixing improvement. Column-type and mass stabilization scenarios were analyzed using strength and compressibility values from laboratory test results. Both technologies showed reductions in settlement and increase in stability. Based on the figures presented, the effectiveness of various solutions can be evaluated at the first design stages easily and rapidly. Using the trends from the figures, an optimal solution can then be arrived at during the detailed design phase by making only some calculations with PLAXIS for the actual design conditions.

In the future, a further refinement of the proposed method can be achieved by assessing and involving the cost-effectiveness of the alternatives in the design.

**ABSTRACT:** The article is an answer proposal for the conclusion stated in European regulations regarding the environment friendly and more sustainable development, which among others includes utilising secondary and recycled material in order to obtain durable and stable cuttings and embankments. Bearing in mind that the slope stability and erosion control on embankments are the issues rising the nowadays geotechnics awareness through all around the world, the paper content provides the alternative engineering solutions to such problems. The techniques proposed in the paper mainly consist of the proper vegetation cover implementation on embankment slopes, the reinforcement of earth structures by utilising geotextiles and a combination of those two. Additionally, it is presented how secondary materials could be used as a vegetation development accelerating and enhancing material. In order to prove the reliability and efficiency of such activities the laboratory material tests and numerical modeling of slope failures were conducted.

**RÉSUMÉ :** L'article est une proposition de réponse à la conclusion énoncée dans les règlements européens concernant l'environnement de développement favorable et plus durable, ce qui comprend entre autres l'utilisation des matériaux de récupération et de recyclage afin d'obtenir des déblais et remblais stables et durables. Il est admis que la stabilité des pentes et le contrôle de l'érosion sur les remblais sont des problèmes qui apparaissent comme des priorités pour la géotechnique actuelle. Le papier propose des solutions d'ingénierie à ces problèmes. Les techniques proposées dans le document se composent principalement de la mise en œuvre de couverture végétale sur les talus, le renforcement des structures en terre en utilisant par géotextiles et une combinaison des deux. En outre, il est présenté comment les matériaux secondaires pourraient être utilisés comme un développement de la végétation accélérant et en améliorant le matériau. Afin de prouver la fiabilité et l'efficacité de telles activités, les essais de matériaux en laboratoire et la modélisation numérique des ruptures de pente ont été effectuées

**KEYWORDS:** slope stability, reinforcement, vegetation cover, recycled materials, landfill.

### 1 INTRODUCTION.

The most significant element of the embankment type landfill reclamation process is the reinforcement and biological stabilisation of slopes, which are very sensitive to several destabilisation processes like i.e surface erosion. The landfill stability improvement activities are divided into phase 1 - technical reclamation (implementation of civil engineering techniques), and phase 2 - biological restoration (establishment of the vegetation cover). For both of them it is highly recommended to use such recyclable materials as sewage sludge and fly ash as a landfill reinforcement filling (CEN/BT, 2009).

In 2012, in Poland the production of fly-ashes from the coal combustion was 18.5 mln tones. The amount of slag and ashes disposed on Polish landfills and usable for the road embankment construction and land reclamation is 261.8 mln tons. Furthermore, the annual production of sewage sludge in Poland is also significant - 500 000 tones, and could be successfully utilised in landfill reclamation process, as a rich in nutrients fertilizer (Koda et al 2012). The combination of carefully selected types of fly-ash, sewage sludge, soil and vegetation cover can be excellent alternative for the heavy engineering activities for the landfill slopes reinforcement. All the presented solutions are based on the analyses conducted at the Radiowo landfill site located near Warsaw.

### 2 SITE DESCRIPTION

The Radiowo landfill (embankment type) was established in 1962. It covers approximately 15 ha and the altitude is 60 m high. No protection system against the environmental pollution was introduced into the surrounding area at the start of the landfill operation.

The municipal solid waste was disposed there up to the early 90's. The local landslides treatment, changes in further exploitation, and the reinforcement treatment were required. Since 1993 only non-composted waste from the compostory plant has been disposed there (approximately 300 tons/day). The remediation works on the landfill have been carried out since 1994. They include: slopes forming and planting, stability improvement solution, mineral capping, bentonite cut-off wall as a limitation of the groundwater pollution and a peripheral drainage.

The in situ and laboratory tests for Radiowo landfill has been performed since 1993. The field investigation consists of settlement measurements, geotechnical tests of waste, back analysis (as well as slope failure tests), quality tests of sealing (capping layer and vertical barrier) and filter materials. In the Radiowo landfill case, the morphological composition of waste creates an additional factor influencing the mechanical parameters. The organic matter content for non-composted waste is ca. 5 %. A location map involving cross sections selected for slope stability analyses is presented in Figure 1.

Nowadays, the landfill site is planning to be adopted as a winter sports activity complex. The construction plan has already been accomplished and accepted by a legal body, which is a requirement when considering new development plan for contaminated sites (for more detail please refer to Koda 2012).

### 3 UTILISATION OF ANTHROPOGENIC MATERIALS

One of the elements of the landfill reclamation process is the construction of capping system. It is a landfill surface cover protecting against the rainfall infiltration (limitation of leachate penetration). It provides good establishment conditions for the vegetation cover, and significantly enhances slopes stability.

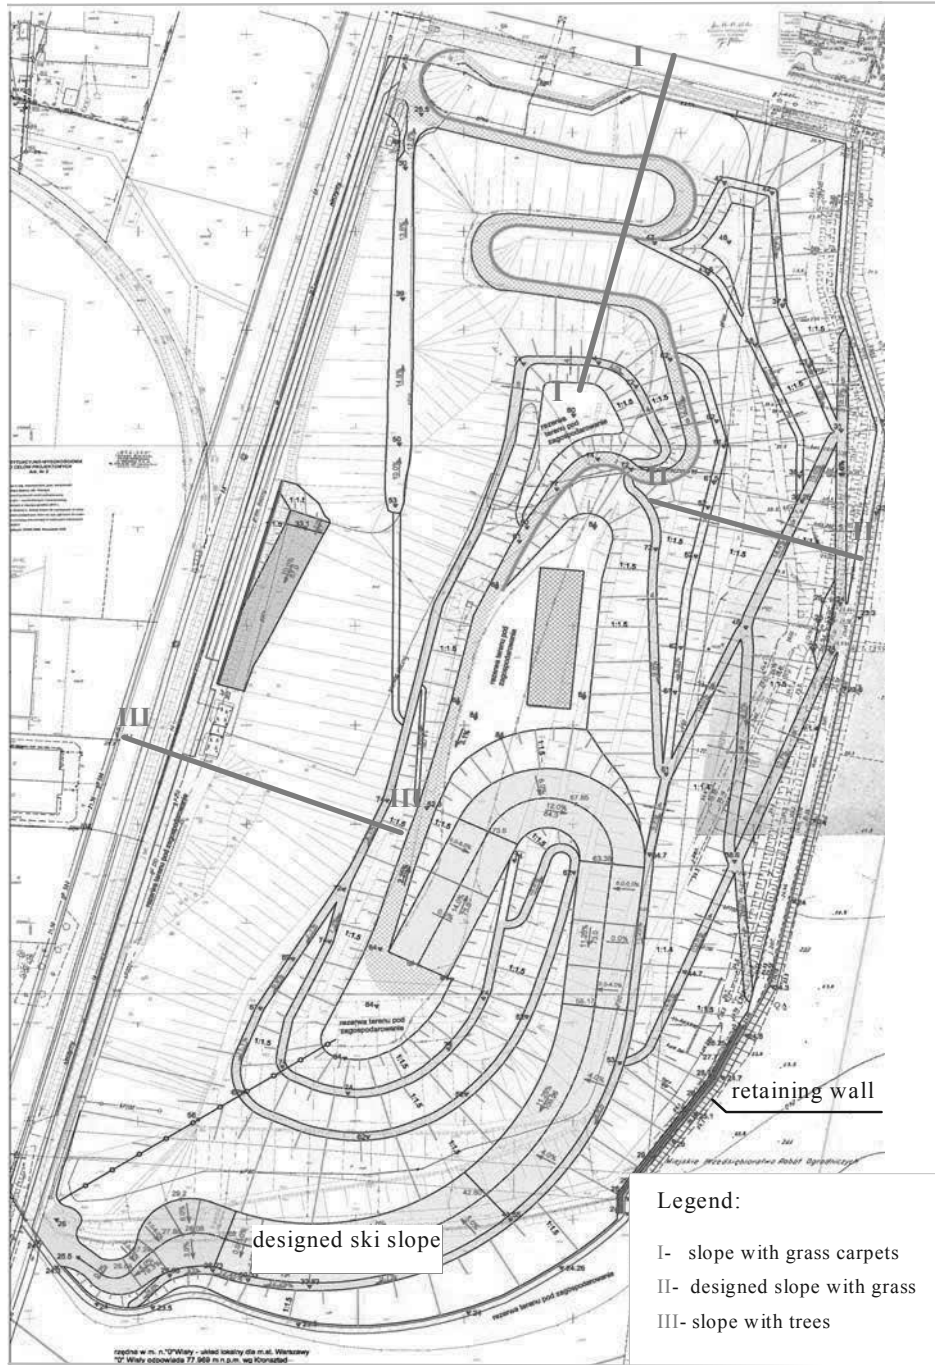

Figure 1. Current development plan of Radiowo landfill, and location of cross-section for slope stability analyses.

Because of its appropriate geotechnical properties like impermeability and good compaction conditions, fly-ashes mixed with cohesive soil are a great material for the capping system. Recently it was recommended to use geomembrane instead of mineral barriers to insulate the surface of the landfill, however there are lots of disadvantages like decreasing slope stability or slowing down the bio-chemical decomposition of waste. Applying mineral capping systems (made of ashes and sewage sludge), in many cases resulted in enhanced fermentation processes (Koda 2011).

The fly-ash is basically a by product of the coal combustion process in power plants. The mineral and chemical composition is determined by mineral elements present in coal. These minerals are: iron oxides, carbonates and clayey minerals. The properties of the fly-ash mainly depend on shape and size distribution of its particles. The bulk density of ashes contains in the range of 2000-2500 kg/m<sup>3</sup>.

The reason for this is some of the particles are filled with gas. The chemical reactions proceeding during the coal combustion process produce mineral phases stated in Table 1.

Table 1. Mineral phases of the fly-ash (Koda and Osinski 2011).

Mineral phases	% content of total mass
Glass	60-83
Millite	4-25
Quartz	4-18
Hematite	0.5-2
Magnetite	1-7
Coke	0.5-5

The additional anthropogenic component which also presents high usability in terms of slope surface reinforcement is sewage sludge (Katsumi et al. 2010). The mineral elements of

the sewage sludge are developing slowly and are not exposed to the erosion processes. This kind of material is hazardous when disposed but when treated by vegetation and additives it is safely absorbed and utilized by plants. Additionally it has to be mentioned that sewage sludge supply is free of charge. The mixture is applied by hydraulic seeders supplied with high pressure pumps, which enables spraying on different soil/material types. The advantage of using sewage sludge is that seeds are protected from the erosion and excessive drying. The viscosity of the sludge and its mixing ability with other components, assure even and smooth protection cover, and moreover, high adhesion to the sprayed surface. The most significant advantage of using the sewage sludge is the nutrition content, essential for the vegetation cover establishment. Especially the undrained sludge is rich in microelement, nitrogen, phosphorus, potassium and organic matter. Some of them are highly valuable for plants (Koda 2011), however cannot exceed normative values of dry mass. The usability of ashes and sewage sludge for the geotechnical purpose is determined by several physical and mechanical properties such as: capacity index in saturated conditions, grain-size distribution, maximum dry bulk density, swelling, internal friction angle, and passive capillarity.

#### 4 VEGETATION COVER AS A RELIABLE METHOD OF SLOPE STABILITY IMPROVEMENT

Beyond described activities for the slope stability and erosion control improvement purpose on the Radiowo landfill, there were also bio-engineering techniques applied with additional use of geosynthetics. Due to the usability assessment of the compost, from organic waste as an enhancing material for the grass carpets, an experimental plot was established within the compostory plant area (Koda, 2012). A composite (grass carpet) consisting of three elements was constructed: reinforcing material, substrate and grass seeds mixture was prepared. As a reinforcing material the geotextile (G) and geogrid (Gs) was used. A reinforcing material task was to connect particular elements of the carpet, improving the shear strength and hydraulics conditions, and also an increase of erosion control on landfill slopes. A porous structure of geotextile and geogrid enhances establishment of the root zone deeper into the surface.

During the selection of reinforcing material the mechanical properties and the stock was considered. The polypropylene materials guarantee long term durability and resistance to aggressive environmental conditions. A seeding suspension consisted of a mixture of three types of grass seeds: lawn type (MT), pasture type (MP) and "gazon" type grass seeds (G). A substrate consisted of sand and compost mixture in three different volumetric proportions: 1P/1K- 1:1 (1 measure of sand + 1 measure of compost), 1P/2K- 1:2 (1 measure of sand + 2 measures of compost), and K- pure substrate (100% compost). The scheme of experimental plot is presented in Figure 2.

Additionally an application of already described fly-ash and sewage sludge suspension on such slopes to accelerate the establishment of a green cover was also provided. The grass carpets were introduced in order to maintain the observation and to conduct further research on how does such solution influence conditions of slopes. The assessment of the effectiveness of bio-engineering activity on landfill slopes were undertaken after 1, 2, 6, and 10 years of the experiment duration. The result of the observation confirms the reinforcing purpose of the method, as even after 10 years of grass carpets establishment the slopes are evenly covered with plants, while on the slopes where only traditional method of planting was applied, the slope conditions are significantly worse. Additionally, the numerical analyses involving the influence of reinforcing layer also proved the correctness of applied method on slope of section I-I marked on Figure 1 where location map is provided. For the results please refer to Table 3.

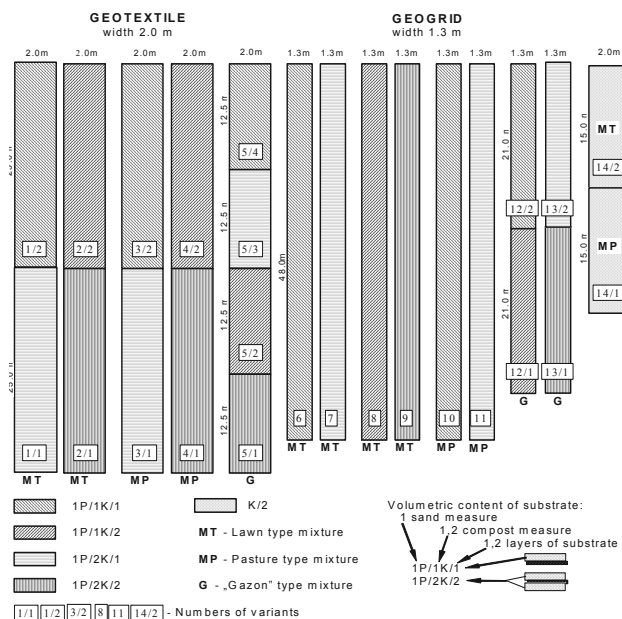

Figure 2. Scheme of the experimental plot established at Radiowo landfill slopes (Koda 2011).

The additional solution improving the slope stability is a proper establishment of high trees and shrubs on slopes (Coppin and Richards 1990, Norris and Greenwood 2003, Clark et al. 2003). Such activity was also conducted for Radiowo landfill site. Comprehensively analysed plant species were selected in terms of root system characteristics and assimilation ability in such specific ecosystem as contaminated land (Coppin and Richards 1990, Greenwood 2006).

In the present study, slopes where the vegetation cover was applied, have been assessed to see whether implementation of plants affected the resulting stability significantly. Firstly, however the geotechnical parameters of waste had to be determined. For such purpose back analyses, CPT and WST tests were conducted on site. The back-stability analysis by the Bishops', Swedish (GEO-SLOPE program) and FEM (Z-SOIL numerical program) methods were performed for three chosen cross-sections of Radiowo landfill slopes and were applied for the shear strength parameters verification. The results are listed in Table 2.

Table 2. Shear strength parameters for municipal solid waste (Koda, 2011)

Material	$\gamma$ [kN/m <sup>3</sup> ]	$\phi$ [°]	c [kPa]	Method
non-composted waste	11.0	20	25	failure tests, CPT, WST
non-composted waste + sand	12.0	25	23	failure tests, CPT, WST
old municipal waste	14.0	26	20	back-analysis CPT, WST

The computations of factor of safety including vegetation cover influencing slope stability were conducted with use of General Greenwood Method. Greenwood (2006) developed an equation, based on the limit equilibrium method, where parameters of plants existing on the slope are considered. These parameters are: root reinforcement forces, wind forces, or the mass of vegetation, or related to these, changes in the pore water pressure. In Slip4EX the Factor of Safety can be calculated by using several equations developed by Greenwood (2006), however in this study the Greenwood General Method was used, as it presents similar characteristics to other methods used in this study. A powerful equation of FOS concerning a vegetation influence, proposed by Greenwood is as follows:

$$F = \frac{\Sigma[(c' + c'_v)l + ((W + W_v)\cos\alpha - (U + \Delta U_v)l - ((U_2 - \Delta U_{2v}) - (U_1 + \Delta U_{1v}))\sin\alpha - D_w \sin\alpha(\alpha - \beta) + T \sin\Theta)\tan\phi']}{\Sigma[(W + W_v)\sin\alpha + D_w \cos(\alpha - \beta) - T \cos\Theta]} \quad (1)$$

Figure 3. Numerical analysis of slope stability including the influence of vegetation cover (cross-section III-III please refer to Figure 1).

where all the parameters indexed with v mean changes according to vegetation influence. Additionally such parameters like  $D_w$  (wind force),  $T$  (tensile root strength) are also included in the equation. This method was basically developed to assess the stability of slope according to the soil reinforcement by anchors or geotextiles, or vegetation effects. By using the Slip4Ex spreadsheet (Greenwood 2006), it is possible to assess how the distribution and type of vegetation can influence the Factor of Safety. After full establishment and grow of proposed plants the numerical analyses of slope stability were conducted. A distribution of high vegetation cover on analysed slope (cross-section III-III) is presented in Figure 3.

Firstly the numerical analyses were conducted for bare slopes. The computations were based on Bishop method which was employed during analyses performed in GeoStudio2007 software. The second step was to determine factor of safety influenced by plants.

The results obtained proved that the factor of safety for the slopes covered with plant was improved as much as 20%. The initial results of numerical modeling for bare slopes has presented unstable condition, however long term monitoring proved that no signs of failure were noticed. The only reliable explanation for such state could be a presence of well developed vegetation on slopes. The example of results of numerical analyses for slope stability for bare and vegetated slopes is presented in Table 3.

Table 3. Comparison of numerical analyses of factor of safety for bare and vegetated slopes

Cross Section	Factor of safety	
	Bare slope Bishop method	Vegetated slope Greenwood method
I-I	1.30	1.38
II-II	1.35	1.42
III-III	1.15	1.32

## 5 CONCLUSIONS

The instability of slopes is one of the most significant problem concerning reclamation processes of landfill sites. The partial solution for this issue is presented in the paper. There are available methods, which are relatively simple, efficient, and cost effective. The use of fly ash and sewage sludge for the reclamation of the surface of landfill is an alternative. It also solves the problem of the ash storage which, from the economical and environmental point of view, is very positive.

The reinforcement of slope does not require only heavy engineering methods, basic solution as a proper selection and implementation of plants is always worth consideration. It is definitely cost effective, environment friendly and reasonable technique accelerating landfill reclamation works. Furthermore, other waste material like compost could be a great substitute of humus for the surface reclamation layer establishment. The compost could be used for reinforced grass carpets production, which positively influences the erosion control on slopes, a factor which often determines processes of slope failure.

# Evaluation of Vertical Drain-enhanced Radial Consolidation with Modified Analytical Solution

## Évaluation de la consolidation radiale améliorée par des drains verticaux par une solution analytique modifiée

**ABSTRACT:** The installation of vertical drains accelerates the consolidation process by reducing the drainage path and predominating horizontal flow within the soft deposits. However, the radial consolidation of the vertical drain installed into the soft ground is governed by the permeability of a smear zone. Modification of Hansbo's analysis is proposed to analyze the degree of consolidation on a horizontal plane by considering the properties of the soil within the smear zone in this study. A parametric study is carried out to investigate the effects of the soil properties on the proposed analysis. The proposed equation is observed to be relatively insensitive to the uncertainty of the horizontal permeability ratio between the undisturbed and smear zones. The validity of the proposed analysis is examined by comparison with the settlement data from a field measurement. It is revealed that the proposed analysis provides a reliable prediction on the consolidation rate of soft ground installed PVD.

**RÉSUMÉ :** L'installation de drains verticaux accélère le processus de consolidation en réduisant les chemins de drainage et d'écoulements horizontaux prédominant dans les dépôts mous. Toutefois, la perméabilité de la zone d'influence détermine le degré de la consolidation radiale induite par les drains verticaux installés dans les sols mous. Une modification de l'analyse de Hansbo est proposée dans cette étude pour analyser le degré de consolidation dans un plan horizontal en considérant les propriétés du sol dans la zone d'influence. Une étude paramétrique est notamment menée pour étudier les effets des propriétés du sol sur l'analyse proposée. L'observation montre que l'équation proposée est relativement insensible à l'incertitude du rapport entre perméabilités horizontales entre les zones non perturbées et les zones d'influence. La validité de l'analyse proposée est examinée par comparaison avec les données de tassement d'une mesure sur site. Il s'est révélé que l'analyse proposée fournit une prévision fiable sur le taux de consolidation des drains verticaux installés dans les sols mous.

**KEYWORDS:** Permeability, Radial consolidation, Smear zone, Vertical drain

## 1 INTRODUCTION

The radial consolidation flow into the vertical drain induces a reduction in the flow channel and an increase in flow rate approaching the drain. It causes that the hydraulic head is dramatically decreased as the distance to the drain decreases. Therefore, the permeability of drain and soil near the drain control the rate of consolidation by the vertical drain. Since the permeability of drain is generally designed to be larger enough than that of soil, it is known that the well resistance is negligible if the discharge capacity exceeds the required discharge capacity (Holtz et al. 1987, Lo 1991). On the other hand, the installation of vertical drains induces a soil disturbance in the vicinity of the mandrel. The disturbed zone, called smear zone, is an area where has reduced permeability and increased compressibility comparing with an undisturbed soil. Reduced permeability in the disturbed zone governs the rate of consolidation, because the hydraulic head loss in soil near the drain further increases when the permeability decreases.

Many researchers insisted that the soil adjacent to the drain is remolded, and several researches were investigated the smear effect by obtaining the permeability of the disturbed zone from the permeability of remolded clay (Tavenas et al. 1983, Bergado et al. 1991, Hird and Moseley 2000, Sathanathan and Indraratna 2006). In this study, modification of Hansbo's solution is proposed to evaluate the degree of radial consolidation, considering the consolidation characteristics of remolded clay. Characteristics of the modified solution are discussed, in comparison with Hansbo's solution. And the consolidation settlement predicted by the modified solution is compared with measured settlement data in the field.

## 2 MODIFIED ANALYTICAL SOLUTION

Hansbo's (1981) solution has been widely used to evaluate the consolidation behavior with vertical drain. It is simple and accurate as compared with other rigorous solutions and numerical analysis (Onoue 1988, Lo 1991). According to Hansbo (1981), the average degree of radial consolidation ( $\bar{U}_r$ ) by vertical drain is

$$\bar{U}_r = 1 - \exp(-8T_h / \mu_s) \quad (1)$$

where,  $\mu_s = \ln(d_s/d_w) + (k_h/k_s - 1) \ln(d_s/d_w) + \pi \cdot z(2L - z)(k_h/q_w) - 0.75$ ,  $T_h$  is a time factor ( $= c_h \cdot t/d_c^2$ ),  $c_h$  is the coefficient of horizontal consolidation in the field,  $d_c$  is the circular diameter influenced by the drain,  $d_w$  is the drain diameter,  $k_h$  is the coefficient of horizontal permeability in the undisturbed zone,  $k_s$  is the coefficient of horizontal permeability in the disturbed zone,  $d_s$  is the disturbed zone diameter,  $L$  is the drainage path length, and  $q_w$  is the drain discharge capacity.

Hansbo's analysis is based on the horizontal flow characteristics of the undisturbed zone ( $k_h$  or  $c_h$ ) to evaluate the radial consolidation. However, it is difficult to obtain due to the anisotropy of permeability and difference between laboratory and field measurement values (Bergardo et al. 1991, Chai and Miura 1999).

The consolidation characteristics of the disturbed zone are homogeneous and isotropic due to the disturbance (Lo 1991). To analyze the radial consolidation based on the consolidation characteristics of disturbed zone, Hansbo's solution is modified in this study. Since Hansbo's solution assumes an equal vertical strain, the ratio of horizontal permeability between the undisturbed and disturbed zones ( $k_h/k_s$ ).

Figure 1. Effect of  $k_h/k_s$  on the degree of consolidation: (a) Hansbo's method, (b) Proposed method

is the same as the consolidation coefficients ratio between the undisturbed and disturbed zones ( $c_h/c_{hs}$ ). By using this condition, rearranged the average degree of radial consolidation ( $\bar{U}'_r$ ) is

$$\bar{U}'_r = 1 - \exp(-8T_{hs} / \mu'_s) \quad (2)$$

where,  $\mu'_s = \ln(d_s/d_w) + [\ln(d_c/d_s) + \pi \cdot z(2L-z)(k_h/q_w) - 0.75] / (k_h/k_s)$ ,  $T_{hs}$  is a time factor based on  $c_{hs}$ .

The permeability reduction in the disturbed zone, frequently represented as  $k_h/k_s$ , is important factor for the vertical drain-enhanced consolidation. The effect of  $k_h/k_s$  on the analysis results is investigated both Hansbo's solution and modified solution. Figure 1 shows the effect of  $k_h/k_s$  on  $\bar{U}'_r - T_{hs}$  and  $\bar{U}'_r - T_{hs}$  curves. Other factors are maintained as a constant value ( $d_c/d_w=25$ ,  $d_s/d_w=5$ ), and well resistance is ignored.

As shown in Figure 1(a), the rate of consolidation by Hansbo's method is continuously retarded with increasing in  $k_h/k_s$ . However, the consolidation rate by proposed method (Figure 1(b)) is slightly speeded up and finally converged with increasing in  $k_h/k_s$ , because the rate of vertical drain-enhanced consolidation is governed by the permeability of disturbed zone (Basu and Prezzi 2007).

### 3 APPLICATION (BUSAN NEW-PORT SITE)

The consolidation behavior in Busan New-port site is analyzed to verify the proposed analysis. The rate of consolidation settlement is evaluated by Hansbo's solution and modified solution, and these results are compared with observed settlements in field.

#### 3.1 Soil properties of clay layers

The profiles of clay layer properties (Busan New-port) are shown in Figure 2. The natural water content ( $w_n$ ) and liquid limit ( $w_L$ ) vary 35~75% and 40~80%, respectively. The plastic limit ( $w_p$ ) exists in relatively narrow range from 20 to 30%.

Table 1. Void ratio and compression index of each clay layer

Property	Layer 1		Layer 2		Layer 3	
	U	R	U	R	U	R
$e_L$	1.81		2.22		1.35	
$e_0$	1.65	1.32	1.95	1.46	0.94	0.78
$C_c$	0.84	0.46	1.04	0.57	0.57	0.34
$c_v$ ( $10^{-4}$ cm <sup>2</sup> /sec)	7.1	3.8	13.0	4.8	22.0	5.0

Note. U: undisturbed clay, R: remolded clay

Figure 2. Profiles of soil properties

Although OCR at shallow depth is slightly larger than 1, the clay layers can be presumed normally consolidated. Busan clay can be divided into upper and lower clay layers based on EL - 30m.

#### 3.2 Consolidation properties of each clay layer

In this study, the clay layers of Busan New-port are divided into 3 layers for the consolidation analysis based on the soil properties. The consolidation tests were carried out for 50 samples for the natural clay and 3 samples for the remolded clay to figure out the consolidation characteristics of clay layers. Table 1 shows the void ratio, compression index ( $C_c$ ) and coefficient of consolidation ( $c_v$ ) representing the each clay layer.

#### 3.3 Extent of the disturbed zone

In this study, several assumptions are made to evaluate the extent of the disturbed zone: 1) the soil adjacent to the drain is completely remolded. Therefore, the void ratio of the clay adjacent to the drain is the same as that of the remolded clay at the same effective stress level; 2) the void ratio reduction due to the disturbance around the drains occurs faster than the consolidation settlement under a surcharge load. Therefore, ground settlement that occurred without applying the surcharge load is mainly caused by the void ratio reduction due to the disturbance; 3) the extent of the disturbed zone and the variation of the void ratio within the disturbed zone are a invariable property with depth; 4) the shape of disturbed zone is a circular cross section. With these assumptions, the extent of the disturbed zone is evaluated from measured ground settlement, which occurred in the interval between PVD installation and a surcharge loading.

Burland (1990) suggested that the  $e$ -log  $\sigma'_v$  relation for the remolded clay:

$$e_r = e_L (A - B \log \sigma'_v) \quad (3)$$

where,  $e_r$  is the void ratio of the remolded clay,  $e_L$  is the void ratio at the liquid limit,  $\sigma'_v$  is a vertical effective stress (kPa), and A and B are constants. For Busan clay, the values of A and B are 1.224 and 0.256, respectively (Hong 2011). Therefore, the

void ratio reduction ( $\Delta e$ ) due to the disturbance can be evaluated from the liquid limit and the natural water content.

Figure 3. Variations of void ratio in disturbed zone

Figure 3 shows two possible variations of the void ratio with radial distance from the center of the drain. Case a assumes a constant permeability or void ratio within the disturbed zone ( $r_s$ ). However, most studies (Onoue et al. 1991, Indraratna and Redana 1998, Shin et al. 2009) were consistently insisted a decrease in the permeability or the void ratio within the disturbed zone, although there are some differences in shape of variation (e.g. linear, bilinear, and parabolic). To consider variation of the permeability or the void ratio within the disturbed zone, case b assumes that the void ratio linearly increases from the value equal to  $e_r$  at the outer boundary of the fully disturbed zone ( $r_f$ ) to the initial void ratio ( $e_0$ ) of the undisturbed soil at the outer boundary of the transition zone ( $r_t$ ). For cases a and b, the volume changes due to the disturbance induced by PVD installation can be expressed as:

$$\Delta V = \pi \cdot r_s^2 \cdot H \cdot \Delta e / (1 + e_0) \quad \text{Case a (4)}$$

$$\Delta V = \pi \cdot [(r_f^2 + r_f \cdot r_t + r_t^2) / 3] \cdot H \cdot \Delta e / (1 + e_0) \quad \text{Case b (5)}$$

where,  $\Delta e$  is the void ratio reduction due to the disturbance, and  $H$  is the thickness of the target clay layer.

Figure 4 shows the ground elevation and total ground settlement during the entire period of the improvement. The measured settlement that occurred between the PVD installation and surcharge loading is 85.6 cm. This ground settlement could be occurred by the two reasons: 1) void ratio reduction within the disturbed zone; and 2) consolidation settlement in the undisturbed zone due to the sand mat. The consolidation settlement in the undisturbed zone is calculated as 13.8 cm by using Zeng and Xie's solution (1989). Therefore, the ground settlement caused by the void reduction within the disturbed zone is 71.8 cm.

Figure 4. Ground level and settlement of Busan New-port site

Table 2. Analysis conditions

Case	Analytical condition	
	Hansbo's method	Proposed method
1	No disturbance, $c_h = c_v$	No disturbance, $c_h = c_v$
2	$c_h = c_v$ in disturbed zone, $c_h = 2c_v$ in undisturbed zone	No disturbance, $c_h = c_{hs}$
3	$c_h = c_v$ in undisturbed zone, $k_h/k_s = 2.5$	$c_h = c_{hs}$ in disturbed zone, $k_h/k_s$ or $k_h/k_f = 2.5$
4	$c_h = c_v$ in undisturbed zone, $k_h/k_s = 5.0$	$c_h = c_{hs}$ in disturbed zone, $k_h/k_s$ or $k_h/k_f = 5.0$
5	$c_h = c_v$ in undisturbed zone, $k_h/k_s = 10.0$	$c_h = c_{hs}$ in disturbed zone, $k_h/k_s$ or $k_h/k_f = 10.0$

The extent of the disturbed zone ( $r_s$ ) for case a is easily calculated as 21.6 cm based on 71.8 cm of the ground settlement. However, it is hard to calculate the values of  $r_f$  and  $r_t$  for case b because both  $r_f$  and  $r_t$  values are variables. For the linear spatial variation, previous studies suggested that the  $r_f$  is approximately 1.0~1.6 $r_m$  (Onoue et al. 1991, Hird and Moseley 2000, Sharma and Xiao 2000), where  $r_m$  is the equivalent radius of the mandrel. In this study, since the  $r_f$  is assumed to be 1.0 $r_m$  (8.0 cm), calculated value of  $r_t$  is 4.1 $r_m$ .

### 3.4 Consolidation analysis

The consolidation rate of Busan New-port is predicted using both Hansbo's method and proposed method. To evaluate effect of consolidation properties, parametric study is performed for a set of different conditions, as shown in Table 2. In case of proposed method, two possible permeability variations within disturbed zone are considered. Based on the PVD property,  $d_w=6$ ,  $d_c=135$ cm, and  $q_w=15$ cm<sup>3</sup>/sec are used for analysis.

Figure 5 shows the rate of consolidation settlement predicted by both Hansbo's method and proposed method, and the measured settlement for the layer located above EL -30 m. The average degree of consolidation ( $\bar{U}$ ) is calculated by using Carillo's suggestion (1942), and then the consolidation settlement is calculated by considering the non-linear relationship between the consolidation settlement and the degree of consolidation.

As shown in Figure 5(a), Hansbo's analysis for cases 1 and 2 overestimate the settlement rate compared with the measured one because the coefficient of horizontal consolidation in the disturbed zone is assumed to be the same as  $c_v$ . All cases do not fit well with the measured settlement. To obtain the best result by Hansbo's analysis, it is necessary to know proper values of  $c_h$  and  $k_h/k_s$ . However, the suitable  $k_h/k_s$  ratio appears to vary with the assumed  $c_h$  value.

Proposed analysis (Case a) results show in Figure 5(b). The settlement rate at a certain time is underestimated to compare with the measured settlement, since the extent of disturbed zone is evaluated relatively large compared with the real condition due to an assumption for a constant permeability or void ratio within the disturbed zone. Basu et al. (2006) suggested the simplified  $\mu_s$  for the linear spatial variation in disturbed zone (Case b). Using this suggestion, the settlement rate for case b is calculated by the proposed method, as shown in Figure 5(c). Case 4 ( $k_h/k_f = 5.0$ ) is well matched with measured settlement within 100 days, and then case 3 ( $k_h/k_f = 2.5$ ) shows good agreement with the measured settlement after 100 days. Since the typical value of  $c_h/c_v$  could be larger than 1.0 in nature, the  $k_h/k_f$  is presumed larger than 3.0, based on the consolidation test results. The slightly underestimation of the settlement rate predicted with the presumed  $k_h/k_f$  value may occur due to the difference in the surcharge schedule. In the analytical solution,

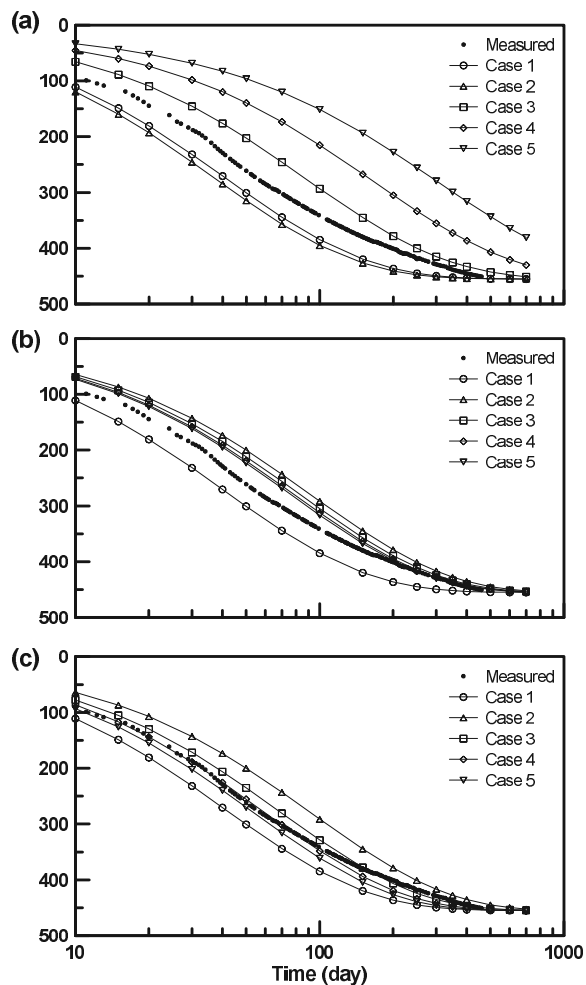

Figure 5. Measured and predicted settlement rate for the layer above EL -30m: (a) Hansbo's method, (b) Proposed method with case a, (c) Proposed method with case b

the surcharge load is assumed to be applied all at once, while, in the field, the surcharge load is applied incrementally.

#### 4 CONCLUSION

In this study, the radial consolidation enhanced by the vertical drain is discussed with the analytical method existed, and the modified solution is suggested. Through parametric study and comparison between the calculated and measured settlement rates, the results are summarized as follows.

As the degree of disturbance increases, Hansbo's analysis shows that the time factor  $T_h$  increases for a certain degree of radial consolidation. However, the time factor for proposed analysis ( $T_{hs}$ ), which corresponds to a certain degree of radial consolidation, slightly decreases as the degree of disturbance increases. Furthermore, proposed analysis gives the almost identical  $\bar{U}_r - T_{hs}$  curves when the  $k_h/k_s$  value becomes larger than 20.

For Busan New-port site, the extent of the disturbed zone is evaluated using two possible void ratio variations within the disturbed zone. When a constant permeability or void ratio within the disturbed zone is assumed, the extent of the disturbed zone  $r_s$  is estimated to be  $2.7r_m$ . For the linear spatial variation within the disturbed zone, the extent of the transition zone  $r_t$  is estimated to be  $4.1r_m$  with the same equivalent radius between fully disturbed zone and mandrel ( $r_f = 1.0r_m$ ).

The settlement rate predicted by the proposed analysis is well matched with the measured field settlement when the  $k_h/k_f$  ratio is 2.5 with a linear spatial distribution of the permeability

within the disturbed zone. The proposed method has advantages to evaluate the extent of disturbed zone and it is less influenced by the disturbance effect than Hansbo's method.

# Adjusting the soil stiffness with stabilisation to minimize vibration at Maxlab IV – Asynchrotron radiation facility in Sweden

Ajustement de la rigidité du sol par stabilisation pour minimiser les vibrations à Maxlab IV, un centre de rayonnement synchrotron en Suède

Lindh P.  
*Peab Anläggning AB, Sweden*

Rydén N.  
*Lund University, Sweden*

**ABSTRACT:** In Lund a new next-generation synchrotron radiation facility are under construction, MAX IV. This facility requires extraordinary techniques for the earthworks at site. The vibration requirements are very stringent compared to traditional earthwork standard. The tolerance is 26 nm (1 s rms above 5 Hz) and this requires a very good damping from external and internal vibrations. Different solutions were discussed and simulated during the design phase and the best performance was achieved with a four meter thick layer of stabilised soil below the concrete foundation. The soil consists of clay till with high clay content. During the design phase many different binder combinations were tested to meet the design criteria regarding seismic modulus. In order to achieve a monolith the binders' setting time was critical since the soil is stabilised in 0.35 meter layers were the next layer are mixed into the layer below. The binder to best meet both design and construction requirements were a combination of quicklime and ground granulated blast furnace slag (GGBFS).

**RÉSUMÉ :** Un nouveau centre de rayonnement synchrotron de dernière génération, MAX IV, est en cours de construction à Lund. Ce centre nécessite des techniques exceptionnelles pour les travaux de terrassement sur le chantier. Les exigences de vibrations sont très strictes par rapport à la norme de terrassement traditionnel. La tolérance est de 26 nm (valeur efficace 1 s rms au-dessus de 5 Hz), ce qui nécessite un très bon amortissement des vibrations internes et externes. Des solutions différentes ont été discutées et simulées au cours de la phase de conception et la meilleure performance a été réalisée avec une couche épaisse de quatre mètres de sol stabilisé en dessous de la fondation en béton. Le sol se compose de till argileux à forte teneur en argile. Au cours de la phase de conception, de nombreuses combinaisons de liants différents ont été testées pour répondre aux critères de conception concernant le module sismique. En raison de la réalisation d'un monolithe, le temps de durcissement était critique puisque le sol est stabilisé en couches de 0,35 mètre dont la couche suivante est mélangée dans la couche de dessous. Le liant qui répondait le mieux aux exigences à la fois de conception et de construction était une combinaison de chaux vive et de laitier granulé de haut fourneau (SLGHF).

**KEYWORDS:** Soil stabilisation, seismic testing, vibration, P-wave.

## 1 INTRODUCTION

Max-lab is a Swedish facility for materials research based on synchrotron radiation. The new version, Max IV, will be 100 times more efficient than any now existing comparable synchrotron radiation facility in the world. The location of the new Max-lab is placed just outside the city of Lund in southern Sweden. The geology consists of 12 to 16 meters of soil (clay till) on top of the bedrock. Close to Max IV runs a major highway which will introduce ground vibrations. Since the facilities are sensitive to vibrations an extensive measurement program of background vibrations were executed.

Several foundation alternatives were discussed and some of them were tested with FEM-simulations to determine which alternative that fulfilled the requirement of damping both external and internal vibrations. The alternative that best fulfilled external and internal damping was a 4 meter thick stabilised layer underneath the concrete slab.

### 1.1 Geotechnical testing

The pre-investigation of the geology included geotechnical sounding as well as geophysical measurements as well as core drilling through the soil layers down into the bedrock. After the in-situ investigation and evaluation a geological model for the site was developed. From this model minor excavations were performed for soil sampling. The soils were classified and an extensive testing was performed to evaluate which binder or binder combination that was optimal for the soils. The major parts of the soils were clay till with layers of silty sand till.

Three different binders were tested, lime; cement and slag. The slag was ground granulated blast furnace slag (GGBFS). The clay till contained up to 40% clay and the sandy silt till has low clay content. The high clay content indicated that lime should be used to break up the clay. However, lime alone would not work with the sandy silt till. The clay till from this area have been tested in a earlier study and the combination of lime and slag was discovered to be efficient in this type of soil (Lindh, 2004). Two different binder recipes were chosen from the initial laboratory testing;

- Cement/slag (80/20)
- Lime/slag (50/50)

During the construction phase of the mock-up, cement and slag were chosen due to the current weather conditions and the time schedule for the mock-up. During the seismic testing of the mock-up cracks were found in the stabilized material. The results indicated that the cracks were introduced during construction of the stabilised layers. The layer in question was milled 50 mm down into the layer below to ensure interaction between layers. The binder's working period was not sufficient to guarantee that the next layer could be milled into the stabilised bottom layer without causing cracks. This resulted in a change of binder to a combination of lime and slag (50/50).

FE-calculations as well as seismic measurements performed on the mock-up showed that a shear wave velocity needed to be at least 900 m/s in the stabilised soil. In this case it corresponds to a compression wave velocity (P-wave) of 1430 m/s. The seismic velocity testing was performed according to a methodology developed at Lund University and tested on

cement stabilised soils (Rydénet *et al.*, 2006). New samples were prepared to measure the early strength development, see Figure 1. After more than 1200 hours the samples were removed from the plastic mould that supported the samples during compaction and in the beginning of the curing period of the samples. This resulted in a small drop in P-wave velocity.

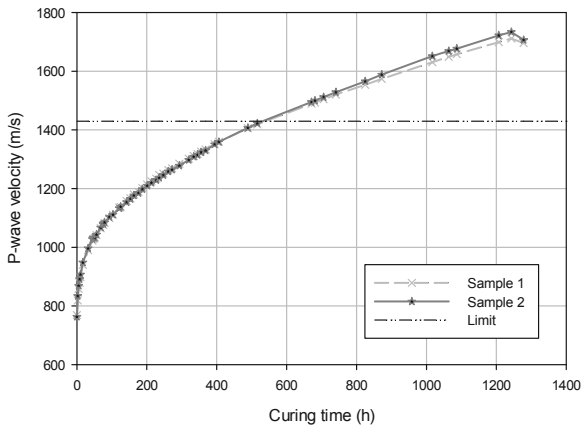

Figure 1. The figure shows the development of compressive wave velocity with time. The drop in velocity after 1240 hours is caused by removing the samples from the plastic mould.

The seismic measurements of the prepared samples were performed several times every 24 hours for the first 400 hours. In Figure 2 the measured frequency is shown together with higher frequency modes.

Figure 2. Different frequency modes for sample number 2 after 56 hours curing. The lowest frequency peak corresponds to a fundamental mode longitudinal resonance frequency of 2074 Hz which corresponds to a P-wave velocity of 1043 m/s.

The longitudinal resonance frequency of 2074 Hz corresponds to a P-wave velocity of 1043 m/s for sample 2. The samples needed approximately 500 hours of curing in 20 degree Celsius to meet the requirements regarding P-wave velocity.

## 2 IN-SITU MEASUREMENTS

The quality testing in-situ was done both as ordinary testing with binder content, MCV, pulverization and  $E_{vib}$  measurement with the compaction roller. The testing procedure also included sampling from the stabilised soil when the mixer had made two mixing passes. The stabilised soil that would be tested was excavated and transported to a field laboratory for compaction in plastic moulds. After compaction the P-wave velocity was measured and compared with the laboratory mixed samples. Most of the production samples (PS) were stored in room temperature to ensure the same conditions compared with the laboratory compacted samples.

There was a great variation in the development of P-wave velocity versus curing time for different samples, see Figure 3.

The causes of this variation were a combination of different parameters such as;

- Variation in water content
- Variation in density
- Variation in grading (clay content)
- Variation in the degree of pulverization

In order to study the development of P-wave at different temperatures two pairs of specimens were manufactured. One pair was stored in room temperature and the other pair was stored at outside temperature. The difference in P-wave development is shown in Figure 3. The different samples are denoted PS9 and PS11 in the figure. The sample PS 9 was stored at room temperature and the sample PS 11 was stored at outside air temperature.

Figure 3. Development of compressive wave velocity with time for

reference and production samples.

The production sample denoted PS9 required more than 2400 hours achieving the limit value of 1430 m/s and the sample PS 11 did not achieve the required limit. However, storing a specimen in an outside air temperature is not fully correct compared to the in situ conditions due to larger volume of stabilised soil and in the in-situ case the heat transfer is one dimensional. It does however give an idea of how low temperature will affect the stabilised soil in-situ.

An example of the in situ seismic measurements is shown in Figure 4.

Figure 4. A result from seismic in-situ measurement along the surface of the stabilised layer is presented in the figure. The top layer has almost reached a surface wave velocity ( $\sim 0.92V_s$ ) of 800 m/s at the time for measurement. The target shear wave velocity after curing is 900 m/s.

The in-situ measurement of the stabilised soil is performed with the same equipment as used for sample testing. However, the in-situ testing involves the whole volume and gives a true value of the stabilised soils' performance. The seismic testing will be followed up in future with testing on the concrete slab.

### 3 CONCLUSIONS

Soil stabilisation with binders increases the stiffness (E-modulus) of the soil and thereby changes the resonance frequency of the soil. In this project the soil stabilisation has been a key issue to meet the requirements regarding vibrations in a cost effective way. It has been proven that it is possible to achieve a homogenous stabilised monolithic ring with a circumference of 528 meters and a depth of 4 meters.

The homogeneity of the stabilised material is a result of an extensive testing program in both laboratory and full scale. The binders' working period has also been an important issue to ensure a crack-proof construction.

It has also been shown that seismic testing works very well for both laboratory and in-situ testing of stabilised soils.

**ABSTRACT:** In a major port development project in Singapore, a containment bund using modified geotextile tubes (M-GT) filled with cement mixed soil has been constructed. The main purpose of this bund is to create a containment area to contain any sediment plumes due to construction activities (i.e. dredging activities, dumping activities and sand-filling activities). The containment bund also serves as a retaining structure to retain dredged materials during the sand-key construction and other port expansion works. This paper presents the key consideration in the innovative design and construction of a geotextile containment bund. In addition, instead of usual sand fill, the dredged soil mixed with cement was used as the fill material in this bund. Among the challenges faced in this project were the great water depth of this containment bund location (>25m) and high traffic volume in Singapore water course as the site is next to the existing operating port terminal. Extensive field instrumentation and monitoring were carried out during and post construction phase to verify the design, as well as ascertain the performance of the geotextiles containment bund system.

**RÉSUMÉ :** Dans un important projet de développement portuaire à Singapour, une digue de confinement utilisant des tubes géotextiles modifiés (M-GT) et remplis de terre mélangée au ciment, a été construite. Le but principal de cette digue est de créer une zone de confinement afin de contenir les débris de sédiments provenant des travaux de construction (c'est-à-dire travaux de dragage, de déversement et de remplissage au sable). La digue de confinement sert également de structure de retenue pour retenir les matériaux de dragage lors de la construction de la tranchée d'étanchéité et d'autres travaux d'extension de port. Cette étude présente le facteur clé dans la conception innovatrice et la construction d'une digue de confinement en géotextiles. En outre, au lieu du remplissage au sable habituel, le sol dragué est mélangé avec du ciment avant d'être utilisé comme matière de remplissage dans cette digue. Parmi les défis relevés durant ce projet étaient la grande profondeur des eaux à l'emplacement de la digue de confinement (> 25m) et le volume du trafic maritime dans les eaux de Singapour vue que le site se trouve à proximité du terminal portuaire existant. Des instrumentations et mesures approfondies ont été menées pendant et après la phase de construction pour vérifier la conception, de même que la performance du système de digue de confinement en géotextiles.

**KEYWORDS:** Geotextile tubes, containment bund, cement mixed soil.

## 1 INTRODUCTION

A containment bund consisting of modified geotextile tubes (M-GT) filled with cement mixed soil has been constructed for a major port development project in Singapore. This containment bund forms part of the Pasir Panjang Terminal Phase 3 & 4 Expansion Project, which is located at the Southern part of Singapore water (Figure 1). During the project construction phase, this bund serves as a retaining structure to retain dredged materials and at the same time contains any sediment plumes arises from construction activities from being transported towards the nearby forest reserve area by currents. This containment bund, termed as a geotextile containment bund, is being constructed by systematically stacking of modified geotextile tubes (M-GT) and filling of cement mixed dredged soil. A typical cross section of the geotextile containment bund is shown in Figure 2.

A "geotextile tube" is a tubular container (diameter 1m to 10m) that is formed in-situ, on land or in water, by hydraulically filling the tube with sand or dredged material (Pilarczyk, 2000) and Lawson, 2006). On the other hand, "geotextile container" is made of geotextile sheet laid onto a split-bottom barge, filled mechanically with sand or other fill material, and sewn the top opening to form into a closed "container". The barge will then

move to the desired position, and the bottom of the barge will open allowing the containers to sink into the sea at the intended location. The volume of these containers can range from 100m<sup>3</sup> to 800m<sup>3</sup>.

Figure 1 Location of project site in Singapore (Google image)

The modified geotextile tube (M-GT) introduced in this paper is an innovative application, which combines the structure / shape of a “geotextile tube” and the method of installation of a “geotextile container”. The diameter of M-GT is 5m and the length is 25m (limited by barge length). The theoretical maximum volume of M-GT is 490m<sup>3</sup>. However, for practical reasons, the filled volume is only about 290m<sup>3</sup> or 60% filled in this project.

Figure 2 Typical cross section of geotextile containment bund

Two geotextile containment bunds were constructed in this project. The length of bund 1 is 500 m and bund 2 is 1800 m. Bund 1 was constructed first in order to provide a staging ground for other construction activities at the site. The layout and length of the bunds are shown in Figure 3.

Figure 3 Length of geotextile containment bund 1 and 2 (Plan view)

## 2 DESIGN AND CONSTRUCTION OF GEOTEXTILE CONTAINMENT BUND

In the design of this bund, there are a few stability criteria that have to be fulfilled: Stability against hydraulic force of waves and current, local stability against sliding failure, local stability against slip failure, settlement and deformation. The tensile strength of the geotextile material is one of the major design parameters. This is because the installation of the tubes at water depth of 25m is deemed to be ‘extreme’ in the field installation of geotextile tubes and containers.

The installation process of the M-GT consists of five (5) main phases, namely:-

1) Filling of the M-GT – The dredged material mixed with cement, known as cement mixed soil, is being pumped into the modified geotextile tube via the inlet ports that are available at the top face of the M-GTs.

2) Opening of split-hopper barge – the bottom of the split-hopper barge opens slowly to allow the exit of the filled M-GTs through its opening. High tension in geotextile is expected to be experienced at this stage.

3) Free-falling of M-GTs onto the seabed – Air pockets inside the tube or container during free-falling would exert certain forces onto the geotextile and cause higher strain (Pilarczyk 2000). Tensions are generated in the tube due to the balancing of these forces, fill weight, buoyancy, drag, etc. (Lawson, 2006).

4) Impacting onto the seabed – At the point of impact, the kinetic energy of the falling tube is converted to elastic energy, which will reshape the tube, from a cone shape into a transitional cylindrical shape and eventually into a semi-oval shape or rectangular shape (Pilarczyk, 2000).

5) Stabilized phase of the M-GTs – The final shape of the tube attained depends on a number of interrelated factors such as the volume of fill, internal shear resistance of the fill material and the stiffness of the geotextile material (Lawson, 2006).

There are a number of equations and formulas available for the determination of the tension development in some of the stages mentioned above. The equations used in the design of M-GT in this project can be found in Chew et al. (2010).

The construction sequence of the bund is illustrated in five steps (Figure 4(a) to (e)).

Figure 4 (a) to (e) Construction sequence of geotextile containment bund (cross-section view)

## 3 USE OF CEMENT MIXED SOIL (CMS) AS IN-FILL MATERIAL

Discarded soil from other excavation projects on land or sea in Singapore, and dredged materials from port extension works have been mixed with cement to form into Cement Mixed Soil (CMS), and was used as in-fill material in the M-GTs and as the core of the geotextile containment bund as shown in Figure 2. In order to satisfy the stability criteria of the geotextile containment bund, the cement mixed soil has to achieve a design value of unconfined compressive strength  $q_u$  of 200kN/m<sup>2</sup>. After taking into account of soil variability and the factor between the laboratory test result and in-situ achieved results, the targeted in-situ unconfined compressive strength is state as 1.3x200, which is 260kN/m<sup>2</sup>.

## 4 PERFORMANCE OF CONTAINMENT BUND

The performance of the bund has been monitored during and after the construction through an extensive instrumentation plan.

A total of 28 numbers of M-GTs were instrumented and monitoring at various stages of the installation process. One of the key parameters was that monitored closely is the strain development of the M-GT at different stages. The results of the monitoring during the installation process were presented by Chew et al. (2011) and it showed that high tensile forces of about 180kN/m were recorded at the bottom of M-GT during the impact onto the seabed.

Hydrographic survey was used to monitor the shape of the installed M-GTs, which is one of the performance indicators of this design. The accuracy of the installation was determined by using survey results conducted before and after the dumping of the instrumented M-GTs. The overall construction progress of the bund was also tracked using hydrographic surveys that were conducted every 5 days. The profile of the bund can be plotted using the survey results as shown in Figure 5, which shows one of the completed bund.

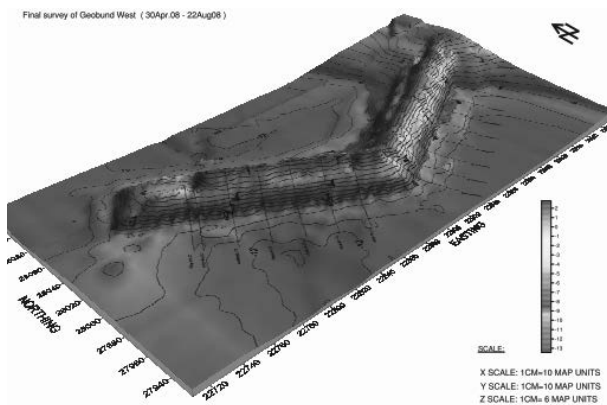

Figure 5 Profile of completed bund 1

After the completion of the bund, a total of 11 instrument clusters have been installed to monitor the performance of the containment bund during other construction activities such as the filling of dredged soil behind the containment bund and soil improvement works for the dumped material within the containment bund.

Out of the 11 instrumented clusters, 6 of them were placed at the top of the bund and the remaining was installed to monitor the slope of the bund by using a staging. The cross section of the instrument clusters is given in Figure 6.

Figure 6 Instrumentation cluster installed in the containment bund

The results from the inclinometers installed at the top and side faces of the bund are discussed here. The location of the inclinometer is at CH. 1370 (Figure 7). The lateral deformation in the section perpendicular to the centre line of the bund is plotted in Figure 8 for both top and side inclinometer.

Figure 7 Location of inclinometers at CH. 1370 of the bund (Plan view)

The inclinometer readings show that the maximum deformation of the bund centre is 10mm at elevation of -8.5m (Figure 8a). The measurement was taken at 911 days after the completion of the bund at that location. This shows that the containment bund has remained stable throughout the period of other construction activities that occurred during this period.

Figure 8b shows the lateral deformation at the sides of the bund, which was also found to be within 10mm, where the maximum deflection occurred close to the bottom of the bund. Higher lateral deformation of up to 30mm was also recorded by the inclinometer at elevation above the bund (i.e. -5m to +10m). The lateral movement above the surface of the bund (side inclinometer) indicates that the dredged filled material has been placed onto the sides of the bund and at the same time being treated.

The settlement measured by extensometers installed on the top and side instrumentation clusters and settlement plates at the top of the bund are given in Table 1. The settlement readings showed that the geotextile containment bund filled with cement mixed soil has remained stable and performed as expected throughout the construction period of this project.

Table 1 Settlement of containment bund

Elevation	Settlement (mm)

## 5 CONCLUSION

The construction of the geotextile containment bund using modified geotextile tubes (M-GT) filled with cement mixed soil (CMS) has been completed successfully over a total length of 2.3 kilometres in Singapore. Field measurements of lateral deformations and settlements showed that the bund has performed well within the design limits and expectations. The innovative use of discarded soil from other excavation projects on land or sea via mixing with cement is proven to be a good fill material. This CMS material was shown to be able to achieve highly uniform and well controlled properties, and deemed to be suitable as in-fill material for geotextile tubes and the core portion of a containment bund.

# Reinforcement of completely decomposed granite with discrete fibres

## Renforcement de granite complètement décomposé avec des morceaux fibres

Madhusudhan B.N., Baudet B.A.

*The University of Hong Kong, Hong Kong*

**ABSTRACT** :The use of discrete fibres as reinforcing material for soils has been researched by many, e.g. Gray and Al-Refeai (1986), Maher and Ho (1994), Crockford et al. (1993), Santoni et al. (2001), Consoli et al. (2009a), but these studies have been generally done independently and have not always been consistent. Silva dos Santos et al. (2010) used data gathered through many years of study to develop a framework of behaviour for a poorly graded quartzitic sand reinforced with polypropylene fibres. In Hong Kong, the construction industry has used reinforcement with continuous fibres for some time, but it is mainly applied to landscaping of otherwise stabilised slopes, for example as a green cover on an existing shotcreted slope. Using randomly distributed short discrete fibres in Hong Kong completely decomposed granite (CDG) could help stabilise the soil while keeping the density low enough to allow growth of vegetation. It is not guaranteed, however, that a well graded residual soil like CDG would behave in the same way as sands used by previous researchers. Laboratory tests have been carried out on completely decomposed granite using short discrete polypropylene fibres as a reinforcing material. The fibres are randomly distributed in the soil. It was found that the fibres increase the unconfined compressive strength of the CDG prepared at its maximum dry density by up to tenfold for fibre contents less than 1%. The behaviour of the fibre-CDG mixture during drained triaxial compression changed from dilative to compressive, with more effects at low confining pressures. These tests seem to indicate that discrete fibres could be considered for improving the performance of CDG.

**RÉSUMÉ** : L'utilisation de fibres pour renforcer les sols ont déjà fait l'objet de nombreux travaux de recherche e.g. Gray and Al-Refeai (1986), Maher and Ho (1994), Crockford et al. (1993), Santoni et al. (2001), Consoli et al. (2009a), mais ces études ont été généralement faites indépendamment et elles n'ont pas toujours été synthétisées. Silva dos Santos et al. (2010) ont utilisé les données obtenues au cours d'années de recherche pour développer un modèle de comportement pour un sable quartzitique uniforme renforcé avec des fibres en polypropylène. A Hong Kong, l'industrie de la construction a utilisé des fibres continues comme moyen de renforcement depuis longtemps, mais l'application se limite à l'aspect paysager de pentes déjà stabilisées, par exemple pour la plantation de surfaces de pentes recouvertes de béton projeté. L'utilisation de fibres courtes distribuées de façon aléatoire dans le granite complètement décomposé de Hong Kong (CDG) pourrait aider à stabiliser le sol tout en gardant sa densité assez basse pour permettre à la végétation de pousser. Il n'est pas garanti cependant qu'un sol résiduel a la distribution granulométrique bien calibrée comme le CDG se comportera de la même façon que les sables utilisés par les chercheurs précédents. Des essais de laboratoire ont été faits sur du granite complètement décomposé en utilisant du béton projeté et des fibres courtes en polypropylène comme matériau de renforcement. Les fibres sont distribuées de façon aléatoire dans le sol. On a trouvé que les fibres ont pour effet de multiplier par presque dix fois la résistance en compression simple du CDG préparé à sa densité sèche optimale, pour une teneur en fibres de moins de 1%. Le comportement du mélange CDG-fibres lors de l'essai triaxial drainé en compression est passé de dilatant à contractant avec plus d'effet aux pressions faibles. Les essais paraissent indiquer que l'utilisation de fibres courtes pourrait être considérée pour améliorer la performance du CDG.

**KEYWORDS**: laboratory tests ; reinforced soils ; residual soil

## 1 INTRODUCTION

Adding fibres to soil can be an effective way of strengthening it, by providing tensile strength at high strains. The factors influencing the effectiveness of the fibre-reinforced soils are a) the type of soil and its deformation behaviour; b) the type of fibre and its specifications (fibre length, fibre content and its aspect ratio). A careful study of the mechanics of the fibre-reinforced soil will help practising and design engineers to understand better its behaviour under different loading conditions.

Hong Kong is a modern city with growing population, so that engineers are pressed to optimise land utilisation. The topology of Hong Kong has led to urban development on natural or man-made slopes. Conventional methods of stabilising slopes such as shotcreting the whole face of the slope (current practice) are neither cost effective nor environmentally friendly and alternative sustainable methods are being sought after.

Many researchers have produced a large body of research on the performance of discrete fibres with soils (Gray and Al-Refeai, 1986; Maher and Ho, 1994; Crockford et al., 1993; Santoni et al., 2001; Consoli et al., 2009a), but these studies

have been generally done independently and they have not always been consistent (Silva dos Santos et al., 2010). This paper presents initial results from laboratory tests performed on completely decomposed soil reinforced with discrete fibres.

## 2 MATERIALS AND METHODS

Completely decomposed granite was used as the host soil. It originates from in-situ weathering of the parent igneous rock, and is one of the most common geo-materials in Hong Kong. The short discrete fibres used in the tests presented here were similar to those used by Silva dos Santos et al. (2010).

### 2.1 *Materials tested*

The completely decomposed granite (CDG) host soil was obtained from a construction site near Beacon Hill, Hong Kong. Completely decomposed residual soils are well-graded in nature as the tropical climate has weathered the parent rock to a material comprising gravel and sand grains down to silt and clay-sized particles. Coarser particles are usually of quartz origin owing to its high chemical resistance while finer particles are most likely other primary hydrous minerals, such as

kaolinite and feldspar (Yan and Li, 2012). The grain size distribution (shown in figure 1) reflects that the soil has 16% particles finer than 63 $\mu$ . The specific gravity of the soil was found to be 2.65. From Standard Proctor compaction tests, the maximum dry density of the soil was determined as 1.93Mg/m<sup>3</sup> with an optimum moisture content of 12.3%. Tests on particles finer than 425 $\mu$  indicated the plastic and liquid limits to be 25.6% and 35.6% respectively. Using the Unified Soil Classification System (USCS) the soil can be classified as clayey sand of low plasticity (SC-CL).

The fibres used are short filaments made of polypropylene similar to those used by Silva dos Santos *et al.* (2010). They are chemically inert and have uniform characteristics, with a relative density of 0.91, a tensile resistance of 120MPa, an elastic modulus of 3GPa and a range of linear deformation at rupture between 80% and 170%. The dimensions of the fibres used in the tests were 0.023mm in diameter and 24mm long (Silva dos Santos *et al.*, 2010). After performing a series of unconfined compression tests on CDG reinforced with a range of fibre contents (0.3 – 1%), it was decided to continue the study with 0.3% of fibre per weight in the triaxial tests.

Figure 1. Particle size distribution of CDG.

## 2.2 Testing apparatus, methods and sample preparation

### 2.2.1 Uniaxial Compression Test

Unconfined compression tests on CDG and CDG+fibre soils were performed in a uniaxial compressive testing machine. The particle sizes passing 2mm diameter sieve were used for preparing specimens in a 38mm diameter; 76mm height mould at maximum dry density and optimum moisture content. The compression tests were performed at 0.5mm/min in all cases.

### 2.2.2 Triaxial Testing

Drained triaxial tests were performed using a conventional triaxial apparatus with a computer controlled GDS cell and back pressure controllers. The shearing tests were performed with a constant effective stress on specimens of both unreinforced and reinforced (with polypropylene fibres) CDG soil.

The soil was first soaked in water with a deflocculating agent and left for air drying, then it was sieved to constituent particle sizes so that the samples could be prepared in exact proportion as shown in figure 1, discarding particles above 5mm. Loose specimens were prepared, avoiding macro-voids and taking care of minimising membrane penetration. The specimens of 76mm diameter and 152mm height were prepared in a sample preparation mould.

The samples were saturated under back pressure and the effective confining pressures ranged from 100 to 500kPa. Saturation was monitored in each test, ensuring Skempton *B* values of at least 0.92 throughout the testing programme. The axial strains were measured outside the cell using a standard displacement transducer. The triaxial tests were run at a low

axial strain rate of 0.01% per minute to ensure no excess pore pressure development within the sample (this was checked by measurement at the opposite end of specimen). The membrane and area corrections were made as per the recommendations proposed by La Rochelle *et al.* (1988). The void ratios are calculated averaging from that obtained by the initial density of the sample and the final moisture content, taking account of the measured volume change in all the stages. In all tests the difference in specific volume compiled was less than 0.02.

## 3 TEST RESULTS

### 3.1 Unconfined compressive strength

Representative unconfined compression test results on pure CDG and CDG + 0.5% fibre are presented in figure 2. The plot clearly shows that the specimens of reinforced CDG yielded at very high strain, contributing an additional tenfold strength to the soil. On the other hand unreinforced CDG yielded at very low strength (131kPa) and low strain.

Figure 2. Unconfined compression of CDG and fibre-reinforced CDG.

### 3.2 Triaxial shearing

Triaxial drained tests were performed on isotropically consolidated specimens of pure CDG and reinforced CDG (Table 1). Some specimens were over-consolidated by a ratio of OCR=5 before being sheared. Details of the tests are shown in Table 1 (UR and R refer to unreinforced and reinforced specimens respectively).

Table 1. Summary of the triaxial tests.

Test	$v_0$	$v_c$	$p_c$ (kPa)	OCR
UR 100	1.42	1.32	112.0	5
UR 200	1.42	1.37	210.4	1
UR 500	1.48	1.32	499.6	1
R 100	1.58	1.36	98.9	5
R 200	1.43	1.32	202.9	1
R 500	1.58	1.41	499.4	1

The void ratios determined after consolidation (before shearing) were found to vary between 0.32 and 0.37 for pure CDG specimens and 0.32 and 0.42 for CDG-fibre specimens. Only dense specimens were prepared for the test programme. Looser specimens were difficult to prepare due to the presence of macro-voids which caused an initial collapse of the specimen, resulting in void ratios after consolidation within the same range as those for the dense specimens.

The stress-strain and volumetric responses during shearing are shown in figure 3. The stress-strain response (figure 3a) shows that the reinforced specimens generally have higher

strength and higher initial stiffness at the beginning of shearing, when compared to their unreinforced counterparts. However the reinforced specimens that mobilised their full strength only did so at shear strains in excess of 20%. The unreinforced specimens on the other hand either reached a constant stress by 20% strain or they showed strain-softening, depending on their consolidation history. Unlike the other reinforced specimens, R100 kept gaining strength and never reached critical state even at large strains (about 50%). This may be due to the over-consolidation history of the specimen, which may have released some of the tension in the fibres prior to shearing. The peak strengths of reinforced CDG were calculated to be 1.76 (100kPa), 1.29 (200kPa) and 1.26 (500kPa) times that of the pure CDG.

Similar behaviour on fibre-reinforced sands is reported by Consoli *et al.*, 2007, Consoli *et. al* (2005) and Silva dos Santos *et al.* (2010). For example Silva dos Santos *et al.* (2010) found that the effect of fibres depends on the effective stress at which they are sheared, reducing marginally with increasing effective stress. For sands, it is already reported that at low effective stress, adding fibres contributes to reducing the degree of dilation in the reinforced specimens (Silva dos Santos *et al.*, 2010). The persistent strain hardening behaviour (figure 3a, R100) was also observed by Consoli *et. al* (2005) on Botucatu residual soil, however their data were limited to strains of about 25%. In the present study, the specimens were sheared to strains up to 50% and it is clear that the strain hardening behaviour of specimens R200 and R500 stopped beyond  $\varepsilon_s > 35\%$  to reach a critical state. The governing mechanism for the strain hardening behaviour of R100 specimen might therefore be due either to the effect of low effective stress or to the effect of over-consolidation, or a combined effect.

The effect of the fibres on the volumetric response of the reinforced CDG in comparison seems to be that of restricting the degree of dilation in the specimen sheared at lower effective stresses, while at higher effective stress this effect is not so evident (figure 3b). The over-consolidated specimen of reinforced CDG shows a different volumetric response i.e. it tends to dilate after 20% shear strain even though it is expected that reinforcement will impede dilation. This behaviour is again either due to over-consolidation or to low effective confining stress. Previous findings on Botucatu residual soils (Consoli *et. al.*, 2005) and other pure sands may be extrapolated to normally consolidated CDG, but the effect of over-consolidation is new and more test results are required to explain it within the critical state framework.

The stress-dilatancy behaviour of CDG (black symbols) and reinforced CDG (grey symbols) samples tested at different effective stress are shown in figure 4. All normally consolidated specimens, reinforced and unreinforced, show a typical frictional behaviour. The pure CDG specimens converge to a unique frictional critical state stress ratio ranging from  $M=1.57$  to  $M=1.61$ . The reinforced CDG specimens tested at effective stresses of 200 and 500kPa converged to a critical stress ratio of  $M = 1.83$ . For the lower effective stress of 100kPa (R100), the specimen reached a higher stress ratio of  $M = 2.14$ , which is similar to what was found by Silva dos Santos *et al.* (2010) on fibre-reinforced sand. The over-consolidated specimens, UR100 and R100, did not follow the frictional trend but showed much less volumetric deformation up to critical state, which was also observed in the stress-strain behaviour. This may have been caused by locking of the fibres during compression and swelling prior to shearing.

Figure 3. Stress-strain-volumetric response of CDG and fibre-reinforced CDG sheared at different effective confining stresses.

Figure 4. Stress-dilatancy response of CDG and fibre-reinforced CDG.

The deviatoric stress and corresponding mean effective stress in the test that reached a stable critical state are plotted in a  $q$ - $p'$  plane in figure 5. These points form a critical state envelope for the pure CDG with a critical state gradient  $M=1.57$ . This is found to be consistent with critical stress ratio  $M = 1.57 - 1.61$ , obtained from the stress-dilatancy plot (figure 4). The end of test points are also plotted for the reinforced specimens but no attempt has been made in this paper to define the critical state envelope for fibre-reinforced CDG because at low stresses, the deviatoric stress does not stabilise (figure 3a). More tests are required over a larger range of stresses to do so, as was done by Silva dos Santos *et al.* (2010) who found that the critical state lines of the unreinforced and reinforced specimens converge at large stresses of the order of 5MPa.

Figure 5. Critical states and end of test points for CDG and fibre-reinforced CDG in  $q$ - $p'$  plane.

#### 4 CONCLUDING REMARKS

The results presented indicate that using discrete fibres can be an effective means of reinforcing CDG, specifically at low effective stresses. The unconfined compressive strength tests showed a tenfold increase in strength with 0.5% fibres content in the soil prepared at maximum dry density and optimum moisture content. In triaxial drained tests, adding fibres seems to increase the shear strength by up to two times the strength of the unreinforced specimens, as well as its initial stiffness. Dilation was also found to be reduced. Unique critical states were reached for the unreinforced CDG and reinforced CDG tested at high effective stress. The stress-dilatancy was found to be frictional for all normally consolidated specimens, but with different critical state stress ratios ( $M$ ) for the fibre-reinforced specimens depending on their effective confining stress. Initial results also seem to indicate that the over-consolidation ratio affects the performance of the reinforced CDG, noticeably in the stress-dilatancy response, but more work is needed to confirm it.

#### 5 ACKNOWLEDGEMENTS

The authors wish to acknowledge Ku Hei Man, Gloria (final year project student 2012, The University of Hong Kong) for providing the Unconfined compressive test results. The financial support provided by Hong Kong Research Grant Council GRF No.70211 is gratefully acknowledged.

# Hybrid Application of Deep Mixing Columns Combined with Walls as a Soft Ground Improvement Method Under Embankments

Application hybride de la méthode de « Deep Mixing » sur des colonnes combinées à des murs en tant que méthode d'amélioration des sols mous sous remblais

Matsui H., Ishii H., Horikoshi K.  
 Technology Center, Taisei Corporation, Yokohama, JAPAN

**ABSTRACT:** In this paper, we introduce the concepts and general functions of a hybrid application of deep mixing columns combined with walls. This new method for improving the soft ground under embankments helps control ground deformation. We briefly describe a case in which the method was applied under an embankment 7 m in height. The method effectively restricted the induced deformation of the ground surface to a target level, not only under the embankment but also adjacent to the embankment toes. Two-dimensional finite element analysis was adopted to the case and found effective for simulating the performance. Also proposed is a design flow for the new method to efficiently determine the best arrangement of deep mixing columns and walls. Numerical parametric studies were carried out to compare the new method with conventional methods.

**RÉSUMÉ :** Dans cet article, nous présentons les concepts et les fonctions générales de l'application hybride de méthode de « Deep Mixing » sur des colonnes combinées à des murs. Cette nouvelle méthode d'amélioration de sols mous sous remblais aide à contrôler la déformation du terrain. Nous décrivons brièvement un cas dans lequel la méthode a été appliquée sous un remblai d'une hauteur de 7 m. La méthode a permis de limiter efficacement la déformation induite de la surface du sol à un niveau cible, non seulement sous le remblai, mais aussi dans les zones adjacentes aux pieds de talus. Une analyse par éléments finis en deux dimensions a été appliquée à ce cas et s'est avérée efficace pour simuler les performances. Une méthode d'optimisation est également proposée en vue de déterminer de manière efficace la meilleure disposition des colonnes et des murs. Des études paramétriques numériques ont été menées pour comparer la nouvelle méthode avec les méthodes classiques.

**KEYWORDS:** soft ground improvement method, finite element analysis, deep mixing method

## 1 INTRODUCTION

Deep mixing methods have been widely used in Japan for the foundation systems of embankments constructed on soft clayey ground, and various low improvement ratio arrangements have been proposed (Miki and Nozu 2004, Ishikura et al. 2009, Miki et al. 2011). Typical of recent applications is to achieve limited soil improvement—around 10-20%—through an arrangement of soil improvement columns. This reduces the volume of soil that must be improved and limits the ground settlement under the embankments. Moreover, embankment construction in urban areas requires strict control of ground deformation, especially in the areas adjacent to the embankment toes.

The authors propose a new hybrid application of deep mixing columns combined with walls (Tsutsumi et al. 2009) as a method of improving the soft ground under embankments to control ground deformation. In this paper, the concepts and general functions of the method are introduced. The paper then describes a case in which the method was applied under a tall embankment 7 m in height. Two-dimensional finite element analysis was adopted to simulate the performance. Also proposed is a design flow for the new method that efficiently determines the best arrangement of deep mixing columns and walls. Finally, numerical parametric studies were carried out to compare the new method with conventional methods.

## 2 CONCEPTS AND GENERAL FUNCTIONS OF A HYBRID APPLICATION OF DEEP MIXING COLUMNS COMBINED WITH WALLS

The basic concept of this method is to place deep mixing walls in the ground directly under the embankment slopes, which

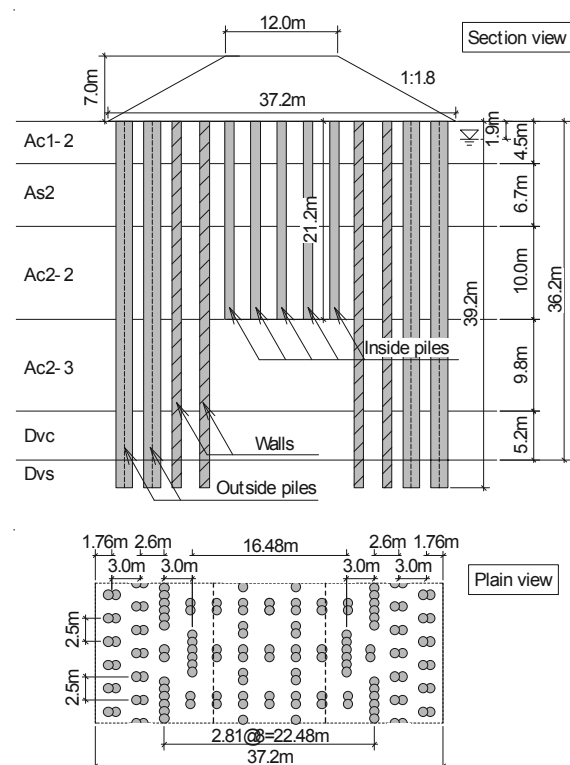

Figure 1. Geological profile and arrangement of the deep mixing columns and walls at the construction site where the method was applied.

Figure 2. Ground surface after soil improvement.

bear the embankment loads as well as the lateral movement of the soft ground. Deep mixing piles are placed inside and outside the walls to restrict vertical and horizontal deformation caused by the embankment.

Figure 1 shows an example of the arrangement of deep mixing columns and walls at a site. The function and placement of each pile and wall are explained below.

**Inside piles:** Columns placed in the ground directly under the crown of the embankment. This part transfers the load from the center part of the embankment to the deep layer.

**Walls:** Walls are placed in the ground under the edges of the embankment crown. This part bears a large part of the embankment load and prevents the soil from moving.

**Outside piles:** Columns placed in the ground directly under the embankment slopes. This part transfers the load of the embankment slopes.

This method is designed to economically satisfy the limit value of settlement by optimizing and minimizing these parts in the design.

### 3 TRIAL EMBANKMENT

#### 3.1 Work outline

The effectiveness of this method was demonstrated in a road construction project along the Ariake Sea in Kumamoto Prefecture. The soft clay at the construction site was about 40 m thick, so a large volume of settlement could be expected after constructing an embankment 7m in height. Some parts of the proposed road were close to residential buildings. Therefore, a limit value for deformation was set not only for the embankment but also for the area adjacent to the embankment, as described below.

**Embankment:** Settlement since the start of service is equal to or lower than 300 mm.

**Adjacent area:** Lateral and horizontal displacement since the start of construction is equal to or lower than 20 mm.

During the design stage, many of the arrangements were compared using two- and three-dimensional effective stress analysis. After considering all of the above, the arrangement shown in Fig. 1 was determined to be optimal. Each column had a design strength of 1.0MN/m<sup>2</sup>, and the arrangement had an improvement ratio of 18.5%.

Before the embankment was constructed, settlement plates and pressure gauges were installed for the purpose of taking measurements. The ground surface after soil improvement is shown in Fig. 2.

#### 3.2 Result of construction

Figure 3 shows the settlement history of the ground surface at the center of the embankment. The same figure also shows a similar settlement history, observed at a trial embankment nearby with no subsoil treatment. In the improvement case, 200mm of settlement occurred one year after embankment construction. Subsequently, settlement converged in both cases. Table 1. Material properties used for numerical model

Figure 3. History of ground surface settlement in at the center of the embankment.

Figure 4. Distribution of ground surface settlement after construction of the embankment.

Figure 5. Section view of the numerical model.

Figure 4 shows the settlement history for a one-year period after the construction road was removed. In the improvement case, large walls prevented deformation under the embankment, keeping the settlement around the embankment below the limit value. The vertical strain measured in the walls is shown in Fig. 7; this, too, was kept below the fracture strain value.

#### 3.3 Back-analysis

To investigate the applicability of two-dimensional effective stress analysis under actual construction conditions, the geological profile and mechanical properties of the deep mixing columns were analyzed using Plaxis 2D Ver.9.02.

The numerical model is shown in Fig. 5. Due to the symmetry of the embankment, only half of the geometry was considered for the model. The distance from the embankment

\*1 The deformation modulus of the deep mixing columns was derived from quality verification tests, which reduced dependence on the improvement ratio.

\*2 The coefficients of permeability of the deep mixing columns are same as those for each layer.

toe to the lateral boundary is 80m. As a boundary condition of deformation, the bottom surface was fixed. The side surface was free vertically and fixed horizontally. As a drainage condition, excess pore water pressures at the ground surface and bottom surface were set to zero.

The soil layer is modeled as an elasto-plastic material using the Sekiguchi-Ohta model (Sekiguchi and Ohta 1977). The sand layers and deep mixing columns are modeled as a linear elastic material. The embankment is modeled as an elasto-plastic material using the Mohr-Coulomb model. Table 1 lists the model parameters used for the analysis.

The history of the embankment construction was modeled by building up the elements. In converting from actual three-dimensional ground to the two-dimensional numerical model, the deformation modulus of the deep mixing columns was reduced according to the improvement ratio and the coefficient on permeability for deep mixing columns was set to the value for each layer of ground.

The following figures are for the sake of comparison and analysis: Figure 6 shows the history of ground-surface settlement at the center of the embankment; Fig.7 shows the distribution of ground-surface settlement after construction of the embankment; Fig. 8 shows the horizontal displacement and vertical strain of the walls. The settlement history and displacement of the ground surface and walls are quantitatively evaluated using two-dimensional analysis. However, a clear difference in the vertical strain exists at greater depths. In the numerical models, the deformation modulus of walls less than 21 m in height is lower than that of walls greater than 21 m in height as per the arrangement of the deep mixing columns. This is thought to be the cause of the difference in vertical strain. Individual material properties are effective for evaluating the strain distribution of walls.

#### 4 DETERMINING THE OPTIMUM ARRANGEMENT OF DEEP MIXING COLUMNS

In this method, the piles and walls are effectively arranged according to the limit values of deformation in the embankment and the adjacent area. Due to the countless combinations of planar arrangements and improvement depths, arbitrary parametric studies require considerable time to identify optimum arrangement. Therefore, the following 3-step method is proposed for determining the optimum arrangement.

1) Determine the planar arrangement: First, walls are placed in the ground under the edges of the embankment crown. Next, inside and outside piles are arranged equidistantly by an amount not less than the necessary improvement ratio  $\alpha$ , defined as

$$\alpha = \gamma \cdot H / q_{uck} \quad (1)$$

Figure 6. Settlement history of ground surface in center of the embankment

Figure 7. Distribution of ground surface settlement after construction of the embankment

Figure 8. (a) Horizontal displacement of walls (b) Vertical strain in walls

Figure 9. Example of confining the range of consideration and the result of the consideration for in-situ construction in Kumamoto

in which  $\gamma$  is the unit weight of the embankment,  $H$  is the height of the embankment and  $q_{uck}$  is the design strength of the deep mixing columns.

2) Confine the range of consideration: For the planar arrangement noted above, the deformation of three arrangements with different improvement depths (as shown in Fig. 9) is calculated. The relation between the improvement volume and the deformation of the three arrangements is illustrated in Fig. 9. The range of consideration is narrowed by comparing with the limit value of deformation in the adjacent area.

3) Identify the optimum arrangement: The optimum arrangement in the range noted above is the arrangement with the lowest improvement volume that satisfies the limit value.

Figure 9 shows the results of a search for the optimum arrangement in areas along the Ariake Sea in Saga Prefecture. Figure 9 also shows the results of a search in Kumamoto as an example of an arbitrary parametric study. The positional relation between both cases is fitted and the results indicate the effectiveness of the search method.

## 5 COMPARISON WITH CONVENTIONAL METHODS

To confirm the effect of displacement suppression, a hybrid arrangement is compared with conventional columns arrangements as well as an arrangement in which the columns are equidistant and narrowly spaced.

Under the same geological conditions and embankment height as in the Kumamoto case, the settlement of the embankment and at a point 10 m from the embankment toes of each arrangement were calculated using two-dimensional analysis.

Figure 10 shows the relation between individual settlement values and improvement volumes per meter in the longitudinal direction. Regarding settlement of the embankment, the settlement of the hybrid arrangement and the equidistant arrangement are lower than the arrangement under the slopes, confirming the effect of displacement suppression. For the settlement at a point 10 m from the embankment toes, the hybrid arrangement is the lowest among same improvement volumes. When the limit value of settlement in the adjacent area is 20 mm, the hybrid arrangement is more effective than conventional methods in reducing the improvement volume.

## 6 CONCLUSIONS

On-site measurements confirmed the method's effectiveness in suppressing displacement. The validity of deformational estimation using two-dimensional effective stress analysis also

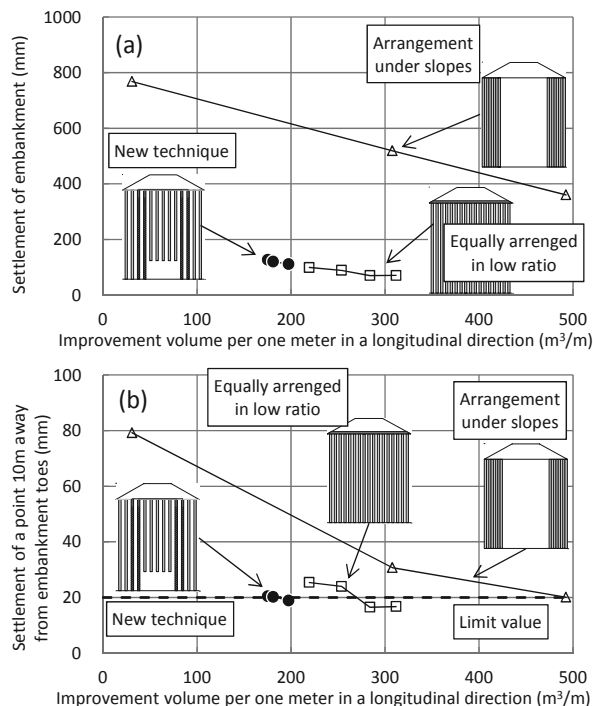

Figure 10. (a) Settlement of embankment (b) Settlement at a point 10 meters from the embankment toes.

was confirmed. However, little difference was seen in the estimation of stress and strain distribution in the walls. Using individual material properties for the walls, however, is effective. The two examples of searching for the optimum arrangement using the method proposed in this paper confirmed the method's effectiveness. Analytical comparison of the new method with conventional methods also confirmed the economic efficiency of the new method.

## 7 ACKNOWLEDGEMENTS

The development of this column link method is the result of collaborative research involving the Public Works Research Institute, Japan, and thirteen private corporations in Japan. The authors are particularly grateful for the kind assistance of Shouichi Tsutsumi (PWRI), Hirota Kawasaki (Shimizu Corp.), Shouichi Tsukuni (Takenaka Civil Eng. & Const. Co., Ltd.), and Naotoshi Shinkawa (Fudo Corp.).

# Application of cement deep mixing method for underpinning

## Application de colonnes de sol-ciment pour travaux de reprise en sous œuvre

Melentijevic S., Arcos J.L.  
Grupo Rodio-Kronsa, Madrid, Spain

Oteo C.  
Universidad de A Coruña, A Coruña, Spain

**ABSTRACT:** This paper presents a case history of the application of wet deep soil mixing columns for underpinning of the existing floor slab of an industrial building, which settled due to different encountered post-constructive pathologies related to ground conditions. The soil-cement columns were constructed with the application of the new developed Springsol<sup>®</sup> tool that permits the underpinning of existing foundations, infrastructure transport platforms and embankments, as well as working in limited spaces and under low headroom conditions. The quality control regarding laboratory testing of core and wet grab samples is reported. Design procedure and the finite element analysis that verify settlement calculations are described. The FEM is focused on the axisymmetric numerical modeling in Plaxis.

**RÉSUMÉ :** Cet article présente une étude de cas de réalisation de colonnes de sol mixing par voie humide pour la reprise en sous œuvre du dallage d'un bâtiment industriel, ayant tassé après sa construction à cause de pathologies du sol. Les colonnes de sol-ciment ont été réalisées avec la méthode Springsol<sup>®</sup>, qui permet la reprise en sous œuvre de fondations existantes, d'infrastructures de transports et de remblais, à partir d'emprises étroites et sous faible gabarit. Les contrôles de qualité réalisés en laboratoire sur des éprouvettes carottées et sur des prélèvements frais y sont présentés. Le mode de dimensionnement ainsi que les analyses par éléments finis pour estimer les tassements sont également décrits. Les calculs EF ont été réalisés avec le code Plaxis en axi-symétrie.

**KEYWORDS:** deep mixing, soil-cement columns, Springsol<sup>®</sup>, underpinning, FEM.

### 1 INTRODUCTION

In order to reduce settlements, increase bearing capacity of natural ground and improve the overall stability, different ground improvement techniques can be put into practice, but not all of them can be applied for underpinning projects. The limitations for the applications are mainly related to capacity of the machinery to pass existing foundation structures as reinforced slabs or footings, and insufficient working spaces and/or low headroom conditions.

The soil-cement deep mixed columns for ground improvement of soft soils have an extensive application for different geotechnical projects due to their higher strength and lower compressibility than the untreated natural soft soil. The application of traditional deep mixing methods, both wet and dry, was very restricted for the underpinning of existing foundations, improvement of existing embankments and infrastructure platforms, due to the form and dimensions of the mixing tool.

With objective to present new wet deep soil mixing system called Springsol<sup>®</sup> a case history with its application in underpinning project is reported in this paper. To prevent further settlements and guarantee bearing capacity of the foundation of the industrial building that presented various post-constructive pathologies, the Springsol<sup>®</sup> deep mixing columns were proposed as an alternative method to basic project underpinning solution comprising jet-grouting, traditional tuba-manchette grouting and micropiles for different areas of the building. Due to its technical, economic and environmental advantages, soil-cement columns were accepted and executed as a global solution. In the following chapters the main characteristics of the Springsol<sup>®</sup> system will be described as well as the analysis of the solution adopted and performed for this project. Some recent applications of the Springsol<sup>®</sup> technique are given in Melentijevic et al., 2012.

### 2 SPRINGSOL<sup>®</sup> SOIL CEMENT COLUMNS

Springsol<sup>®</sup> device was originally developed for improvement of soils under existing railways due to its spreadable form (Innotrack 2009, Le Couby 2010). The folded tool is introduced through the casing to the required depth at the beginning of the column head. Once it reaches the end of the casing and penetrates the underlying soft soil, the blades spread out forming the soil-cement column down to the required depth.

Figure 1. The Springsol<sup>®</sup> spreadable tool: (a) original and (b) modified.

At present, Springsol<sup>®</sup> columns permit an application in ground improvement for underpinning of existing foundations (both slabs and footings), paving, embankments and subbase below infrastructures (both highways and railways). Originally it was developed to form columns of 400 mm diameter. Due to continuous necessity for construction of soil-cement columns of larger diameters the Springsol<sup>®</sup> soil mixing tool has technically evolved into the new modified version, permitting achievement of different column diameters ranging from 400 to 700 mm. The modified tool also includes the automatic system for opening and closing blades thus having the possibility to form variable

diameter along the column depth. Figure 1 shows the nowadays available original and modified improved Springsol<sup>®</sup> tool. The folded tool is of a diameter of 150 and 165 mm for the original and modified version respectively.

Some of the advantages of the method are:

- No pollution of the subgrade layer with the cement slurry, due to insertion of the casing that enables the recovery of spoil.
- The spoil collection with the system installed at the base of the mast of the drilling rig, connected to the peristaltic pump drawing the spoil directly to the container.
- The high production rate.
- Working under difficult execution conditions and limitations, i.e. under low headroom conditions and within reduced spaces.
- Execution with small batching plants and small drilling rigs in reduced limited spaces, etc.

The quality of soil-cement columns regarding their homogeneity and strength is influenced by two parameters:

- Im (rev/m) - blade rotation number determining the mixing efficiency defined as a total number of mixing blades passing along one meter of tool penetration, and
- li (kg/m<sup>3</sup>) - cement quantity introduced per m<sup>3</sup> of the treated soil.

Table 1. Springsol<sup>®</sup> columns performance and geo-mechanical parameters.

Parameter	
Diameter (mm)	400-700
Water / Cement ratio	0.6-1.2
Penetration velocity (cm/min)	15-50
Im (rev/m)	min 350
li (kg/m <sup>3</sup> )	150-350
UCS (MPa)	0.5-6.0
E <sub>50</sub>	(50-500) UCS
Shear strength	20-40% UCS
Bending strength	8-15% UCS

The general execution parameters and geo-mechanical characteristics (unconfined compressive strength - UCS, stiffness modulus – E<sub>50</sub>, shear and bending strength) of the soil-cement columns executed by the Springsol<sup>®</sup> device are given in Table 1. These data are established on experiences gained on different projects and field tests carried out recently in Spain (Melentijevic et al 2012, Melentijevic et al 2013). These findings on geo-material properties are in agreement with worldwide published information on deep mixed columns (Bruce 2001, CDIT 2002, etc.).

### 3 PROJECT DETAILS AND ADOPTED GROUND IMPROVEMENT SOLUTION

In this chapter an example of application of the Springsol<sup>®</sup> technique for underpinning is presented. The industrial building in the central Spain presented different post-constructive pathologies regarding differential settlements of floor slabs and pavements as a consequence of poorly compacted anthropic fill material. The main structure (walls and columns) were founded on a natural ground, and due to its adequate geotechnical characteristics did not present any pathology. The shallow foundation on a natural ground was performed after a massive excavation of superficial layers of natural soil, applying the

same material for construction of a fill without its appropriate compaction.

The affected area included more than 8000 m<sup>2</sup> with the installation of more than 2500 soil-cement columns. The length of soil-cement columns ranged from 5.50 m to 8.00 m in function of the thickness of the man-made fill, with the total length of columns of more than 15000 meters. Due to the form of the Springsol<sup>®</sup> tool, the columns were embedded approximately 20 cm in the natural ground. The columns of a 400 mm diameter, performed with the originally developed tool, were distributed in a square grid pattern ranging from 1.50 m to 2.00 m in function of the surcharge to be transmitted from the slab. The performed solution is schematically presented in Figure 2.

Figure 2. Cross section of the ground treatment solution.

The post pathology site investigation consisted of 46 dynamic penetration tests and 5 drilled boreholes with standard penetration tests, executed from the working platform, i.e. the existing floor slab level. The natural ground, detected at the depth of 5.50 to 8.00 m from the surface, consisted of clays of high consistency with gravels and boulders, with the N<sub>20</sub>>40 (DPSH). The overlying treated loose man made fill was formed of clays with gravels (N<sub>20</sub><10) proceeding from the natural ground after a massive excavation for the foundation of the main structure elements.

The soil treatment solution included following steps:

- Coring of the existing slab (diameter = 62 mm) for grouting of the gap between slabs and fill.
- Contact grouting between the slab and the fill in order to fill gaps due to settlement of badly compacted man made fill.
- Coring of the existing slab and contact grouted gap (diameter = 182 mm) for the passage of the spreadable tool.
- Execution of Springsol<sup>®</sup> columns (diameter = 400 mm).
- Filing the gaps of coring the existing slab.

Visual description of the executed steps previously mentioned is shown in Figure 3.

Figure 3. Visual control of the excavated treatment area.

#### 4 GEOMATERIAL SOIL-CEMENT COLUMN CHARACTERIZATION

The cement used for the construction of soil-cement columns was of the Portland type CEM I 52.5 SR. The slurry mix was of a Cement / Water type with the relation 1/1. The average penetration rate for the construction of columns was 30 cm/min with the rotation velocity of 50 to 55 rpm and the average cement consumption of 350 kg/m<sup>3</sup>.

The unconfined compressive strength tests (UCS) were performed both on drilled core samples and wet grab samples (cylinder dimensions height / diameter > 2), both of them usually being the main mean of the quality control of wet deep mixing methods. Three core samples were taken from different soil-cement trial test columns, 21 days after the completion of the soil-cement columns. The samples were cored at a distance of 110 mm to 120 mm from the centre of columns. The overall average total core recovery was more than 97% for all soil-cement columns. Wet grab samples were taken in the half an hour after execution of columns and were tested at same age as core samples. The UCS tests were also used to determine the stiffness modulus  $E_{50}$  (secant value of Young's modulus of elasticity determined at 50% of UCS).

The UCS values of wet grab samples after 7 days varied from 1.4 to 3.9 MPa, while UCS values for drilled core samples on 28 days ranged from 2.2 to 4.4 MPa and axial failure strain values varied from 1 to 1.2 %. Stiffness modulus values determined from UCS tests varied from 270 to 330 MPa, with the average relationship between  $E_{50}$  and UCS resulting in approximately 100.

Some of the drilled core samples extracted from soil-cement trial test columns is presented in Figure 4. It can be observed uniformly treated Springsol<sup>®</sup> columns.

Figure 4. Drilled core samples of soil-cement columns.

#### 5 NUMERICAL MODEL

##### 5.1 General data

When using finite element analysis to model deep mixed columns installed in a periodic pattern, the problem is usually modelled in a 2D axisymmetric model, referred as a unit cell model. The homogenization equivalent model is usually not used due to lack of access to column stresses.

The radius of the unit cell depends on the grid spacing:

$$R_{eq} = \frac{s}{\sqrt{\pi}} \quad (1)$$

where:  $R_{eq}$  is the radius of the unit cell and  $s$  is the grid spacing.

In this project different square grid patterns (grid spacing varying from 1.50 to 2.00 m) depending on the surcharge of the slab (ranging from 10.00 to 20.00 kN/m<sup>2</sup>) are taken into account.

In this study the commercial finite element code used for 2D modelling is Plaxis (version 8.6). Both the soft soil and the soil-cement column behaviour are modelled by the elastic-plastic Mohr-Coulomb failure criterion, while the slab is characterized

by the elastic law. The load transfer layer formed by grouting the gap within the contact gravel layer below the existing slab of the approximate thickness of 20 cm is modelled by the Mohr-Coulomb law. Geotechnical parameters of each material (LTL-load transfer layer, CU-upper clay layer, CM-medium clay layer, NSC-natural soil clay layer, SC-soil cement column) used in the numerical analysis are given in Table 2.

The cross section of the FE model is presented in Figure 6 showing the geometry and soil layers used in analysis, as well as the finite element mesh.

Table 2. Material parameters.

Parameter	LTL	CU	CM	NSC	SC
Thickness (m)	0.2	4.0-6.5	1.5	>4.5	
Density (kN/m <sup>3</sup> )	22	16	17	18	20
Cohesion (kPa)	500	5	10	20	500
Friction angle (°)	40	18	20	22	35
Young's modulus (MPa)	300	2.5	5.0	50	300
Poisson ratio	0.2	0.3	0.3	0.3	0.2

##### 5.2 Results

Figure 6 present the employed mesh in the FEM model, and the results regarding vertical displacements and axial stresses for the case of the grid spacing of 1.50 m corresponding to the surcharge of 20 kN/m<sup>2</sup>.

Figure 6. Numerical modeling results for reinforced soil. (a) Geometry of the unit cell - mesh and model dimensions. (b) Vertical displacements. (c) Axial stresses.

The homogenized settlements as well as negligible differential settlements due to high rigidity of the load transfer layer, formed by grouting the layer of gravel below the slab, and soil-cement columns can be observed in Figure 6-b.

The maximum allowable axial stresses in soil-cement columns defined by the UCS value and verified by the FEM analysis was not exceeded for different cases of grid spacing, surcharge and column lengths taken into consideration in the project.

The comparative study of the maximum vertical displacement, in cases without and with the soil improvement for different grid meshes is shown in Figure 7. The significant settlement reduction with the applied soil improvement can be observed in function of grid spacing and for different thicknesses of the soft soil layer.

Figure 7. Maximum vertical displacements.

The numerical calculations were also analyzed in terms of load and settlement efficiency (ASIRI 2012) in order to determine the effectiveness of the soil improvement method. The load efficiency ( $E_L$ ) is defined as a ratio of a transmitted load to the head of a soil-cement column and the total load acting on the unit cell. The settlement efficiency ( $E_{set}$ ) represents the reduction of a settlement by a soil-cement column compared to the settlement of the unit grid without ground improvement. They are represented by the following equations:

$$E_L = \frac{Q_p}{W+Q} \quad (2)$$

$$E_{set} = 1 - \frac{S_M}{S_0} \quad (3)$$

where:  $Q_p$  is the load acting on the head of soil-cement column,  $W$  is the dead load of the load transfer platform and  $Q$  is the force of the surcharge applied to the slab.  $S_M$  is the settlement of the soil reinforced by soil-cement columns measured at the surface of the load transfer platform and  $S_0$  is the settlement of the natural soil without ground improvement.

Figure 8. Load and settlement efficiency.

The results of the load and settlement efficiency are given in Figure 8 in terms of different grids adopted in the project for different surcharge loads and for different column length in function of the thickness of the soft layer. Both terms of

efficiency have the same tendency. The load efficiency ranges from 36 to 50 %, while the settlement efficiency varies between 64 and 78 %. The difference of approximately 25 to 30 % between load and settlement efficacy relationships is observed.

It is important to emphasize that the estimated settlements obtained by the analysis by FEM were in accordance with the observed settlements after ground improvement by the performance of soil-cement columns and re-loading of the slab of the industrial building.

## 6 CONCLUSIONS

The general application of the wet deep mixing method by the Springsol<sup>®</sup> system for ground improvement of existing paving, embankments and subbase below railways and roads, and underpinning of existing structures is presented. The case history of underpinning of existing industrial building, which settled due to poorly compacted anthropic fill, with the use of the Springsol<sup>®</sup> system is reported.

The design procedure and the estimation of settlements by the finite element method (Plaxis commercial code) based on axisymmetric model is in concordance with the monitored settlements. The general homogenized nature of settlements, as well as insignificant differential settlements are achieved by the good interaction of the performed soil-cement column and load transfer layer formed by grouting of the layer of gravel below the slab. The evaluation of efficiency of the soil treatment by soil-cement columns, in terms of load and stress efficiency, is determined confirming its effectiveness.

## 7 ACKNOWLEDGEMENTS

The authors wish to thank to the personnel of Grupo Rodio-Kronsa for their technical assistance, especially to Juan Ignacio López, Juan Manuel Dimas, Francisco Martín and Esteban Casado. Also, the collaboration and provision of all necessary information by the Proprietary of the Industrial building is highly appreciated.

# Lime Remediation of Reactivated Landslides

## Traitement à la chaux pour la stabilisation des glissements réactivés

Mesri G.

*University of Illinois at Urbana-Champaign, Urbana, Illinois 61801, U.S.A.*

Moridzadeh M.

*Montgomery Watson Harza, Chicago, Illinois, U.S.A*

**ABSTRACT:** Lime improvement of frictional resistance was examined using samples of Brenna Clay Formation from North Dakota. The montmorillonitic stiff clay samples had a natural water content, plastic limit, liquid limit, clay size fraction, fully softened friction angle, and residual friction angle, respectively, in the range of 42 to 85%, 20 to 40%, 62 to 154%, 60 to 95%, 14 to 24°, and 7 to 9°. Immediately after introduction of hydrated lime, pH increased to a range of 12.2 to 12.7; within hours, however, pH began to decrease. Whereas there was a large increase in plastic limit, the liquid limit response to lime treatment was dependent on the effective confining pressure. Lime treatment increased fully softened friction angle by 5 to 10° at effective normal stress of 100 kPa and by 3 to 5° at 300 kPa. Lime treatment increased the residual friction angle by 3 to 6° at both 100 kPa and 300 kPa.

**RÉSUMÉ:** L'amélioration par addition de chaux de la résistance en frottement est examinée sur des échantillons de la formation d'argile de Brenna dans le Dakota du Nord. Les échantillons d'argile raide montmorillonitique ont une teneur en eau, une limite plastique, une limite liquide, une fraction de dimension argileuse, un angle de frottement après remaniement et un angle de frottement résiduel respectivement de l'ordre de 42 à 85%, de 20 à 40%, de 62 à 154%, de 60 à 95%, de 14 à 24°, et de 7 à 9°. Immédiatement après l'addition de chaux hydratée, le pH augmente à des valeurs de 12,2 à 12,7 mais commence ensuite à décroître dans les heures qui suivent. L'augmentation de la limite de plasticité suite au traitement à la chaux est importante, l'augmentation de la limite de liquidité dépend cependant de la pression de confinement. Le traitement à la chaux augmente l'angle de frottement après remaniement de 5 à 10° sous une contrainte effective normale de 100 kPa et de 3 à 5° sous 300 kPa. Le traitement à la chaux augmente l'angle de frottement résiduel de 3 à 6° autant sous une pression de 300 kPa plutôt que de 100 kPa.

**KEYWORDS:** Brenna clay, frictional resistance, lime treatment, landslides.

## 1 INTRODUCTION

The effectiveness of lime treatment of soils has been commonly evaluated in terms of improved workability and increased undrained unconfined stiffness and compressive strength, in connection to road and airfield construction (Bell 1996). Soil improvement is expected to result from the flocculation of clay minerals and cementing action of lime-soil chemical reactions. On the other hand if the objective of lime treatment is to improve long-term stability of first-time or reactivated landslides in stiff clays and shales, permanent changes in the size and shape of clay particles must be realized to increase drained frictional resistance. Lime-soil interactions that may produce less platy and larger soil particles begin and continue with time under the highly alkaline pH environment. For Brenna clay samples treated with lime, measurements of pH as an indicator of chemical environment, Atterberg plastic limit and liquid limit as indirect measures of changes in particle size and shape, and fully softened friction angle and residual friction angle, were used to examine possible mechanisms of lime-soil interactions. The main variables, in addition to soil mineralogy, are soil water content, lime content, and duration of lime-soil interactions.

## 2 LIME-SOIL INTERACTION

When dry hydrated lime is thoroughly mixed with a wet soil, lime is consumed, in the absence of carbonation, through two mechanisms: (a) part of the lime particles is adsorbed on soil particles during the mixing process, and (b) part of the remaining lime is dissolved in the soil porewater. The solubility of calcium hydroxide in water is rather small (0.75 g/l). Therefore, the maximum lime content as percent of dry weight

of soil that can dissolve in the porewater during the mixing process is quite small and a function of soil water content (only 1.5% of lime for 5% lime content at soil water content of 100%). Dissociation of hydrated lime to (OH)<sup>-</sup> and Ca<sup>2+</sup> leads to a rise in the pH. If enough lime is left, after satisfying the adsorption, soil porewater becomes saturated and pH increases to approximately 12.3 to 12.4. Under the strong alkaline condition, soil mineral particle surfaces become unstable and begin to dissolve in the porewater. Simultaneously, under the elevated pH condition, adsorbed lime particles begin to attack the soil particle surfaces at the points of contact.

Dissolved silica and alumina react with the dissociated calcium hydroxide and form new compounds. As the dissolved hydrated lime is used up in the chemical reactions with silica and alumina, the remaining free lime, if any, dissolves in the porewater and pH is maintained at 12.3-12.4. The dissolution of soil particles and local attack of adsorbed lime on the particle surfaces continue at the initial rate until all free lime is completely consumed. Thereafter, pH begins to decrease as the dissociated calcium hydroxide is used up in the chemical reactions with dissolved silica and alumina. This has been confirmed by pH measurements and chemical analyses conducted by Clare and Cruchley (1957) and Diamond et al. (1964). Dissolution of soil particle surfaces continues at a decreasing rate, becoming insignificant as pH drops to values probably less than around 9 (Eades and Grim 1960, Eades et al. 1962, Hunter 1988). The reaction products begin to harden or crystallize as pH decreases. A calcium hydroxide particle is attached to more than one soil particle, connecting them together and producing silt- and sand-sized flocs and agglomerates (Diamond et al. 1964, Verhasselt 1990). The Atterberg plastic limit increases, often dramatically, because large amount of water is enclosed within the flocs and

agglomerates. In other words, only part of the porewater contributes to plasticity. This is similar to diatoms with poriferous particles in soils such as the Mexico City clay, and andosols containing allophane in which water is trapped within soil aggregates (Mesri et al. 1975, Terzaghi et al. 1996). Both soils display unusually high plastic limits. In summary, total lime content,  $l_c$ , is used up through adsorption,  $l_{ca}$ , and dissolution,  $l_{cd}$ .

The time-dependent manifestation of adsorbed lime is a gradual chemical reaction of calcium hydroxide with soil particle surfaces. As the reaction products continue to form and later harden or crystallize at the reaction sites of adsorbed lime particles, they improve soil particle connections within the flocs and agglomerates that may mature into porous soil aggregates (Baver 1956). The proposed concept of lime particle adsorption on soil particles is somewhat similar to physical adsorption of calcium hydroxide molecules proposed by Diamond and Kinter (1965). However, considering that a clay-sized hydrated lime particle may contain  $10^{11}$  molecules of  $Ca(OH)_2$ , a more significant time-dependent chemical reaction of adsorbed lime with soil particle surfaces is expected for adsorbed lime particles than for adsorbed lime molecules. Richardson et al. (1994) have mentioned layers of  $Ca(OH)_2$  sandwiched between silicate layers.

particle size decreases and therefore, surface area increases,  $l_{ca}$  increases. Lime content consumed through adsorption is probably also related to the soil water content as it influences dispersion of soil particles and facilitates thorough mixing to allow full distribution and intimate contact between lime and soil particles, degree of pulverization of hydrated lime, and the intensity of mixing.

Because the solubility of calcium hydroxide in water is very small, for typical soil water contents a very small lime content is required to saturate the porewater. However, experience indicates that pH remains below 12.3-12.4 for lime contents far in excess of that required for the saturation of porewater. This behavior appears to suggest that lime adsorption must be satisfied before lime is dissolved in the porewater to increase the pH. Zolkov (1962) considered it as remarkable that in spite of the very small solubility of lime in water, large amount of lime was required "to bring the pH of the soil slurry to 12.6."

Most of the chemical reaction products have a layer structure, have high surface area, and a particle morphology that has been described as thin plates, foils, and rolled up sheets (Diamond et al. 1964; however sometimes fibers or laths occur which could contribute to particle interlocking, Richardson et al. 1994). On the other hand, adequate but not excessive lime attack may improve morphology of existing soil particles by producing ragged, irregular, frosted or serrated particles and following proper compaction connect them by the new reaction products. These features are expected to improve mechanical behavior of soils.

Because some of the reaction products during the stabilization process are amorphous and hydrated, drying of lime-treated soils during stabilization is likely to result in some irreversible dehydration as well as irreversible aggregation.

### 3 BRENNA FORMATION

The highly plastic lacustrine clays of Lake Agassiz lead to slope instability along the banks of the Red River that separates Grand Forks, North Dakota from East Grand Forks, Minnesota, as it flows north to Lake Winnipeg in Manitoba, Canada (Mesri and Huvaj 2004). The clays of the Red River slopes are the glacio-lacustrine deposits of glacial Lake Agassiz that is believed to have existed from 13,000 to 8,500 years before present, during the Late Wisconsin Glacial Episode of the Pleistocene Epoch (Quigley 1980).

The Brenna Formation, which is characterized as a uniform, soft to firm, dark grey, glacio-lacustrine clay with little or no visible stratification, is full of slickensided surfaces. The major source of sediment for the Brenna Formation was the highly plastic montmorillonitic Pierre Shale bedrock (Quigley 1968, Baracos 1977). The clay size fraction of Brenna Formation ranges from 60 to 95% (Arndt 1977). This unit is divided into Lower Brenna and Upper Brenna members. The natural water content, plastic limit and liquid limit of Lower Brenna are in the range of 42 to 69%, 20 to 40%, and 62 to 103%, respectively, and the corresponding range for Upper Brenna are 60 to 85%, 27 to 38%, and 107 to 154%, respectively. Samples of both Lower Brenna and Upper Brenna were used in the present investigation.

### 4 TESTS ON LIME-TREATED BRENNIA CLAY

Drained direct shear tests on lime-treated Brenna clay were performed using reconstituted specimens. Drained multiple reversal direct shear tests on precut specimens were used to measure residual shear strength, and drained direct shear tests on uncut specimens were used to measure fully softened shear strength. Air dry Brenna clay was pulverized until all of a representative sample passed the no. 200 US standard sieve.

Figure 1. Lime-Brenna clay interaction under effective confining pressure

The lime content required to fully satisfy adsorption is mainly related to soil particle size and shape and therefore, the mineralogy of soil solids (Goldberg and Klein 1952, Eades and Grim 1960) and degree of dispersion or aggregation. As soil

The pulverized clay was mixed with dry hydrated lime, and was thoroughly rehydrated using distilled water. Two halves of the pre-cut specimen were formed by remolding or compaction and separately consolidated inside the top and bottom halves of the shear box using the procedure described by Mesri and Cepeda-Diaz (1986) and Mesri and Huvaj-Sarihan (2012). The consolidation pressure ranged from 100 to 450 kPa, and shear displacement rate was in the range of  $3.3 \times 10^{-4}$  to  $5 \times 10^{-4}$  mm/min.

Lime content as a percent of dry weight of clay ranged from 0 to 10%, and water content was in the range of 30 to 274%. In a few direct shear tests, dry hydrated lime was sprinkled on the exposed shear surface or on the top and bottom, of the direct shear specimen to examine lime diffusion.

For one series of direct shear specimens with lime content of 6.6%, liquid limit and plastic limit were determined at the end of the test. These data are shown in Fig. 1. For another series of lime-treated Brenna clay samples with lime content of 2, 5 and 9% and water content of 80, 100, 150 and 230%, pH and Atterberg limits were measured as a function of time. These samples were sealed; however, they were not subjected to confining pressure. The pH measurements are shown in Fig. 2, and the liquid limit and plastic limit at lime content of 5% and water contents of 80 and 100% are shown in Fig. 3.

The data on residual friction angle and fully softened friction angle from drained direct shear tests are summarized in Table 1. All index tests and direct shear tests reported here were performed at laboratory temperature of  $20 \pm 2^\circ\text{C}$ .

Figure 2. pH measurements of lime-Brenna clay

## 5 INTERPRETATION OF THE MEASUREMENTS

The pH measurements on lime-treated Brenna clay, such as those in Fig. 2 as well as others, show that immediately after introduction of lime, pH increases to a range of 12.2 to 12.7; shortly thereafter, however, pH begins to decrease. This observed behavior suggests that either within hours no free lime is left to dissociate to maintain pH above 12, or dissociated  $(\text{OH})^-$  is simultaneously consumed by the silica and alumina dissolved from Brenna minerals. Nevertheless, during the 60 day observation period, pH remained above 9 suggesting continued lime-clay chemical reactions.

The rather immediate large increase in plastic limit above that of the untreated Brenna clay, such as observed in Figs. 1 and 3 results from flocculation and agglomeration of lime-treated clay, especially as the water content is reduced during the plastic limit measurements. Rapid chemical attack of adsorbed lime on clay particles contributes to the production of porous flocs and agglomerates that entrap water.

When the curing of lime-Brenna clay takes place unconfined, liquid limit dramatically increases above the liquid limit of untreated clay (Fig. 3); whereas when curing takes place under an imposed effective stress condition, such as the  $\sigma'_n$  in

the range of 100 to 450 kPa in the direct shear tests, there is a minor increase in liquid limit (Fig. 1). The interpretation of this significant observed behavior appears to be that when aluminosilicates form in unconfined condition, they hydrate fully, thus holding significant amount of water that contributes to the high liquid limit. On the other hand when lime-clay reaction products form under effective confining pressure, either the resulting aluminosilicates do not hydrate much or they experience irreversible dehydration through consolidation, thus resulting in little change in the liquid limit. The implication of this behavior, which is under more detailed examination, is significant for both laboratory study of lime-soil interaction to improve frictional resistance as well as field application of lime to remediate reactivated landslides.

Figure 3. Lime-Brenna clay interaction under unconfined condition

The fully softened friction angle and residual friction angle of stiff clays and shales decrease with the increase in effective normal stress (Mesri and Shahien 2003, Mesri and Huvaj-Sarihan 2012). The secant friction angles of Brenna clay in

Table 1 correspond to effective normal stresses of 100 kPa and 300 kPa. Lime treatment of Brenna clay increased fully softened friction angle by 5 to 10° at effective normal stress of 100 kPa, and by 3 to 5° at 300 kPa. Lime treatment increased the residual friction angle by 3 to 6° at both 100 kPa and 300 kPa. These results suggest formation of stable clay aggregates through the lime-clay chemical reactions. These increases in frictional resistance were realized with lime contents in the range of 3 to 8% and treatment periods of 2 to 8 weeks. The detailed correlation between improvement in frictional resistance of Brenna clay as well as other stiff clays and shales, with lime content and with duration of treatment, is under further investigation with additional index and direct shear tests, including scanning electron observations of reaction products.

**Notes:**

- a- Lower Brenna was used for these specimens.
- b- Lime was sprinkled on top and bottom of the sample to investigate the treatment caused by lime diffusion.
- c- Lime was sprinkled on the shear surface.
- d- Lime-treated sample was stored for 120 days before being placed in the shear box.

For the 27<sup>th</sup> Avenue slide in Grand Forks, North Dakota (Mesri and Huvaj 2004), with entire slip surface in Brenna clay at residual condition, 5% lime content treatment of fifty percent of the slip surface increases computed factor of safety from 1.00 to the range of 1.26 to 1.37 (φ<sub>r</sub><sup>°</sup> = 7 to 8° increases to φ<sub>r</sub><sup>°</sup> = 12°). This level of lime remediation effort is expected to have a significant effect on rate of movement of the slide.

A combination of horizontal directional drilling (HDD), mechanical deep mixing (MDM) with augers and paddles, and dry jet mixing (DJM), together with signal receivers at the ground surface, is being investigated for introducing lime into clay along a pre-existing slip surface. The longest crossing of HDD to date has been 2000 m and borehole diameter of up to 160 mm.

## 6 CONCLUSIONS

Remediation of the montmorillonitic Brenna clay from North Dakota using lime contents of 3 to 8% and treatment periods of 2 to 8 weeks increased drained fully softened friction angle by 3 to 10° and drained residual friction angle by 3 to 6°, in the

effective normal stress range of 100 to 300 kPa. The increase in drained frictional resistance suggests formation of stable clay aggregates through lime-clay chemical reactions under the highly alkaline pH 12.5 to 9.8 environment measured over a period of 8 weeks. The measurements of liquid limit as an indicator of changes in particle size and shape resulting from lime treatment must be carried out on samples cured under an effective stress condition rather than sealed but unconfined. Unconfined lime treatment results in a significant increase in liquid limit, thus underestimating the decrease in plasticity index and associated increase in frictional resistance resulting from lime remediation.

# Improvement of the Soil under the Concrete Pavement of a Plant's Hall

## Amélioration du terrain d'assise sous la dalle en béton d'une halle d'usine

Mihova L.

University of Architecture, Civil Engineering and Geodesy, Sofia, Bulgaria,

Kolev Ch.

Todor Kableshkov University of Transport, Sofia, Bulgaria,

**ABSTRACT:** The geological profile of the ground for the construction of a hall of the "Stilmet" plant in Sofia includes soft saturated soils. The improvement is developed of the natural ground by constructing a geosynthetic reinforced pad of crushed stone. To determine the mechanical parameters of the improved soil ground, in situ tests have been performed and settlement/load relationships and E modulus values have been obtained. A numerical model is made of the ground by the finite element method. The undrained short term stability and the consolidation long term stress-strain process of the improved soil ground are investigated.

**RÉSUMÉ :** Le profil géologique du terrain d'assise, prévu pour la construction d'une halle de l'usine "Stilmet" à Sofia, contient des sols peu solides, imbibés d'eau. On a effectué une amélioration du terrain d'assise naturel par la mise en place d'une semelle en pierres concassées, armée de matériaux géosynthétiques. Pour définir les paramètres mécaniques de la fondation consolidée, on a exécuté des essais in situ et l'on a obtenu la relation affaissement-charge, ainsi que le module E. On a établi un modèle numérique suivant la méthode des éléments finis. La stabilité à court terme (non drainé) et l'évolution des contraintes et déformations (consolidation) des sols améliorés sont étudiés.

**KEYWORDS:** soft saturated soil, geosynthetics, reinforced foundation pad, FEM

## 1 INTRODUCTION

The design of reinforced earth structures to replace natural soft soils is a modern practice in geotechnical engineering of improving the foundation ground. High bearing capacity and low ground deformation values are obtained by applying a foundation pad constructed of layers of hard soil, like compacted crushed stone, and of geosynthetic reinforcement. The required thickness of the reinforced pad is much smaller compared to unreinforced soil replacements. Some projects based on this way of soil improvement are realized in Bulgaria in the recent years (Mihov Y. and Mihova L. 2012, Kolev Ch. and Mihova L. 2012).

This paper presents some investigations of the improvement of soft saturated ground under the hall of the "Stilmet" plant in Sofia, which specializes in producing aluminum elements. The geological profile includes uncompacted non-homogeneous fillings at a depth of up to 4 m and soft clays at a depth of up to 10 m. The design of the ground improvement by the reinforced pad involves the following steps: (1) Choosing the thickness of the pad and the number of reinforced layers, based on FE analysis of various configurations of reinforced soil replacement; (2) Construction of an experimental improved ground area and realization of "in situ" settlement/load tests, using a circular steel plate with a diameter of 300 mm; (3) FE modeling using the actual mechanical parameters, and analyzing the stress-strain behavior and the stability of the improved ground; (4) Realization of the improvement of the hall's ground, and verifications of its deformation behavior using plate settlement/load tests.

## 2 GEOTECHNICAL CONSIDERATIONS

The "Stilmet" plant hall, whose area is 3000 m<sup>2</sup>, is being constructed near halls of the same kind (Fig. 1). It has a frame steel structure with spread footings constructed after a 4-meter-

deep strip excavation in three longitudinal axes. The pavement of the hall is made of fibre concrete with a thickness of 20 cm. The equipment of the hall is composed of steel shelves, each being supported at 8 points, and each being 12 m high and weighing 12 tons. Longitudinal beams on the concrete pavement of the hall transform the point loading into striped. The seismic loads on the pavement are obtained by performing a dynamic analysis of the shelf structures.

Figure 1. Steel hall structure (a) and equipment shelf (b).

### 2.1 Geological profile

The geological profile is shown in figure 2, and the properties of the different layers are summarized in table 1. The water level is 1.5 m under the surface. The high water level requires analysis of both the undrained short-term stability and the consolidated long-term stress-strain behavior of the soil ground. The ground

is being examined at a depth of up to 10 m, where solid clay lies.

Figure 2. Geological profile

Table 1. Average values of the soil layers characteristics.

No.	Soil type	$e$	$\gamma$ kN/m <sup>3</sup>	$c'$ kPa	$\phi'$ deg	$E$ MPa
1	Top soil	1,35	1,45	11,0	8,0	3,5
2	Black clay	1,30	1,62	15,0	5,0	3,5
3	Brown clay	0,95	1,86	32,5	7,0	8,5
4	Silty clay	1,41	1,70	11,0	5,0	6,0
5	Sandy clay	0,82	1,89	32,5	18,5	15,0

### 2.2 Structure of the reinforced crushed stone pad

Investigations about the stress-strain behavior of the improved soil ground with various thickness values of the crushed stone pad, various numbers and various stiffness values of the geosynthetic layers have been carried out in advance by FEM models. The optimal structure of reinforced pad with regard to mechanical behavior of improved soil is obtained (fig. 3).

Figure 3. Structure of the reinforced crushed stone pad

Figure 4. TENAX 3D Geogrid XL (www.tenax.net)

The pad should be built of stone particles sized 0–85 mm, and should be 1.3 m thick. The reinforcement is composed of two polypropylene TENAX 3D geogrid XL layers which have particularly large concave shaped ribs that enhance the interaction mechanism between grids and stone particles by restricting the horizontal movement of particles (fig. 4). Technical characteristics of the geogrids are: bi-axial stiffness

900/600 kN/m at 0.5% strain and coefficient of friction soil/geogrid 1.2 (www.tenax.net).

### 3 FIELD TESTING PROCEDURE

To determine the E-modulus of the improved ground, a field test program is performed. It includes the construction of the reinforced pad of area 150 m<sup>2</sup> and an application of a static loading by rigid plate of dimension 30 cm at the following four stages of construction: (1) After compaction of the natural ground; (2) After building the first layer of crushed stone with a thickness of 30 cm; (3) After placing the first geogrid layer and building the second crushed stone layer with a thickness of 50 cm; (4) At the end of the pad construction. At each stage three loading/unloading cycles are applied by steps of 0.05 MPa and settlement/load curves are obtained. The  $E$ -modulus of total settlement and the  $E_c$ -modulus of their elastic part are estimated, and the results are shown in table 2. The settlement/load curves for the first and the last stage of pad construction are shown in figure 6. The moduli values increase more than five times after the soil ground improvement.

Figure 5. Construction of the experimental reinforced crushed stone pad

Figure 6. Settlement/load curves for the plate loading tests

Table 2. Values of the  $E$ -moduli of the soil ground at field testing

No.	Stage of the pad construction	$E$ MPa	$E_c$ MPa
1	Compaction of the natural ground	10,0	33,0
2	The first 30-cm-thick stone layer	25,7	60,0
3	The first geogrid layer and the second 50-cm-thick stone layer	44,3	121,0
4	The end of the pad construction	57,7	181,0

## 4 NUMERICAL ANALYSES

### 4.1 Finite element model

Plane-strain finite element model of the improved ground is made (fig. 7). The behavior of soil is modeled as Mohr-Coulomb material. Linear bar elements that only have tensile strength are used for the geogrids. The concrete pavement is modeled by using linear beam elements. Interface elements are included for modeling the interaction between the soil and the structure elements.

The loading of the pavement is assumed as uniformly distributed with a value of 30 kPa for combination of dead and live static loads and with a value of 45 kPa for seismic load combination. Before the pavement loading calculations, the initial condition of gravity loading is formed by the  $k_0$ -procedure. The construction stages of consecutive excavation and the replacement of the soil are simulated by means of phases of calculation with various FE meshes. An impermeable bottom boundary of the FE model is assumed in consolidation analysis.

Figure 7. Finite element model

### 4.2 Results from FE analyses

#### 4.2.1 Consolidation of the ground at dead and live loads

The consolidation process is investigated, and 3 years and 4 months is the time of the pore pressure dissipation. The maximum value of the pavement settlement is 2.62 cm at point A (fig. 7) and this value corresponds to the end of the consolidation process. The distribution of the vertical displacements is shown in figure 8.

Figure 8. The vertical displacements

Figure 9. Pore pressure distribution

The maximum pore pressure values are obtained immediately after the load application, and its distribution is represented in figure 9. It is evident that in all clayed soils under the pavement the pore pressure increases up to the value of the applied load. The 29.6 kPa maximum value of pore pressure is calculated at point B situated at the bottom of the field. The consolidation curves pore pressure vs. distance at 18 time steps are shown in figure 10 for the cross section A – B. Step number 6 is related to the loading completion.

Figure 10. The curves pore pressure vs. distance

The membrane forces of geogrids, caused by vertical loading, reduce the normal stresses under it. The maximum value of the normal stresses on the soft subsoil at the bottom of the crushed pad is 52.3 kPa. Figure 11 presents the tensile forces in geogrids.

Figure 11. The forces in geogrids at time moments: (a) at a pavement loading; (b) at the end of consolidation

#### 4.2.2 Stability of the ground at seismic load combination

The undrained analysis is performed and the lateral displacements are estimated. The vectors of the total displacements are shown in figure 12. The maximum horizontal displacement is 1.4 cm and it occurs at depth of 4 m under the crushed stone filling of the foundation excavation. The zones of lateral displacements are located, as shown in figure 13, and the stability of the ground is provided.

Figure 12. The vectors of the total displacements

Figure 13. The horizontal displacements

The stability of the ground has been estimated using the  $\varphi, c$ -reduction method. The coefficient of stability has a value  $F_s = 3.42$  for deep slide surface.

## 5 CONCLUSION

The required thickness of reinforced crushed stone pad is about two times smaller compared to the unreinforced pad. The improvement of the ground by replacing of the soft foundation soil by the reinforced crushed stone pad is an effective modern technology which decreases excavation works and increases the heartedness of the foundation soil.

**ABSTRACT:** Sand columns traditionally known as sand compaction piles-(SCPs) have been used to increase the load carrying capacity of soft clays and accentuate consolidation during preloading. Installation of SCPs is known to cause disturbance due to smear in a limited zone of the soil surrounding the SCP. In this study, conventional triaxial tests have been performed on 200mm long and 100mm-diameter clay samples installed with SCP to simulate the strength behaviour of composite ground under different confining pressures ranging from 50kpa to 575kpa. The SCPs were prepared using area replacement ratio of 6.25 to 64% and compacted using pneumatic compactor. The smear zone was created by using a rough casing to drill the hole. The results seem to suggest that the stress-strain behaviour of the clay was influenced by the presence of smear zone. The effect of smear zone on SCP was investigated by observing the change in pore pressure during undrained shear strength of the composite ground. The natural fabric of the soil was destroyed adjacent to the SCPs and the shear-induced pore pressures were less in composite specimens with smear-effect. In addition, as the area replacement ratio was increased, both the stiffness and the strength of the specimen increased.

**RÉSUMÉ :** Des colonnes de sable traditionnellement connues comme piles de compactage (SCPs) de sable ont été utilisées pour augmenter la capacité portante des argiles molles et accentuer la consolidation au cours du préchargement. L'installation de MCS est connue pour causer des perturbations dues au frottis dans une zone limitée du sol entourant le SCP. Dans cette étude, les essais triaxiaux conventionnels ont été réalisés sur les échantillons d'argile, de 100 mm de long et de 200 mm de diamètre, installés avec SCP pour simuler le comportement de la résistance du terrain composite sous différentes pressions de confinement allant de 50 kPa à 575 kPa. Les MCS ont été préparés à l'aide du coefficient de remplacement de 6,25 à 64 %, et compactées au pneumatique. La zone de souillure a été créée en utilisant une enveloppe rugueuse pour percer le trou. Les résultats donnent à penser que le comportement de contrainte-déformation de l'argile a été influencé par la présence de la zone de souillure. L'effet de zone de souillure sur SCP a été examiné en observant le changement de pression interstitielle au cours de la consolidation et de la résistance au cisaillement du sol composite. Le tissu naturel du sol a été détruit adjacent à la SCP et les pressions interstitielles induites par cisaillement étaient inférieures dans les échantillons composites avec un effet de maculage. En outre, lorsqu'on augmente le ratio de remplacement du frottis, la rigidité et la résistance de l'échantillon augmentent.

## 1 INTRODUCTION

Soft ground is widely distributed especially along the coastal area, having large potential for settlement with low inherent shear strength. In the recent years, improvement of soft soils has been extensively implemented for the various development projects all over the world due to extremely limited stable construction sites. Granular piles such as sand compaction piles (SCPs) are considered as cost-effective and alternative solution to the problem of stability and settlement posed by construction on soft ground. The insertion of SCPs into soft clay has been shown to have a positive effect on the load carrying capacity of the clay, resulting in a composite soil mass that has greater shear strength and improved stiffness compared to the unreinforced clay. Sand compaction pile (SCP) is a method of constructing large diameter sand column in the ground. This method of ground improvement has been widely used for rapid improvement of soft ground, and also in near-shore regions for land reclamation works (e.g. Aboshi and Suematsu 1985, Bergado and Balasubramniam 1994). In India, the granular columns have been used to improve ground for container freight station at Navi Mumbai and the construction of dry dock at Pipavav shipyard (Raj and Dikshith 2009). Many researchers (e.g. Bergado et al. 1991, Juneja and Mir 2011) have investigated the effect of SCP installation on disturbance to the surrounding soil. The extent of the disturbed or smear zone can

affect the engineering behaviour of the composite ground. The disturbance in this zone depends upon the column diameter and the tools used in the installation (e.g. Singh and Hattab 1979, Madhav et al. 1993). Shear induced pore pressures were found to be less in specimens which had the smear zone surrounding the sand column. However, pore pressures began to increase close to failure due to rearrangement of soil particles (Mir 2010). Laboratory and field tests previously conducted to determine the extent of the disturbance caused by pile driving into soft clay deposits have demonstrated that the natural structure of the clay around the pile is excessively disturbed (Randolph et al. 1979, Xu et al. 2006). It was observed that the diameter of the severely disturbed or remoulded ground around a driven closed-ended casing was about 1.4 times the diameter of the casing. Recently, Weber et al. (2010) compared the smear zone around model SCPs to that observed around driven piles. It was observed that the smear zone around SCPs installed on the centrifuge extended up to 1.2 to 1.4 times the SCP diameter. Dissipation of the excess pore pressures often results in increase in the shear strength. Aboshi et al. (1979) observed up to 50% increase in the undrained strength in about one month after the SCP installation at test sites in Japan. Matsuda et al. (1997) also reported an increase in strength of the composite SCP ground within three months of the SCPs installation.

In this study, the effect of smear zone on strength of model SCP installed in 100mm diameter and 200mm long clay specimens is investigated using conventional triaxial compression tests under different confining pressures ranging from 50kPa to 575kPa. The composite specimen were prepared by driving a small diameter PVC casing into the sample and then backfilling the cavity with sand column after removing the casing. The casing was roughened using sand glued to its outer walls prior to insertion to replicate the smearing effect. The SCPs were prepared using area replacement ratio of 6.25 to 64% and compacted using pneumatic compactor. SCPs of different diameters (25-80mm) were used to investigate the improvement in the load-carrying capacity of the specimens. The effect of smear zone on SCP was investigated by observing the change in pore pressure during consolidation and undrained shear strength of the composite ground. The test results suggest that, tress-strain behavior of the clay was influenced by the presence of smear zone. The natural fabric of the soil was destroyed adjacent to the SCPs with smear zone which in turn affected pore pressure response of the composite soil sample. Shear induced pore pressures were less in soil specimens with smear-effect, but this difference was not apparent when 80mm diameter SCP with smear zone was used. In addition, as the reinforcement area ratio increased, both the stiffness and the shear strength of the specimen increased. Thus, sand compaction piles currently stand as one of the most viable and practical techniques for improving the mechanical properties of soft clays.

2. EXPERIMENTAL WORK

2.1. Materials and methods of sample preparation

The test specimens were prepared in 450mm long and 250mm diameter stainless steel cylindrical mould. Deaired clay slurry was consolidated on the laboratory floor, first under its own self-weight and later under surcharge of 211- to 404 kN/m<sup>2</sup> applied in stages on top of the clay surface using a custom designed pneumatic load frame (Fig.1).

Slurry consolidation Specimen trimming Final specimen size  
Figure 1. Consolidation set-up on the laboratory floor

Upon completion of the 1-D consolidation, the block of clay was extruded and trimmed into three 100mm diameter cylindrical specimens using soil lathe. Up to 3 specimens could together be prepared using this mould. The experimental program consisted of 20 tests on composite clay with sand column. The specimens were held in split cylindrical moulds and a smooth PVC casing slowly pushed along its length to form a cylindrical hole at the centre. The hole was backfilled with fine sand ( $d_{50}=0.3\text{mm}$ ) compacted in layers at 90% relative density using a pneumatic compactor (Fig. 2). Sand column

Figure 2. Preparation of composite specimen  
Diameter of the sand column varied between 25- and 80mm in the specimens. This corresponds to an area replacement ratio,  $a_s$

(Aboshi et al. 1979) that ranges between 6.25- and 64%. The smear zone was created by using a rough casing painted with a paste of coarse sand ( $d_{50} = 1.3\text{mm}$ ) to drill the hole. Thickness of the smear zone was taken equal to the thickness of the paste. The effect of smear beyond this zone was ignored. After preparing the sand column, the ends of the specimen were covered with a thin circular rubber sheets having a central hole. Diameter of the hole was slightly less than that of the sand column so as to only permit radial drainage. Two deaired porous stones were then placed at the two ends of the specimen and the entire assembly mounted on the triaxial chamber. Table 1 shows properties of the clay used in this study. The ratio of the diameter of sand column with smear zone to the diameter of sand column without smear zone ( $d_s/d$ ) was about 1.1 to 1.2 in all tests, which compares well with the values reported by the previous researchers (e.g. Indraratna and Redana, 1998; amongst others). The specimen was enclosed in a rubber membrane and the chamber filled with water. The soil samples were then isotropically consolidated under mean effective stress,  $p'$  which varied between 50 and 575 kN/m<sup>2</sup>.

3. RESULTS AND DISCUSSIONS

Consolidated undrained triaxial tests were performed on 200mm long and 100mm diameter cylindrical samples prepared from remoulded and reconsolidated commercially available kaolin clay installed with SCP. Table 2 shows the details of the soil specimens prepared for testing. In the table, OCR is defined as the ratio of the isotropic preconsolidation pressure,  $p_{0'}$  to  $p'$ .  $p_{0'}$  was taken equal to the higher of either  $p'$  or the mean effective stress after 1D consolidation,  $p'$  estimated using the equation (Wroth 1984):

$$p' = \sigma'_v [1 - 0.67 \sin \phi'] \tag{1}$$

where  $\phi'$  is the effective angle of friction (e.g. Schofield and Wroth 1968). The load-deformation data was analyzed using the unit cell arrangement proposed by Balaam et al. (1977). In this method, the column and surrounding clay are assumed to act as a single element with equivalent distributions of stresses and strains in composite specimens. Figures 3a-b show results of deviator stress,  $q$  plotted against axial strain,  $\epsilon_a$ . As can be seen, all samples reached peak deviator stress ( $q_{max}$ ) at 6 to 10% axial strain. Figures 3a-b also show that the ultimate strength exhibit transient peaks in some tests. This was expected since these soil samples were overconsolidated prior to the shearing. In few tests on normally consolidated clays,  $q$  decreased after passing  $q_{max}$  because of instability of the failed samples at high confining pressure.

\*:  $\sigma'_v$  = Vertical stress at end of 1D loading,  
 #:  $d_s$  = Equivalent diameter of sand column,  
 \$:  $p'_o$  = Preconsolidation pressure,  
 \*\*:  $p'$  = Mean effective stress at end of consolidation,

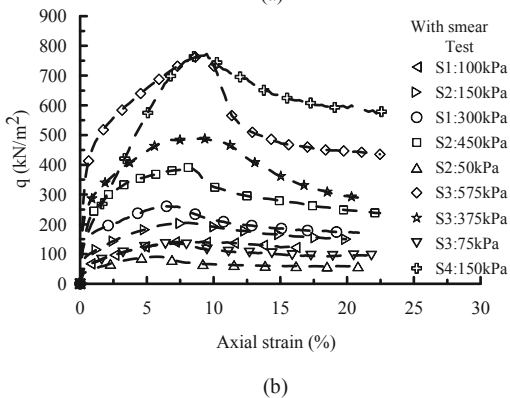

Figure 3a-b Deviator stress versus axial strain relationship for: (a) Samples without smear zone; and (b) Samples with smear zone.

The undrained shear strength ( $s_u$ ) of composite specimen was taken equal to  $\frac{q_{max}}{2}$ , and the effect of stress history induced

over consolidation on undrained strength ratio  $\frac{s_u}{p}$  was expressed as:

$$\left(\frac{s_u}{p'}\right)_{OC} = a(OCR)^m \quad (2)$$

where  $a$  is the normalized undrained shear strength of NC soil equal to  $\left(\frac{s_u}{p'}\right)_{NC}$  for  $OCR=1$ , and  $m$  is an empirical exponent equal to  $\left(1 - \frac{\kappa}{\lambda}\right)$ ,  $\kappa$ ,  $\lambda$  are soil model parameters

obtained from triaxial testing. Using test data, undrained shear strength ( $s_u$ ) of composite ground was expressed in the following form:

$$\left(\frac{s_u}{p'}\right) = 0.44(OCR)^{0.99} \text{ - without smear} \quad (3)$$

$$\left(\frac{s_u}{p'}\right) = 0.33(OCR)^{0.90} \text{ - with smear effect} \quad (4)$$

The evidence of the smear zone was not significant on the ultimate undrained shear strength when 25mm and 30mm diameter sand columns were used. What was surprising is that the effect of smear was apparent on the ultimate shear strength when 80mm diameter sand columns were used. It seems clear that the presence of smear zone has reduced the ultimate undrained shear strength by 25%. In addition, as the area replacement ratio was increased, both the stiffness and the shear strength of the composite samples also increased. Figure 4 show results of Skempton's (1954) pore pressure parameter,  $a$ , plotted against axial strain,  $\epsilon_a$ . As seen, the A-factor in specimens with smear effect was less from early stage of shearing even when the specimens had the same OCR. This was expected because the smear zone did not permit the pore pressures to dissipate within the SCP. However, there was a marginal increase in a-factor after passing  $q_{max}$ .  $a_f$  of these samples was between 0.7 and 1.1 which is typical for normally consolidated clays.

Figure 4. Variation of Skempton's parameter A with axial strain for samples with and without smear zone.

Figure 5. Effective stress paths for samples without smear and with smear zone  
 Figure 5 show the effective stress path in  $p'$ - $q$  stress space.

The figures show that the shear induced pore pressures were found to be less in specimens which had the smear zone surrounding the sand column. Due to the smear zone, these pore pressures within the SCP were reduced because the water was not permitted to flow towards the column during shearing.

This was also evident from Scanning Electron Microscope (SEM) images (Fig. 6a-b) taken on post shear tests of specimens with and without smear. The images of samples with and without the smear zone show differences in the microstructure. The clay minerals in the smear zone appear to be closely packed with reduced pore space. 7.5 mm x 7.5 mm x 7.5 mm air dried samples were prepared at room temperature for the SEM images.

Figure 6. SEM images: (a) Composite samples without smear zone; and (b) Composite samples with smear zone.

#### 4. CONCLUSIONS

The strength behavior of composite ground reinforced with sand compaction piles has been studied using 20 consolidated undrained triaxial tests. Vertical stress of the sand column was examined when the composited specimens were tested to failure in conventional triaxial tests. The test results suggest that the stress-strain behavior of the clay was influenced by the presence of smear zone. It seems clear that the presence of smear zone has reduced the ultimate undrained shear strength by 25%. SEM images indicated that the natural fabric of the soil was destroyed adjacent to the SCPs with smear zone which in turn affected pore pressure response of the composite soil sample. Specimens sheared with smear effect appear closely packed and more homogeneous with partly discernible particle systems, while specimen without smear condition indicate a distinct division between smaller intra-aggregate pore spaces and the larger inter-aggregate voids. Shear induced pore pressures were less in soil specimens with smear-effect because the water was not permitted to flow towards the column during shearing. It was postulated that the difference in the behavior of smear and non-smear specimens was because that the pore pressure measurements were taken within the sand column. This difference was not apparent when 80mm diameter SCP with smear zone was used. These changes affect the effective horizontal stress in the clay and hence the load carried by the individual sand columns.

# Bio-mediated soil improvement utilized to strengthen coastal deposits

## Amélioration du sol biologiquement négociée utilisée pour renforcer les dépôts côtiers

Montoya B.M., Feng K., Shanahan C.  
North Carolina State University, Raleigh, NC, USA

**ABSTRACT** - Vital coastal lifelines can be vulnerable during large storm events. Large wave action and high sea levels erode the sandy soil that supports coastal infrastructure, including highways, structures, pipelines, and other utilities. Damage from these events can result in severe property damage, loss of revenue, and large repair costs. Natural bio-geochemical methods can be used to reinforce the erodible sandy soil to help prevent damage to the infrastructure. Utilizing naturally-occurring biological metabolic activity, calcium carbonate cementation can be induced *in situ* to bind the sand grains together, thereby improving the strength and stiffness of the soil and in turn preventing erosion of the coastal deposits. Microbial induced carbonate precipitation (MICP) has been shown to be an effective method to improve the soil behavior in saturated conditions subjected to undrained monotonic and seismic loading in both laboratory and centrifuge tests. Applying this proven natural treatment technique to unsaturated coastal soils can improve the soil's resiliency during large storm events. Results indicate that the strength of the unsaturated soils increase from intermittent surficial treatments. Rigid-walled soil column tests were conducted to evaluate the effectiveness of treating sandy soils by flooding the surface of the soil with the appropriate microbes and nutrients and allowing free drainage. Clean fine sand, typical of coastal dune deposits, was used in the soil column tests. The strength of the cemented sand was evaluated using unconfined compression tests. A discussion of upscaling the results from the laboratory tests to application *in situ* to improve the resiliency of coastal infrastructure is also presented herein.

### 1. INTRODUCTION

Vital coastal lifelines can be vulnerable during large storm events. Large wave action and high sea levels erode the sandy soil that supports coastal infrastructure, including highways, structures, pipelines, and other utilities. Damage from these events can result in severe property damage, loss of revenue, and large repair costs. The outer banks of North Carolina have seen several hurricanes in recent years (Irene in 2011, and Sandy in 2012) which have inflicted damage to vital coastal lifelines as illustrated in Figures 1 and 2.

Natural bio-geochemical methods can be used to reinforce the erodible sandy soil to help prevent damage to the infrastructure. Utilizing naturally-occurring biological metabolic activity, calcium carbonate cementation can be induced *in situ* to bind the sand grains together, thereby improving the strength and stiffness of the soil and in turn preventing erosion of the coastal deposits. Microbial induced carbonate precipitation (MICP) has been shown to be an effective method to improve the soil behavior in saturated conditions subjected to undrained monotonic and seismic loading in both laboratory and centrifuge tests (Montoya et al., 2013, Mortensen and DeJong, 2011, DeJong et al., 2006). Applying this proven natural treatment technique to unsaturated coastal soils can improve the soil's resiliency during large storm events. Results indicate that the strength of the unsaturated soils significantly increase from intermittent surficial treatments. Rigid-walled soil column tests were conducted to evaluate the effectiveness of treating sandy soils by flooding the surface of the soil with the appropriate microbes and nutrients and allowing free drainage. Clean fine sand, typical of coastal dune deposits, was used in the soil column tests. Changes in the strength of the sand from the unsaturated cementation treatments was evaluated using unconfined compression tests. A discussion of upscaling the results from the laboratory tests to application *in situ* to improve the resiliency of coastal infrastructure is also presented herein.

## 2. MATERIALS AND METHODS

### 2.1. Sand and Specimen Preparation

Four soil column specimens were prepared by dry pluviation to a target relative density of 40%. The soil column specimens had a 50.8 mm (2 in) diameter and an aspect ratio of 2:1. Ottawa 50-70 sand was used for the initial cementation trials, because of the published results with the sand (DeJong et al., 2006, Mortensen and DeJong, 2011, Montoya et al., 2013, Martinez et al., 2013). A summary of the sand characteristics is listed in Table I.

Table I. Ottawa 50-70 Sand characteristics

	Ottawa 50-70 Sand Characteristics
$D_{50}$ (mm)	0.22
$C_u$	1.4
$C_c$	0.9
$G_{max}$	2.65
$e_{min}$	0.55
$e_{max}$	0.87
Mineralogy	Quartz
Shape	Round

### 2.2. Biological Treatment Process

*Sporosarcina pasteurii* (ATCC 11859), a urea hydrolyzing bacterium, was grown at 30 °C in an Ammonium-Yeast Extract medium (ATCC 1376: 0.13 mol l<sup>-1</sup> Tris buffer (pH=9.0), 10 g l<sup>-1</sup> (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, and 20 g l<sup>-1</sup> yeast extract). Individual ingredients were autoclaved separately and mixed together post-sterilization. The growth medium was inoculated with the *S. pasteurii* stock culture and incubated aerobically at 30 °C in a shaking water bath (200 rpm) for approximately 40 hrs before harvesting at a final optical density (OD<sub>600</sub>) of 0.8-1.0. Cultures were centrifuged at 4000 g for 10 min in 15 mL volumes and washed in fresh growth medium. Harvested bacteria were stored in the centrifuge vials at 4 °C for a maximum of 2 days.

Urea-calcium cementation media was used to induce ureolytic-driven calcite precipitation. A summary of the components and concentrations are presented in Table II.

Table II. Chemical recipe for cementation media

Chemical	Chemical Concentration (M)
Urea	1.0
CaCl <sub>2</sub>	0.25

Cementation treatments were performed by flooding the top surface of the soil column, and allowing the cementation media to freely drain through the sand (Figure 3). Bacteria were introduced into the soil during the initial cementation flush. Calcium chloride was not included in the initial treatment with the bacteria to prevent precipitation during inoculation. Cementation treatments were repeated every 3 to 6 hours. Two pore volumes of nutrients were used in each treatment flush (concentrations of nutrients presented in Table II). The cementation treatments were repeated for a total of 40 times.

Figure 3. Initial biological flush through soil columns. Cementation flushes allowed to free drain through pluviated soil.

### 2.3. Specimen Shearing

After cementation was completed, the specimen was flushed with water to remove residual chemicals from the cementation treatments. The cemented sand was removed from the soil columns. The cemented soil columns were then subjected to unconfined compression tests until failure. A GeoJac automated load actuator was used to perform the unconfined compression test.

### 2.4 Mass of Calcium Carbonate Measurements

The mass of calcium carbonate was determined post-test using methods outlined in ASTM D4373, *Standard Test Method for Rapid Determination of Carbonate Content in Soils*. At the end of the cementation treatments, oven dried cemented sands are dissolved in hydrochloric acid and the resulting pressure generated from the dissolution of calcium carbonate is measured. The generated pressure is equated to an equivalent mass of calcium carbonate. The percentage of mass of calcium carbonate is expressed as the mass of calcium carbonate divided by the mass of soil (not including calcium carbonate).

## 3. RESULTS

### 3.1 Calcium Carbonate Content in Soil Columns

Mass of calcium carbonate was taken in the top and bottom of the cemented soil column, which are reported in Table III. As indicated in Table III, the mass of calcite in the four soil columns is relatively small compared to published results from other MICP treatment studies (Weil et al., 2011). However, the cementation within the soil column was extremely uniform, as indicated by the mass of calcium carbonate of the top and bottom samples (Table III).

Table III. Summary of Mass of Calcium Carbonate

Soil Column	Mass of CaCO <sub>3</sub> (%)
1 (top)	0.082
1 (bottom)	0.081
2 (top)	0.102
2 (bottom)	0.103
3 (top)	0.070
3 (bottom)	0.068
4 (top)	0.070
4 (bottom)	0.068

### 3.2 Cemented Sand Compressive Strength

Unconfined compression tests were performed on the cemented soil columns (Figure 4 and Figure 5). As mentioned, the mass of precipitated calcium carbonate is relatively small compared to published results from other MICP treatment studies; however even at low mass of calcium carbonate levels, unconfined compression tests were able to be performed on the cemented sand columns. A summary of the compression test results are listed in Table IV.

Figure 4. Cemented soil column mid-test during the unconfined compression test.

Figure 5. Failed cemented soil column at the end of the unconfined compression test.

Table IV. Summary of Compressive Strength

Soil Column	Unconfined Compressive Strength (kPa)
1	5.2
4	5.4

As indicated in Table IV, unconfined compression tests were performed on only two of the four columns. Two of the soil columns were not able to be tested because they were disturbed during extraction from the soil column walls. The cemented soils were especially vulnerable because of the low levels of cementation. To rectify the tendency for disturbance, the soil in the remaining columns was extracted from the soil column walls by creating vertical slices through the acrylic walls and allowing the soil to be removed through the sliced opening.

The unconfined compressive strength of the cemented sand columns was about 5 kPa. Other studies found that MICP treated Ottawa 50-70 sand could get compressive strengths of about 170 to 350 kPa at higher levels of cementation (Faison and Mahin, 2012).

The angle of the failure plane in soil columns 1 and 4 was about 63 degrees from the horizontal. This failure plane angle is representative of soil with a friction angle of 36 degrees. Untreated Ottawa 50-70 sand has a friction angle of about 33 degrees (Montoya, 2012). Based on previous work, MICP treated sand with a friction angle of 36 degrees is typical of sand treated to a shear wave velocity of 400 m/s (Montoya, 2012). An approximate shear wave velocity of 400 m/s corresponds to the strength data, indicating the cemented soil columns represent lightly cemented sand.

For use as a treatment process for coastal sand deposits, an appropriate level of MICP cementation should be used. A high enough level of cementation should be used to resist induced shear loads from waves and storm surges, and a low enough level of cementation so that native wildlife, such as birds, burrowing animals, and dune grass, can still interact with the coastal deposits. Further work will include upscaling the

treatment process using a wave tank to identify optimum ranges of cementation for treatment of coastal deposits.

#### 4. CONCLUSIONS

MICP can be used to reinforce sandy coastal deposits to improve the resiliency of vital lifelines during large storm events. Soil columns of clean fine sand were treated with MICP, and resulted in lightly cemented sand. The lightly cemented sand had an increase in strength, as demonstrated with the unconfined compression tests, and increase in friction angle. The free-draining treatment process was designed to be similar to likely treatment processes of unsaturated surficial sands in situ. This treatment process provided uniform levels of cementation throughout the height of the soil column. The light levels of cementation achieved in the soil columns provide an increase in shear strength while still allowing for birds, burrowing animals, and dune grass to interact with the coastal deposits. Future work involves investigating the optimal range of MICP cementation to provide enough strength to resist the loads from large storm events while continuing to support the coastal ecology.

*Geotechnical Engineering Laboratory, Department of Civil Engineering, University of Patras, Greece*

**ABSTRACT:** Grouts of three different cement types, each at four different cement gradations, with W/C ratios ranging from 0.6 to 3.0 and bleed capacities ranging up to 70% were injected into two different sands. Permeability, unconfined and triaxial compression and resonant column tests were conducted to investigate the influence of grout bleed capacity on the engineering properties of cement grouted sands. Cement grouting resulted in (a) permeability coefficient values as low as  $10^{-8}$  cm/s, (b) unconfined compressive strength in the range of 1MPa to 35MPa, (c) cohesion in the range of 100kPa to 1400kPa, (d) improvement of the internal friction angle by up to  $5^\circ$ , (e) higher shear modulus by up to 25 times and (f) improved damping ratio by up to 10 times. Bleed capacity is an indicator of sand void volume filled with solidified grout but its degree of correlation with the static and dynamic properties of the grouted sands ranges from very good to negligible.

**RÉSUMÉ :** On a injecté des coulis de trois types de ciments différents, chacun avec quatre dosages en ciment différents, avec un rapport eau/ciment variant de 0.6 à 3.0, et une capacité de ressuage se situant jusqu'à 70% lorsque injectés, dans deux sables différents. On a effectué des essais de perméabilité, de compression simple et triaxiale et de colonne résonnante pour étudier l'influence de la capacité de ressuage des coulis sur les propriétés mécaniques des sables injectés. L'injection du ciment a résulté en: a) des valeurs de coefficients de perméabilité aussi faible que  $10^{-8}$  cm/s, b) une compression simple de 1MPa à 35MPa, c) une cohésion de 100kPa à 1400kPa, d) une augmentation de l'angle de frottement jusqu'à  $5^\circ$ , e) un module de cisaillement jusqu'à 25 fois plus élevé, f) une augmentation du coefficient d'amortissement jusqu'à 10 fois plus élevé. Le ressuage des coulis est un indicateur du volume des vides du sable remplis de coulis solidifié mais son degré de corrélation avec les propriétés statiques et dynamiques des sables cimentés varie de très bonnes à négligeables.

**KEYWORDS:** cement grout, bleed capacity, permeability, strength, shear modulus, damping ratio

## 1 INTRODUCTION

Improvement of the mechanical properties and behavior of soils by permeation grouting using cement suspensions is frequently required in order to assure the safe construction and operation of many structures. The grout water-to-cement ratio (W/C) and the maximum cement grain size ( $d_{max}$ ) are two important parameters controlling the cement grout bleed capacity and, consequently, the effectiveness of cement grouts in terms of the percentage of soil voids volume filled by grouting. Although the bleed capacity of cement grouts has been frequently quantified, its correlation with the engineering properties of the grouted sand has not been investigated so far.

Scope of this presentation is to provide some insights on the effect of grout bleed capacity on permeability, unconfined compressive strength, shear strength parameters and dynamic properties of ordinary and microfine cement grouted sands, in conjunction with the effect of the grout W/C ratio.

## 2 MATERIALS AND PROCEDURES

For the purposes of this investigation, a Portland, a Portland-composite and a pozzolanic cement (CEM I, CEM II/B-M and CEM IV/B according to Standard EN 197-1) were used. Each cement was pulverized to produce three additional cements with nominal maximum grain sizes ( $d_{max}$ ) of 40 $\mu$ m, 20 $\mu$ m and 10 $\mu$ m and average Blain specific surface values of 567, 720 and 928 $m^2/kg$ , respectively. Cements with  $d_{max}=10\mu$ m can be considered as "microfine" according to Standard EN 12715 ( $d_{95}<20\mu$ m and specific surface over 800 $m^2/kg$ ). Also, cements with  $d_{max}=20\mu$ m have adequately small characteristic grain sizes to be considered, marginally, as "microfine". Typical gradations of these cements are presented in Figure 1.

All suspensions tested during this investigation were prepared using potable water since it is considered appropriate for

preparing cement-based suspension grouts. The W/C ratio of the suspensions was set equal to 0.6, 0.8, 1.0, 2.0 and 3.0 by weight, in order to test both stable and unstable suspensions in terms of bleed capacity. A superplasticizer (patented new generation of admixture based on polycarboxylate chemistry) at a dosage of 1.4 % by weight of dry cement was used to improve grout properties. All suspensions were prepared using high speed mixers. As recommended by the superplasticizer producer,

10µm	N/T	N/T	0-2	7-26	38-42

N/T: Not tested

the total amount of cement, 70 % of the water and the superplasticizer dosage were mixed for 5 min. Then, the rest of the water was added and mixing continued for another 5 min. Bleed capacity measurements were conducted for all cement suspensions used and the results are summarized in Table 1.

According to Standard EN 12715, a suspension is stable when it has a bleed capacity of not more than 5 % after 120 min from preparation. It can be observed that a W/C ratio of about 0.6 was required to obtain stable suspension of the coarse cements (d<sub>max</sub>=100µm and 40µm) while microfine cement suspensions were stable for a W/C ratio of 1.0

The soils used were clean, uniform, limestone sands with angular grains and were grouted at a dense (relative density approximately 90%) and dry state. Two different sand gradations were used with grain sizes limited between sieve sizes (ASTM E11) Nos. 10-14 and 14-25 (d<sub>15</sub> size of 1.5mm and 0.8mm, respectively) in order to allow grouting by both the coarse- and fine-grained suspensions. The angle of internal friction of the sands was 42.2° and 42.6°, respectively.

Laboratory equipment, similar to the arrangement described in ASTM D4320-84, was used to produce small-size grouted sand specimens, with a height of 112mm and a diameter of 50mm, ready for testing (Pantazopoulos et al. 2012). Injection was stopped when the volume of the injected grout was equal to two void volumes of the sand in the molds. After 24 h, the specimens were extracted from the split molds and cured in a humid room for 28 days before testing.

Grouted specimens were tested in unconfined compression at a displacement rate equal to 0.1%/min. Hydraulic conductivity tests were performed according to the procedure described by Head (1986) for permeability testing in a triaxial cell with two back-pressure systems. Drained triaxial compression tests were conducted under confining pressures of 100, 200 and 400kPa and axial strain rate equal to 0.1%/min, without initial saturation and consolidation. The dynamic properties of the grouted sands were investigated at confining pressures up to 400kPa by conducting torsional resonant column tests for a shear strain range, γ, of approximately 5\*10<sup>-5</sup> % to 5\*10<sup>-2</sup> %. Testing procedures and interpretation of raw data complied with well established methods (Pantazopoulos and Atmatzidis 2012). For comparison, similar tests were conducted on clean sands.

### 3 COEFFICIENT OF PERMEABILITY

The coefficient of permeability values of all grouted sands tested are presented in Figure 2 with respect to W/C ratio, bleed capacity and maximum cement grain size of the suspensions. The coefficient of permeability decreases considerably (by about 5 orders of magnitude) as the W/C ratio decreases from 3 to 0.6 and attains a value of about 10<sup>-7</sup> to 10<sup>-8</sup>cm/s indicating practically impermeable materials. The permeability of the grouted sands appears not to be affected by the cement grain size. Evaluation of the permeability of the grouted sands in terms of grout bleed capacity indicates a similar trend as with the W/C, but allows some observations to be made in terms of the effect of cement grain size. For cement grouts with d<sub>max</sub> equal to 100µm and 40µm, the coefficient of permeability of the grouted sands attained values in the range of 10<sup>-7</sup> to 10<sup>-8</sup>cm/s and 10<sup>-3</sup> to 10<sup>-4</sup>cm/s, for grout bleed capacity ranging from 6%

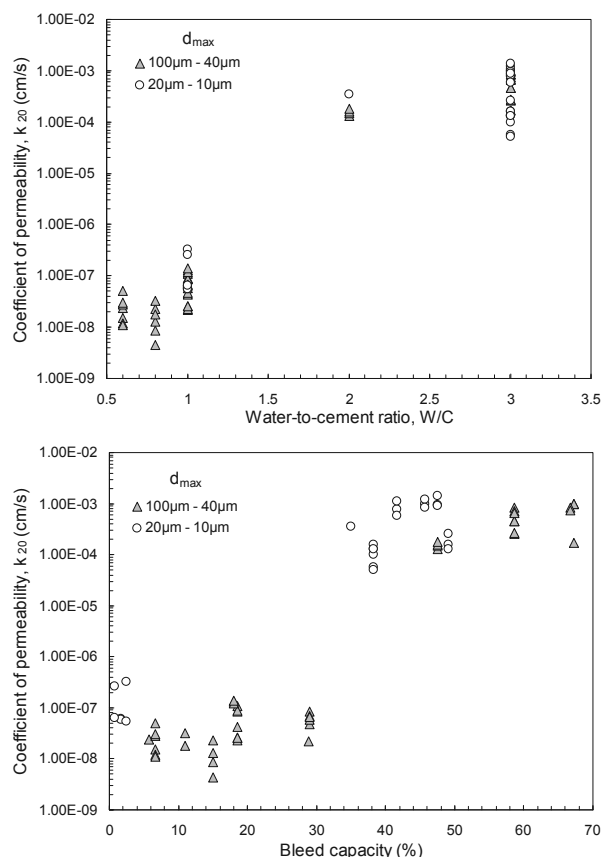

Figure 2. Effect of grout W/C ratio and bleed capacity on the permeability of cement grouted sands.

Figure 3. Effect of grout W/C ratio and bleed capacity on the unconfined compression strength of cement grouted sands.

to 30% and from 48% to 68%, respectively. Sands injected with microfine cement grouts ( $d_{max}=20\mu\text{m}$  and  $10\mu\text{m}$ ) obtained, generally, higher coefficients of permeability, by half to one order of magnitude, compared to sands grouted with the coarser cement suspensions, for similar bleed capacities. This is reasonable and can be attributed to the increased amount of coarse-grained cement needed to obtain the same bleed capacity with suspensions of microfine cements. It should also be noted that (a) similar coefficient of permeability values ( $10^{-7}$  to  $10^{-8}$  cm/s) are obtained when injecting with stable or unstable suspensions for bleed capacity values up to 30% and (b) for higher bleed capacity values, the coefficient of permeability of the grouted sand decreases dramatically but remains in the range of  $10^{-4}$  to  $10^{-3}$  cm/s.

#### 4 UNCONFINED COMPRESSION STRENGTH

The results presented in Figure 3 indicate that the unconfined compression strength of the grouted sands increases significantly with decreasing W/C ratio of the grouts, as verified by other research efforts (i.e. Dano et al. 2004) and seems not to be affected by cement grain size. However, the effect of cement grain size can be clearly demonstrated in terms of grout bleed capacity. The unconfined compression strength of the grouted sands is very well correlated with grout bleed capacity of both the coarse-grained cements ( $d_{max}=100$  and  $40\mu\text{m}$ ) and the microfine cements ( $d_{max}=20$  and  $10\mu\text{m}$ ) but, definitely, microfine cement grouts with the same bleed capacity as cement grouts yield significantly lower grouted sand strength. As with permeability, this can be attributed to the increased amount of coarse-grained cement needed to obtain the same bleed capacity as microfine cement suspensions.

#### 5 SHEAR STRENGTH

The shear strength of the grouted sand specimens is expressed in terms of internal friction angle and cohesion, by applying the Mohr-Coulomb failure criterion. As indicated in Figure 4, the internal friction angle ranged from  $40^\circ$  to  $50^\circ$  and the effect of W/C ratio, bleed capacity and cement grain size appear to be insignificant. In general, the internal friction angle of the grouted sands was up to  $5^\circ$  higher than the value obtained for clean sands. The cohesion of the grouted sands is strongly affected both by the W/C ratio and by the bleed capacity of the grouts. As shown in Figure 5, the cohesion values of the grouted sands ranged from 600kPa to 1450kPa, from 300kPa to 500kPa and from 50kPa to 250kPa, for W/C ratios equal to 1, 2 and 3, respectively. Furthermore, grouted sands injected with stable grouts (bleed capacity values less than 5%) obtained the highest cohesion values ranging from 1200kPa to 1450kPa. Increased bleed capacity values (unstable suspensions) in the range of 15% to 65%, leads to an almost linear decrease of the cohesion values from 800kPa to 100kPa. The effect of cement grain size on grouted sand cohesion, as shown in Figure 5, where the microfine cements exhibit higher values of cohesion than the coarse-grained cements, by 40% to 150%, is misleading since the suspensions used had different bleed capacities for the same W/C ratio. For example, at W/C ratio equal to 1, the microfine cement suspensions are stable (bleed capacity  $< 4\%$ ) and fill the sand voids with cement more completely and uniformly than the coarse cement suspensions with W/C=1 (bleed capacity  $> 16\%$ ).

#### 6 SHEAR MODULUS

Presented in Figure 6 are typical results obtained for the shear modulus,  $G$ , of grouted sands at a confining pressure equal to 50kPa and shear strain equal to  $10^{-5}\%$ . The effect of confining pressure is not pronounced for the grouted sands tested (Pantazopoulos and Atmatzidis 2012). As shown in Figure 6, the shear modulus values decrease, from 4.1GPa to

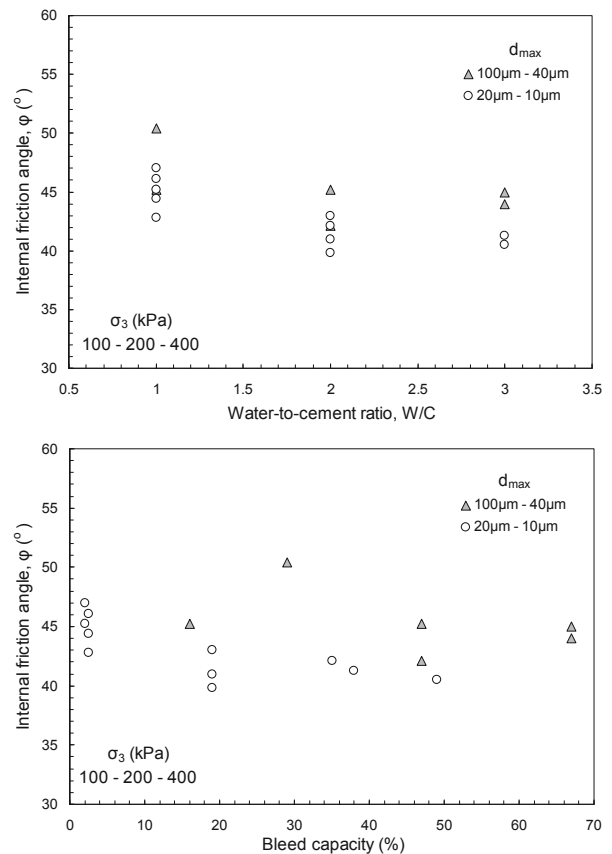

Figure 4. Effect of grout W/C ratio and bleed capacity on the internal friction angle of cement grouted sands.

Figure 5. Effect of grout W/C ratio and bleed capacity on the cohesion of cement grouted sands.

Figure 6. Effect of grout W/C ratio and bleed capacity on the shear modulus of cement grouted sands.

Figure 7. Effect of grout W/C ratio and bleed capacity on the damping ratio of cement grouted sands.

1.5 GPa, with increasing W/C ratio, from 0.6 to 3. The shear modulus values of the clean sands did not exceed 170MPa, indicating an improvement up to 25 times by grouting. The effect of grout bleed capacity on the shear modulus of grouted sand is clearly depicted in Figure 6, where it can be observed that above a bleed capacity value of about 30%, the shear modulus of the grouted sand decreases sharply by about 40%. Cement grain size seems to have a measurable effect on the shear modulus values of the grouted sands. For similar bleed capacity values, the sands grouted with microfine cement grouts have lower shear modulus values, by 15% to 30%, compared to sands grouted with coarse-grained cement grouts.

### 7 DAMPING RATIO

The damping ratio values of the grouted sands are presented in Figure 7 for a confining pressure equal to 50kPa and shear strain equal to  $10^{-3}$ %. The effect of shear strain and confining pressure on the grouted sand damping ratio has been presented elsewhere (Pantazopoulos and Atmatzidis 2012). In general, the values obtained ranged from 0.5% to 8.0%, increased with increasing shear rate (from  $5 \cdot 10^{-5}$ % to  $5 \cdot 10^{-2}$ %) and decreased with increasing confining pressure (from 50kPa to 400kPa). The grout W/C ratio has a measurable effect on the damping ratio values of the grouted sands, which have a tendency to increase with increasing W/C ratio. The effect of grout bleed capacity on the damping ratio of the grouted sand appears to be less dominant, mainly for coarse-grained cements. For microfine cements there is a tendency for the damping ratio of the grouted sands to increase with increasing bleed capacity of the grouts. Even though the available data are limited, grouted sands injected with stable grouts (bleed capacity less than 5%) of microfine cements indicated damping ratios lower by 50% than those for grouting with unstable grouts. The damping ratios of the clean sands (for confining pressure and shear strain equal to 50kPa and  $10^{-3}$ %, respectively) did not exceed 0.5%, indicating an improvement up to 10 times by grouting.

### 8 CONCLUSIONS

Based on the results obtained and the observations made, the following major conclusions may be advanced:

1. Bleed capacity is an indicator of grout effectiveness, since it is representative of the soil void volume filled by cement.
2. The distinction between stable and unstable grouts may not be an indicator of grout effectiveness since similar effects may be produced by both stable and unstable grouts.
3. Bleed capacity values correlate very well with some grouted sand properties (i.e. unconfined compression strength, cohesion) and not at all with other properties (i.e. damping ratio, internal friction angle).

# Numerical Analysis to Quantify the Influence of Smear Zone Characteristics on Preloading Design in Soft Clay

Analyses numériques pour quantifier l'influence des caractéristiques de la zone endommagée sur la conception de préchargement dans les argiles molles

Parsa-Pajouh A., Fatahi H., Khabbaz B.

School of Civil and Environmental Engineering, University of Technology Sydney (UTS), Sydney, Australia

**ABSTRACT:** In this paper, the effects of uncertainties of smear zone characteristics induced by installation of prefabricated vertical drains on the preloading design are numerically investigated. FLAC 2D finite difference software with additional developed subroutines has been employed to conduct the numerical simulations. The finite difference analyses have been verified using a case study. Furthermore, a comprehensive parametric study is conducted to investigate the influence of smear zone permeability and extent on the model predictions. Results of this study indicate that the assumptive properties for smear zone characteristics may result in inaccurate predictions of ground deformations and pore water pressures. This may lead to early removal of the surcharge in the construction process causing excessive post construction settlement. It is recommended to practising engineers to use results of trial preloading to back calculate the required smear zone characteristics in the early stages of embankment construction to optimize the design.

**RÉSUMÉ :** Dans cet article, les effets des incertitudes des caractéristiques de la zone endommagée induites par l'installation des drains verticaux préfabriqués sur la conception du préchargement sont étudiés par une méthode numérique. Le logiciel de différences finies FLAC2D avec sous-programmes additionnels a été utilisé afin de réaliser les simulations numériques. Les analyses de différences finies ont été vérifiées à l'aide d'une étude de cas. Par ailleurs, une étude paramétrique approfondie est effectuée afin d'investiguer l'influence de la perméabilité de la zone endommagée sur les prédictions du modèle. Les résultats de cette étude montrent que les propriétés supposées pour les caractéristiques de la zone endommagée peuvent entraîner des prédictions incorrectes de déformations du sol et de pressions interstitielles. Cela peut conduire à un retrait précoce de la surcharge dans le processus de construction engendrant un tassement post-construction excessive. Il est recommandé aux ingénieurs d'utiliser les résultats de l'essai de préchargement afin de calculer les caractéristiques requises de la zone endommagée pour optimiser la conception.

## 1 INTRODUCTION

Finding efficient ground improvement techniques to modify the soft soil properties, considering the project time limitation and the construction cost has been a continuous challenge for the construction companies. Various ground improvement methods have been proposed to improve the strength properties of the soft soil. In the last two decades, employing prefabricated vertical drain (PVD) assisted preloading has been recognised as a very efficient ground improvement method for sites with deep soft soil deposits (Holtz et al. 1991; Shang et al. 1998; Indraratna et al. 2005). Installation of the prefabricated vertical drains using mandrel, induces disturbance of the soil surrounding the drain, resulting in a smear zone of reduced permeability adversely affecting the consolidation process. Predicting the soil behaviour surrounding the drain requires an accurate estimation of the smear zone properties. Generally, two major parameters are proposed to characterise the smear zone; the permeability ( $k_s$ ), and the extent ( $r_s$ ) of the smear zone. Figure 1 illustrates the cross section of prefabricated vertical drains surrounded by smear zone, which are installed in rectangular pattern. Determining both the smear zone extent and its permeability is a challenging task. According to literature, very diverse values are reported for the permeability ratio ( $k_h/k_s$ ) and extent ratio ( $r_s/r_m$ ), which are illustrated in Figure 2. The proposed range shows that the extent of the smear zone ( $r_s$ ) may vary between 1.6 to 7 times of the drain radius ( $r_w$ ) or, 1.0 to 6 times of mandrel equivalent diameter ( $r_m$ ). The proposed range for the permeability ratio ( $k_h/k_s$ ) is 1.3 to 10, where  $k_h$  is the horizontal permeability of the intact soil.

Figure 1. Cross section of PVD surrounding by smear zone

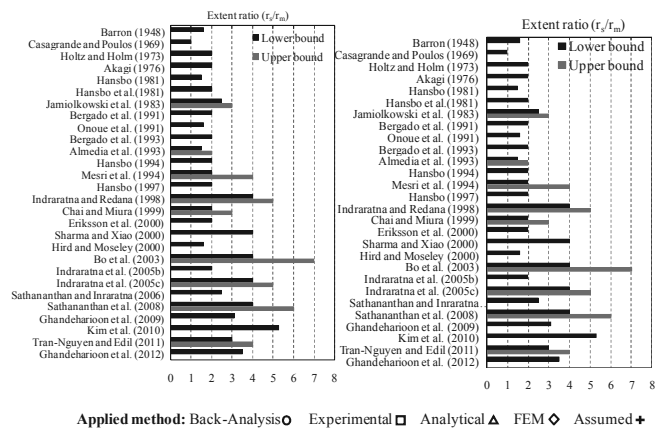

Figure 2. Proposed values for smear zone characteristics

It can be observed that wide ranges are proposed for  $k_h/k_s$  and  $r_s/r_m$  and there is no definite method to predict these parameters precisely to be used by practising engineers. The assumptive properties for smear zone characteristics may result in

inaccurate predictions of the ground behaviour. This can lead to early removal of surcharge in construction process resulting in excessive post construction settlement. Therefore, it is essential to study the influence of the uncertainties in the smear zone size and its permeability on the preloading design to improve the performance of soft deposits. Thus, a numerical code using FLAC 2D has been developed in this study to investigate the uncertainties of PVD smear zone characteristics on the preloading design which can be used to back calculate smear zone characteristics for actual preloading projects.

## 2 NUMERICAL MODELLING

In the present study, FLAC 2D v6.0 has been employed to model the PVD assisted preloading process focusing on smear zone uncertainties. Required new subroutines have been written using the built-in programming language FISH (FLACish) to tailor analyses to suit specific needs for the parametric study, giving the following unique advantages to the developed code for this study; (i) automatic mesh generation process by entering the required parameters to modify the grid pattern inside and outside the smear zone; (ii) ability to change different parameters such as the model dimensions, vertical drain properties, subsoil profile, smear zone characteristics and preloading conditions; (iii) the option to define the exact location of desired points to generate and plot any future history graphs; and (iv) automatic solving process based on the modified input data. Chittagong Sea Port in Bangladesh with 3.0 m high embankment on 9 m deep soft clay, has been selected for the numerical simulations and verification of the developed code and subroutines.

### 2.1. Case Study: Chittagong Sea Port in Bangladesh

According to Dhar et al. (2011), a container yard has been constructed at Chittagong Port, the largest sea port in Bangladesh, for handling loaded containers. The site is located on the bank of Karnafully river beside the Bay of Bengal in the Indian Ocean. The yard covers an area of 60,700 m<sup>2</sup> and was designed to support a container load producing a contact pressure of approximately 56 kPa. Geotechnical investigations revealed the presence of a soft to very soft clayey silt/silty clay deposit with a thickness of approximately 7 m (Figure 3).

Preloading with prefabricated vertical drains was adopted to preconsolidate the compressible soft deposits, which was followed by the field monitoring. Vertical drains were installed down to the depth of approximately 9 m below the ground level in square patten to cover the full depth of the soft clay. A surcharge load consisting of 3.0 m high fill of sand was placed for preloading. Surcharge material was placed in two layers of approximately equal thickness. The sides of the surcharge load were kept vertical along the boundaries of the area using sand bags and brick stacks. Figure 3 shows a profile detailing the ground improvement work schematically. In addition, Figure 4 shows the construction history of the embankment.

Figure 3. Cross section of constructed embankment

Figure 4. Construction history (Chittagong Port embankment)

FLAC 2D numerical code incorporating modified Cam-Clay constitutive soil model has been employed to simulate Chittagong Port preloading process applying plane strain conditions. The zero excess pore water pressure has been considered along the vertical drains and the ground surface boundary to model the PVD and surface drainage, respectively. Adopted soil properties in the numerical analysis are summarised in Table 1.

Table 1. Adopted soil properties (after Dhar et al. 2011)

Layer	Soil type	M	λ	κ	v	e <sub>o</sub>	γ <sub>s</sub> kN/m <sup>3</sup>	k <sub>h</sub> 10 <sup>-9</sup> m/s	k <sub>h</sub> / k <sub>v</sub>
Clayey Silt	Soft soil	0.94	0.13	0.026	0.3	1.28	14.0	2.31	1.5

The equivalent plane-strain permeability ( $k_{hp}$ ) proposed by Indraratna and Redana (2000) has been used in the numerical analysis.

$$(k_{hp}/k_h) = 0.67 / [(\ln(n)-0.75)] \quad (1)$$

$$(k_{sp}/k_{hp}) = \beta / [(k_{hp}/k_h) [(\ln(n/s)+(k_h/k_s) \ln(s)-0.75)]-\alpha] \quad (2)$$

$$\alpha = 2(n-s)^2 / [3(n-1)n^2] \quad (3)$$

$$\beta = [2(s-1) / (n-1)n^2] * [n(n-s-1)+1/3 (s^2+s+1)] \quad (4)$$

where,  $k_h$  and  $k_{hp}$  are axisymmetric and plane-strain horizontal permeability values of intact zone respectively,  $k_s$  and  $k_{sp}$  are axisymmetric and plane-strain permeability values of smear zone, respectively,  $\alpha$  and  $\beta$  are geometric coefficients,  $n$  is the spacing ratio equal to  $B/b_w$  where  $B$  and  $b_w$  are equivalent plane-strain radius of the influence zone and radius of the drain respectively, and  $s=r_s/r_w$ . The value of  $k_h$  needs to be determined first (laboratory or field), then  $k_{hp}$  can be calculated using Equation (1). When  $k_{hp}$  is known,  $k_{sp}$  can be obtained from Equation (2). The discretised plane-strain finite-difference mesh composed of quadrilateral elements is shown in Figure 5, where only half of the trial embankment is considered by exploiting symmetry.

Figure 5. Sample of mesh grid pattern for Chittagong Port embankment considering the smear

Numerical results are compared with the field measurements in Figure 6. According to Figure 6, FLAC predictions are in a good agreement with the field measurements considering  $k_h/k_s=2$  and  $r_s/r_m=3$ . The primary consolidation settlement is

predicted to be approximately 258 mm. As illustrated in Figures 4 and 6, the field settlement is measured immediately after placing the surcharge to the full height of 3 m (after 12 days).

Figure 6. Comparison of numerical results with field data

### 3 PARAMETRIC STUDY AND DISCUSSION

Parametric studies have been conducted to investigate the influence of the smear zone characteristics on the preloading design simulating Chittagong Port case study with the details presented in the previous section. For this purpose,  $k_h/k_s$  (permeability ratio) and  $r_s/r_m$  (extent ratio) have been changed from 2 to 5. Figure 7 illustrates the parametric study results for settlement-time relationships.

Figure 7. Parametric study results for Chittagong port case history at point G1; (a)  $r_s/r_m=2$ ; (b)  $r_s/r_m=3$ ; (c)  $r_s/r_m=4$ ; and (d)  $r_s/r_m=5$

According to Figure 7, the settlement curves are converged to a unique value of approximately 258 mm, which is the primary consolidation settlement. The required time to obtain 90% of primary consolidation settlement (232 mm) has been considered to investigate the effect of smear zone properties on consolidation process. According to Figure 7a, the minimum time of 34 days is needed to achieve 90% degree of consolidation, considering  $k_h/k_s=2$  and  $r_s/r_m=2$ . When smear

zone properties are  $k_h/k_s=5$  and  $r_s/r_m=5$ , the required time would be the maximum and equal to 67 days, which is approximately twice longer than the minimum (see Figure 7d). According to the settlement curves in Figure 7, the influence of smear zone permeability variations is more critical when the smear zone extent ratio is larger. For instance the required time to obtain 90% degree of consolidation has been increased by 56% (from 34 days to 53 days) changing the permeability ratio from 2 to 5 considering the extent ratio equal to 2, while this boost is 80% (from 37 days to 67 days) for extent ratio of 5.

The general trend in Figures 7(a)-7(d) shows that changing the permeability ratio in a smaller range results in large variations of the required time to obtain 90% degree of consolidation considering a constant extent ratio. According to Figure 7(a), the consolidation time is increased by 23% by varying the permeability ratio from 2 to 3, while this change is 17% and 12% when the permeability ratio is changed from 3 to 4 and 4 to 5, respectively.

Figure 8 illustrates the numerical parametric study results investigating the influence of the smear zone properties on the excess pore water pressure (EPWP) dissipation. Graphs are plotted for point G2 located at the depth of 4 m (see Figure 3). Figure 8 confirms that increasing the permeability and extent ratios prolongs the pore water pressure dissipation process considerably. According to Figure 8, the permeability ratio is more critical parameter than the extent ratio, although the influence of extent ratio variation on the consolidation time can not be neglected. For example, according to Figure 8b, there is 160% difference between the predicted excess pore pressure values after 34 days (90% of the field degree of consolidation) for  $k_h/k_s=2$  (EPWP=13 kPa) and  $k_h/k_s=5$  (EPWP=34 kPa), while keeping  $r_s/r_m=3$ .

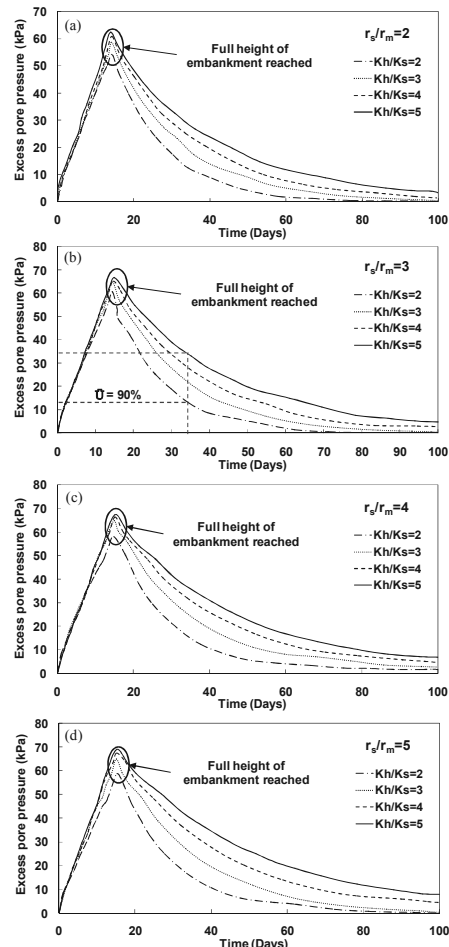

Figure 8. Effect of smear zone properties on excess pore water pressure dissipation for Chittagong port case history at point G2

The required time to obtain 90% degree of consolidation for different smear zone properties is illustrated in Figure 9 using parametric study results, which presents a better interpretation of the effects of the smear zone properties on consolidation time. According to Figure 9, the consolidation time significantly depends on the smear zone permeability and extent. For example, assuming  $r_s/r_m=2$ , for the case with  $k_h/k_s=2$  and  $k_h/k_s=5$ , the required times to obtain 90% degree of consolidation are approximately 33 days and 53 days, respectively, indicating 60% difference. It can be noted that the difference is more significant for larger values of  $r_s/r_m$ .

Figure 9. Predicted time to obtain 90% degree of consolidation

Figure 9 clearly indicates that the smear zone extent ratio ( $r_s/r_m$ ) is an important parameter influencing the consolidation time and cannot be neglected. Varying  $r_s/r_m$  in the range of 2 to 5, assuming  $k_h/k_s$  as a constant parameter can influence the required consolidation time by more than 25%. Combined effects of uncertainties in the smear zone extent and permeability will result in momentous changes of consolidation time. Results presented in Figure 9 indicate that the influence of uncertainties in  $r_s/r_m$  becomes more important when permeability of smear zone decreases.

According to the back calculation results presented in Figure 6, the predicted settlement curve is in the best agreement with the field measurements considering smear zone properties of  $k_h/k_s=2$  and  $r_s/r_m=3$ . The required time to obtain 90% degree of consolidation for this condition is equal to 34 days, which is highlighted as point S2 in Figure 9. A vertical line is plotted from  $t_{90\%}=34$  days, which intersects the set of lines at points S1, S2, S3 and S4. Smear zone properties at these points are summarised in Table 2.

Table 2. Back calculated smear zone properties to achieve  $t_{90\%}=34$  days

Point	S1	S2	S3	S4
$k_h/k_s$	2.10	2.0	1.85	1.75
$r_s/r_m$	2	3	4	5

Numerical analyses applying developed FLAC code have been conducted to compare the settlement and excess pore water pressure variations against the consolidation time. Different combinations of smear zone extent and permeability may result in the same  $t_{90\%}=34$  days and predictions are presented in Figure 10.

Figure 10. FLAC analysis results for points in Table 2 (a) Settlement variation; (b) Excess pore water pressure dissipation

Figure 10 shows that the curves for the settlement variations and the excess pore water pressure dissipations with time follow the same trend for points S1, S2, S3 and S4. Therefore, smear zone properties of any of these points can be adopted for the practical design purposes.

#### 4 CONCLUSIONS

Preloading time during consolidation process can significantly be affected by formation of the smear zone in the vicinity of the prefabricated vertical drains (PVDs). Smear zone is a reduced permeability area induced by mandrel insertion that halts the consolidation process. Available literature proposes a wide range for the smear zone extent and permeability and yet there is no definite prediction method that can be used to estimate the extent of smear zone and its permeability to be used in the design procedure. In this study, numerical analyses have been employed to investigate the effects of uncertainties of smear zone characteristics on the preloading design. FLAC 2D software has been employed to develop a numerical code assisting with the parametric study and back calculating smear zone properties. The verification exercise on Chittagong port case history confirms the validity of the developed numerical code. According to the parametric study results the properties of the smear zone have key roles on the required consolidation time to achieve a certain soil strength and stiffness satisfying both bearing capacity and settlement design criteria. Therefore, accurate estimation of the properties of smear zone based on the soil type and the installation method is vital for the ground improvement projects adopting PVD assisted preloading. Results of this study indicate that assumptive properties for smear zone characteristics may result in inaccurate predictions of ground deformations and pore water pressures. This can lead to early removal of surcharge in construction process resulting excessive post construction settlement. Thus, it is recommended to practising geotechnical engineers to back calculate the smear zone properties using a trial construction similar to the future construction procedure.

# Construction of virtual sites for reliability-based design

## Construction de sites virtuels à des fins de conception fiabiliste

Phoon K.K.

National University of Singapore, Singapore

Ching J.

National Taiwan University, Chinese Taipei

**ABSTRACT:** This paper presents the construction of “virtual sites” using multivariate normal distributions calibrated from actual soil property databases. By doing so, the actual magnitude of uncertainty reduction from conducting better/more soil tests can be estimated realistically, rather than theoretically.

**RÉSUMÉ:** Cet article présente la construction de "sites virtuels" en utilisant des distributions normales à plusieurs variables calibrées à partir de bases de données de propriétés de sols réels. Par cette méthode, la réduction réelle de l'incertitude que l'on peut obtenir en augmentant le nombre et/ou la qualité des essais de sol peut être estimée de manière réaliste, et non plus seulement théorique.

**KEYWORDS:** virtual site; uncertainties; soil properties; correlation; site investigation; reliability-based design.

### 1 INTRODUCTION

This paper presents the concept of a “virtual site”; the purpose is to emulate site investigation efforts as realistically as possible. It is not possible to emulate every aspect of a real site at present. In this paper, the scope is to reproduce the information content arising from a typical mix of laboratory and field tests conducted in a site for the purpose of estimating a design undrained shear strength ( $s_u$ ) for clays and friction angle ( $\phi$ ) for sands. The critical feature here is the consistent and realistic coupling of different test data, which is achieved using multivariate normal distributions. Data from different tests will be correlated, because they are measuring the same mass of soil, although they could be measuring different aspects of soil behavior under different boundary conditions and over different volumes. The purpose of developing a virtual site is not to replace actual site investigation. The purpose is to quantify the uncertainty reduction in  $s_u$  and  $\phi$  by incorporating the test results from better and/or more tests.

The idea of simulating a “virtual site” is not new. For example, Jaksa et al. (2005) and Goldsworthy et al. (2007) used three dimensional random fields and Monte Carlo simulation to simulate the spatially variable elastic modulus of a “virtual” site. Each spatially variable realization constitutes a plausible full information scenario. Site investigation is then carried out numerically by sampling the continuous random field at discrete locations. The site investigation data so obtained constitute the typical partial information scenario commonly encountered in practice. The goal of these studies was to quantify the difference in the designs based on these full and partial information scenarios. In this paper, the virtual site simulation is based on multivariate normal distributions that couple soil parameters such as  $s_u$ , overconsolidation ratio, standard penetration test N-value, cone tip resistance, and Atterberg limits. The distinct features of this paper are: (a) a more realistic bag of multivariate information containing both laboratory and field data and (b) the probability model is constructed from an actual database of clays and sands. These features are critical to the objective of this paper, which is to quantify the uncertainty reduction in  $s_u$  and  $\phi$  by incorporating the test results from better and/or more tests. This objective is only achievable if the information contained in the virtual site is comparable to that contained in a real site, not merely pertaining

to a single laboratory/field parameter, but to a group of parameters that are correlated in a realistic way. By doing so, it is possible to evaluate the *actual* merits of reliability-based design approximately, rather than elaborate on the theoretical merits widely discussed in previous studies. This paper summarizes the current development of such virtual sites.

### 2 MULTIVARIATE GEOTECHNICAL DATA

Multivariate information is usually available in a typical site investigation. For instance, when undisturbed samples are extracted for oedometer and triaxial tests, SPT and/or piezocone test (CPTU) may be conducted in close proximity. Moreover, data sources such as the unit weight, plastic limit (PL), liquid limit (LL), and liquidity index (LI) are commonly determined from relatively simple laboratory tests on disturbed samples. These data could be correlated, and these correlations can be exploited to reduce the coefficient of variation of a design parameter. The impact on RBD is obvious. This section presents statistical characterization of multivariate geotechnical data.

Most soil parameters are not normally distributed, because they are positive valued. Let  $Y$  denote a non-normally distributed soil parameter. One well known cumulative distribution function (CDF) transform approach can be applied to convert  $Y$  into a standard normal variable  $X$ :  $X = \Phi^{-1}[F(Y)]$ , where  $\Phi(\cdot)$  is the CDF of a standard normal random variable, and  $F(\cdot)$  is the CDF of  $Y$ . A set of multivariate soil parameters  $\underline{Y} = (Y_1, Y_2, \dots, Y_n)'$  can be transformed into  $\underline{X} = (X_1, X_2, \dots, X_n)'$ . By definition,  $X_1, X_2, \dots, X_n$  are *individually* standard normal random variables. It is crucial to note here that *collectively*  $(X_1, X_2, \dots, X_n)'$  does not necessarily follow a multivariate normal distribution even if each component is normally distributed. Even so, recent studies by Ching et al. (2010) and Ching and Phoon (2012a) showed that the multivariate normal distribution is an acceptable approximation for selected parameters of clays, and Ching et al. (2012b) arrived at the same observation for selected parameters of sands.

The multivariate normal probability density function for  $\underline{X} = (X_1, X_2, \dots, X_n)'$  can be defined uniquely by a correlation matrix:

$$f(\underline{X}) = |C|^{-\frac{1}{2}} (2\pi)^{-\frac{n}{2}} e^{-\frac{1}{2}\underline{X}'C^{-1}\underline{X}} \quad (1)$$

where  $C$  is the correlation matrix. For  $n = 3$ , the correlation matrix is given by:

$$C = \begin{bmatrix} 1 & \delta_{12} & \delta_{13} \\ \delta_{12} & 1 & \delta_{23} \\ \delta_{13} & \delta_{23} & 1 \end{bmatrix} \quad (2)$$

between  $X_i$  and  $X_j$  (not equal to the correlation between the original physical variable  $Y_i$  and  $Y_j$ ). It is clear that the full multivariate dependency structure of a normal random vector only depends on a correlation matrix ( $C$ ) containing bivariate correlations between all possible pairs of components, namely  $X_1$  and  $X_2$ ,  $X_1$  and  $X_3$ , and  $X_2$  and  $X_3$ . It is not necessary to measure  $X_1$ ,  $X_2$ , and  $X_3$  *simultaneously*. The practical advantage of capturing multivariate dependencies in any dimension (i.e., any number of random variables) using only bivariate dependency information is obvious.

It is simple to obtain realizations of *independent* standard normal random variables  $\underline{U} = (U_1, U_2, U_3)'$  using library functions in many softwares. Realizations of *correlated* standard normal random variables  $\underline{X} = (X_1, X_2, X_3)'$  can be obtained using  $\underline{X} = L\underline{U}$ , in which  $L$  is the lower triangular Cholesky factor satisfying  $C = LL'$ . Finally, each soil parameter is obtained using  $Y_i = F^{-1}[\Phi(X_i)]$ .

## 2.1 Complete multivariate information (structured clays)

A multivariate database of  $Y_1 = LI$  (liquidity index),  $Y_2 = s_u$ ,  $Y_3 = s_u^{re}$  (remolded undrained shear strength),  $Y_4 = \sigma'_p$  (preconsolidation stress), and  $Y_5 = \sigma'_v$  (effective vertical stress) is compiled in Ching & Phoon (2012a). There are 345 data points of structured clays from 37 sites worldwide, covering a wide range of sensitivity,  $LI$ , and clay types, with simultaneous knowledge of  $(Y_1, Y_2, \dots, Y_5)'$ . The OCR values of the data points are generally small, mostly less than 4. Fissured and organic clays are mostly left out of the database. Because  $s_u$  values depend on stress state, strain rate, sampling disturbance, etc., all  $s_u$  values are converted into mobilized  $s_u$  values following the recommendations made by Mesri and Huvaj (1997). The marginal probability density functions (PDF) for  $(Y_1, Y_2, \dots, Y_5)'$  and their statistics (mean of  $Y_i = \mu_i$ , COV of  $Y_i = V_i$ , mean of  $\ln(Y_i) = \lambda_i$ , standard deviation of  $\ln(Y_i) = \xi_i$ ) are summarized in Table 1.

For lognormal  $Y$ , the CDF transform is:

$$X_i = [\ln(Y_i) - \lambda_i] / \xi_i \quad (3)$$

The transformed  $(X_1, X_2, \dots, X_5)'$  are individually standard normal random variables. The correlation matrix  $C$  for  $(X_1, X_2, \dots, X_5)'$  is shown in Table 2, and  $(X_1, X_2, \dots, X_5)'$  is assumed to be multivariate normal with the correlation matrix listed in the table.

The multivariate normal distribution is employed to simulate samples of  $(LI, s_u, s_u^{re}, \sigma'_p, \sigma'_v)$ , shown in Figure 1 together with the calibration database. Not only the correlations among the original random variables ( $LI, s_u, s_u^{re}, \sigma'_p, \sigma'_v$ ) are shown but the correlations among their derived (normalized) quantities, including  $S_t = s_u/s_u^{re}$ ,  $OCR = \sigma'_p/\sigma'_v$ ,  $s_u/\sigma'_v$ , are also shown. The multivariate normal distribution performs adequately, as the simulated samples closely mimic the correlation behaviors of the calibration database, even for those with nonlinear trends, e.g.  $LI-s_u^{re}$  and  $LI-S_t$  correlations.

Table 1. Distributions and statistics of  $(Y_1, Y_2, \dots, Y_5)'$  for structured clays (Source: Ching & Phoon 2012a).

Distribution	Mean	COV	Mean of	stdev of
--------------	------	-----	---------	----------

				$\ln(Y_i), \lambda_i$	$\ln(Y_i), \xi_i$
$Y_1 = LI$	Lognormal	1.25	0.49	0.122	0.459
$Y_2 = s_u$	Lognormal	31.01kN/m <sup>2</sup>	0.95	3.051	0.898
$Y_3 = s_u^{re}$	Lognormal	2.51kN/m <sup>2</sup>	1.52	0.226	1.191
$Y_4 = \sigma'_p$	Lognormal	105.82kN/m <sup>2</sup>	0.98	4.311	0.835
$Y_5 = \sigma'_v$	Lognormal	66.63kN/m <sup>2</sup>	0.80	3.891	0.823

Table 2. Correlation matrix  $C$  for  $(X_1, X_2, \dots, X_5)'$  for the five selected parameters of structured clays (Source: Ching & Phoon 2012a).

	$X_1 (LI)$	$X_2 (s_u)$	$X_3 (s_u^{re})$	$X_4 (\sigma'_p)$	$X_5 (\sigma'_v)$
$X_1 (LI)$	1.000	-0.083	-0.824	-0.176	0.280
$X_2 (s_u)$	-0.083	1.000	0.276	0.915	0.801
$X_3 (s_u^{re})$	-0.824	0.276	1.000	0.365	0.453
$X_4 (\sigma'_p)$	-0.176	0.915	0.365	1.000	0.850
$X_5 (\sigma'_v)$	0.280	0.801	0.453	0.850	1.000

Figure 1. Comparisons between the calibration database and the simulated data points (Source: Ching & Phoon 2012a).

## 2.2 Incomplete multivariate information (unstructured clays)

Ching et al. (2010) presented another clay database containing four soil parameters:  $Y_1 = OCR$ ,  $Y_2 = s_u$  from CIUC test,  $Y_3 = q_T - \sigma_v$  (net cone resistance), and  $Y_4 = N_{60}$  (SPT N corrected for energy efficiency). The range of OCR of this database is wider – from 1 to 50. However, only bivariate data on  $(Y_1, Y_2) = (OCR, s_u)$ ,  $(Y_3, Y_2) = (q_T - \sigma_v, s_u)$ , and  $(Y_4, Y_2) = (N_{60}, s_u)$  are available. Bivariate data on  $(Y_1, Y_3) = (OCR, q_T - \sigma_v)$ ,  $(Y_1, Y_4) = (OCR, N_{60})$ , and  $(Y_3, Y_4) = (q_T - \sigma_v, N_{60})$  are missing, i.e., the bivariate correlations  $\delta_{ij}$  are only partially known. Given that complete bivariate information is not available, it is not possible to apply the aforementioned CDF transform approach directly. It is accurate to say that although it is common to measure more than two soil parameters in a site investigation, it is uncommon to establish correlations between *all possible pairs* of soil parameters.

To deal with this difficulty of incomplete bivariate correlations, Ching et al. (2010) constructed a multivariate normal distribution using a Bayes net model which prescribed a dependency structure based on some postulated but reasonable conditional relationships between the soil parameters. They considered  $Y_1 = OCR$  as a given number and the remaining soil parameters  $(Y_2, Y_3, Y_4)'$  are lognormally distributed random variables. Hence,  $\ln(Y_2) = \ln(s_u) = \lambda_2 + \xi_2 X_2$ ,  $\ln(Y_3) = \ln(q_T - \sigma_v) = \lambda_3 + \xi_3 X_3$ , and  $\ln(Y_4) = \ln(N_{60}) = \lambda_4 + \xi_4 X_4$ , in which  $X_i$  are standard normal random variables. The simulation of  $(Y_1, Y_2, Y_3, Y_4)'$  starts from OCR. The undrained shear strength,  $Y_2$ , is next simulated using this OCR sample and the SHANSEP model (Ladd and Foott 1974):

$$\ln(s_u) = 0.64 \ln(\text{OCR}) + \ln(\sigma'_{v0}) - 0.874 + 0.237U_1 \quad (4)$$

where 0.237 is the standard deviation of the transformation uncertainty, and  $U_1$  is standard normal. The third step is to simulate  $N_{60}$  and  $q_T - \sigma_v$  using the  $s_u$  sample:

$$\ln(N_{60}) = 1.633 \ln(s_u) - 0.403 \ln(\sigma'_{v0}) - 3.845 + 0.456U_2 \quad (5a)$$

$$\ln(q_T - \sigma_v) = \ln(s_u) + 2.54 + 0.34U_3 \quad (5b)$$

where 0.456 and 0.34 are the standard deviations of the transformation uncertainties, and  $U_2$  and  $U_3$  are standard normal. Figure 2 shows the correlation plots for the simulated  $\{\text{OCR}, s_u, N_{60}, q_T - \sigma_v\}$  for a case where OCR is uniformly distributed over [5, 24].

Figure 2. Correlation plots for  $\{\text{OCR}, s_u, N_{60}, q_T - \sigma_v\}$  samples.

Based on the results of Ching et al. (2010), Phoon et al. (2012) further assumed OCR to be lognormal with a reasonable COV = 0.25. Under this assumption, they showed that the underlying standard normal variables ( $X_1, X_2, X_3, X_4$ ) have the correlation matrix shown in Table 3. The correlation matrix in Table 3 should be suitable for unstructured clays covering a fairly wide range of OCR.

Table 3. Correlation matrix C for ( $X_1, X_2, X_3, X_4$ ) for the four selected parameters of unstructured clays (Source: Phoon et al. 2012).

	$X_1$ (OCR)	$X_2$ ( $s_u$ )	$X_3$ ( $q_T - \sigma_v$ )	$X_4$ ( $N_{60}$ )
$X_1$ (OCR)	1.000	0.554	0.355	0.395
$X_2$ ( $s_u$ )	0.554	1.000	0.642	0.714
$X_3$ ( $q_T - \sigma_v$ )	0.355	0.642	1.000	0.458
$X_4$ ( $N_{60}$ )	0.395	0.714	0.458	1.000

### 2.3 Incomplete multivariate information (clean sands)

Ching et al. (2012b) presented a study that is very similar to Ching et al. (2010) but for clean sands. The study was based on a database containing five selected parameters of normally consolidated clean sands:  $Y_1 = \phi_{cv}$  (critical state friction angle),  $Y_2 = I_R$  (dilatancy index, see Bolton 1986),  $Y_3 = \phi_p$  (peak secant friction angle),  $Y_4 = (q_c/P_a)/(\sigma'_v/P_a)^{0.5} = q_{c1}$  (corrected cone resistance), and  $Y_5 = (N_1)_{60}$  (SPT N corrected for energy efficiency and overburden stress). They considered  $Y_1 = \phi_{cv}$  and  $Y_2 = I_R$  as given numbers and the remaining soil parameters ( $Y_3, Y_4, Y_5$ ) are random variables:  $Y_3$  is normal, while  $Y_4$  and  $Y_5$  are lognormal. Hence,  $Y_3 = \phi_p = \mu_3 + \mu_3 V_3 X_3$ ,  $\ln(Y_4) = \ln(q_{c1}) = \lambda_4 + \xi_4 X_4$ , and  $\ln(Y_5) = \ln[(N_1)_{60}] = \lambda_5 + \xi_5 X_5$ , in which  $X_1$  are standard normal random variables. If we further assume  $\phi_{cv}$  and  $I_R$  are normal with reasonable standard deviations of  $3^\circ$  and  $1^\circ$ , respectively, i.e.,  $Y_1 = \phi_{cv} = \mu_1 + 3X_1$  and  $Y_2 = I_R = \mu_2 + X_2$ , and also assume independence between  $\phi_{cv}$  and  $I_R$ , it can be shown that the underlying standard normal variables ( $X_1, X_2, X_3, X_4, X_5$ ) has the correlation matrix shown in Table 4. The correlation matrix in Table 4 should be suitable for normally consolidated clean sands.

Table 4. Correlation matrix C for ( $X_1, X_2, X_3, X_4, X_5$ ) for the five selected parameters of clean sands (Source: Ching et al. 2012b).

	$X_1$ ( $\phi_{cv}$ )	$X_2$ ( $I_R$ )	$X_3$ ( $\phi_p$ )	$X_4$ ( $q_{c1}$ )	$X_5$ [( $N_1$ ) <sub>60</sub> ]
$X_1$ ( $\phi_{cv}$ )	1.000	0.000	0.642	0.491	0.536
$X_2$ ( $I_R$ )	0.000	1.000	0.642	0.491	0.536
$X_3$ ( $\phi_p$ )	0.642	0.642	1.000	0.764	0.835
$X_4$ ( $q_{c1}$ )	0.491	0.491	0.764	1.000	0.638
$X_5$ [( $N_1$ ) <sub>60</sub> ]	0.536	0.536	0.835	0.638	1.000

### 2.4 Undrained shear strengths under various test procedures

The undrained shear strength ( $s_u$ ) of a clay is not a constant. In particular,  $s_u$  of a clay evaluated by different test procedures are different because these tests may have different stress states, stress histories, degrees of sampling disturbance, and strain rates. Ching & Phoon (2013) constructs the multivariate normal distribution of the  $s_u$  values from seven  $s_u$  tests (CIUC, CK<sub>0</sub>UC, CK<sub>0</sub>UE, DSS, VST, UU, UC) based on a large clay database consisting data points from 146 studies. Many  $s_u$  data points are associated with a known test mode (6310 points), a known OCR (4584 points), and a known plasticity index (PI) (4541 points). The geographical regions cover Australia, Austria, Brazil, Canada, China, England, Finland, France, Germany, Hong Kong, Iraq, Italy, Japan, Korea, Malaysia, Mexico, New Zealand, Norway, Northern Ireland, Poland, Singapore, South African, Spain, Sweden, Thailand, Taiwan, United Kingdom, United States, and Venezuela. The clay properties cover a wide range of OCR (mostly 1~10, few studies OCR > 10, but nearly all studies are with OCR < 50) and a wide range of sensitivity  $S_t$  (sites with  $S_t = 1$ ~tens or hundreds are fairly typical).

An important step for the construction of the multivariate distribution is to convert all  $s_u$  data points in the database into the following standardized form:

$$s_{u,NC,1\%,PI20}/\sigma'_v = (s_u/\sigma'_v)/(b_{OCR} \cdot c_{rate} \cdot d_{PI}) \quad (6)$$

where  $s_{u,NC,1\%,PI20}$  is the undrained shear strength of a NC clay with PI = 20 subjected to a 1% per hour strain rate;  $b_{OCR}$ ,  $c_{rate}$ , and  $d_{PI}$  are modifier factors that adjust the reference normalized undrained shear strength for overconsolidation ratio, strain rate, and plasticity. Table 5 shows these factors (Ching et al. 2013; Ching & Phoon 2013). The standardized  $s_{u,NC,1\%,PI20}/\sigma'_v$  is denoted by  $Y_{\text{test mode index}}$ . The test mode indices are respectively 1, 2, 3, 4, 5, 6, and 7 for CIUC, CAUC, CAUE, DSS, FV (field vane), UU, and UC. Hence, there are seven random variables ( $Y_1, Y_2 \dots Y_7$ ). Table 6 shows the statistics of  $Y_i$ . The  $Y$  data points for each test mode are roughly lognormally distributed, i.e.,  $X_i = [\ln(Y_i) - \lambda_i]/\xi_i$  is roughly standard normal. Given a test mode  $i$ , the scatter in the  $Y_i$  data points, quantified by the COV in Table 6, may be due to measurement errors in  $s_u$  and global inherent variability in  $s_u$  ( $s_u$  from different geographic locales) as well as the transformation uncertainties associated with the standardization steps for PI, strain rate, and OCR.

The  $Y_i$  data points are converted to standard normal variables  $X_i = [\ln(Y_i) - \lambda_i]/\xi_i$ . Table 7 shows the correlation matrix C for ( $X_1, X_2, \dots, X_7$ ). The estimated correlation coefficients  $\delta_{ij}$  are quite sensible. The four triaxial compression (TC) test modes ( $X_1, X_2, X_6, X_7$ ) seem mutually highly correlated ( $\delta_{ij} > 0.8$ ), with the exception of ( $X_6, X_7$ ) having  $\delta_{ij} = 0.59$ . The CAUE test mode ( $X_3$ ) has weak correlation with TC test modes ( $\delta_{ij} < 0.5$ ), probably because it imposes a different stress state from TC tests. The correlation coefficients between FV and TC are relatively weak as well ( $\delta_{ij} \leq 0.63$ ). Such relatively low correlation between FV and TC may be due to the fact that the FV test has several distinct aspects (stress state, drainage boundaries, strain rate, and failure mode). It is interesting that the correlation between FV and DSS is high ( $\delta_{ij} = 0.73$ ).

Table 5  $b_{OCR}$ ,  $c_{rate}$ , and  $d_{PI}$  factors (Source: Ching et al. 2013).

Factor	Test type	Formula
$b_{OCR}$	CIUC	$\text{OCR}^{0.602}$
	CAUC	$\text{OCR}^{0.681}$

	CAUE	$OCR^{0.898}$
	DSS	$OCR^{0.749}$
	VST	$OCR^{0.902}$
	UU	$OCR^{0.800}$
	UC	$OCR^{0.932}$
$c_{rate}$		$1.0+0.1 \times \log_{10}(\text{strain rate}/1\%)$
$d_{PI}$	CIUC	$(PI/20)^0 = 1$

### 3 REDUCING UNCERTAINTY IN DESIGN PARAMETER WITH BETTER AND/OR MORE TESTS

As mentioned earlier, it is simple to simulate virtual site investigation data  $(Y_1, Y_2, \dots, Y_n)'$ . First, obtain realizations of independent standard normal random variables  $\underline{U} = (U_1, U_2, \dots, U_n)'$  using library functions in many softwares. Realizations of correlated standard normal random variables  $\underline{X} = (X_1, X_2, \dots, X_n)'$  can be obtained using  $\underline{X} = \underline{L}\underline{U}$ , in which L is the lower triangular Cholesky factor satisfying  $C = \underline{L}\underline{L}'$ . Finally, each soil parameter is obtained using  $Y_i = F^{-1}[\Phi(X_i)]$ . For lognormal distribution,  $Y_i = \exp(\lambda_i + \xi_i \times X_i)$ . Figures 1 & 2 already showed the simulated data  $(Y_1, Y_2, \dots, Y_n)'$ . This section will further discuss how to use the simulated data to quantify the uncertainty reduction in  $s_u$  and  $\phi$  by incorporating the test results from better and/or more tests.

This is illustrated below using results presented in Figure 2. The histogram of the simulated  $s_u$  data for the same virtual site is given in the left plot of Figure 3, showing the simulated  $s_u$  data when no site-specific tests are conducted. Let us consider a site investigation program consisting oedometer, CPTU, and SPT N tests. Suppose the test results show that OCR is within [9.5,13.1],  $N_{60}$  within [7,9], and  $q_T - \sigma_v$  within [1100kN/m<sup>2</sup>,1350kN/m<sup>2</sup>]. Based on the above information, the conditional samples of  $s_u$  can be easily obtained by filtering out samples satisfying  $OCR \in [9.5,13.1]$ ,  $N_{60} \in [7,9]$ , and  $q_T - \sigma_v \in [1100kN/m^2,1350kN/m^2]$  simultaneously from the population at large. The  $s_u$  values associated with this filtered set of (OCR,  $s_u$ ,  $N_{60}$ ,  $q_T - \sigma_v$ ) values are therefore the conditional  $s_u$  samples. The histogram of these conditional samples is

shown in the right plot of Figure 3. It is clear that the uncertainty in  $s_u$  is significantly reduced, given the information from better and/or more tests.

Figure 3. Histograms of the (conditional)  $s_u$  samples.

### 4 CONCLUSION

The construction of “virtual sites” are demonstrated in this paper using multivariate normal distributions calibrated from actual soil property databases. By doing so, it is possible to evaluate the reduction in the uncertainties associated with design parameters as a function of better and/or more tests. The practical goal is to establish an actual (not theoretical) link between the cost of a site investigation program and the potential design savings accrued from reliability-based design.

# Technique of reinforced soil base calculation under fall initiation in ground mass

## Technique du compte armé les raisons du sol à l'apparition des échecs à le massif du sol

Ponomaryov A., Zolotozubov D.  
Perm national research polytechnical university,

**ABSTRACT:** On the basis of carried out investigations, the authors obtained stress and strain development mechanisms of the reinforced ground mass depending on the properties of soils, the characteristics of the reinforcing elements, the depth of their location and their number. The obtained mechanisms allowed to propose the calculation methodology of the reinforced base surface settlement in the territories expose to deformation. To evaluate the proposed method, it was compared with previously obtained results of the experiments and calculations carried out with the help of BS8006, Giroud, Perrier, R.A.F.A.E.L methods and PLAXIS and Sofistik programs.

**RÉSUMÉ :** À la base des études accomplies les auteurs ont reçu les mécanismes du développement de l'effort et l'effort de la masse affermie de la raison en fonction des propriétés des sols, les particularités des éléments du renforcement, la profondeur de leur situation et leur nombre. Les régularités reçues ont permis de proposer la méthode du compte le dépôt de la surface des raisons armées sur les territoires exposés aux déformations. Pour estimer la méthode proposée, c'était en comparaison d'aparavant résultats acquis des expériences et calculs accomplis avec l'aide de BS8006, Giroud, Perrier, les méthodes R.A.F.A.E.L et PLAXIS et les programmes Sofistik.

**KEYWORDS:** reinforced soils, fall in ground mass, technique of calculation.

### 1 INTRODUCTION

When laying foundations of buildings and structures in areas prone to possible vertical deformations (for instance, karstic and technogenic dolines), it is necessary to provide measures to prevent emergency situations.

The choice of measures depends on the type of security – perfect or partial. When it is sufficient to provide only partial security, geosynthetic material reinforcement of a ground base is most commonly used. It is connected with the fact that ground reinforcement is more economical as compared with other methods. In the majority of case reinforcing of the bases by geosynthetic materials apply at building automobile and railways. Besides at building on karstic territories it is expedient to reinforce geosynthetic materials of the bases low-charged constructions, for example, low-rise buildings.

In Russia ground base reinforcement has not been used widely so far due to various factors, including both the increase in the cost of construction connected with the use of geosynthetics and sufficiently large amount of excavation works.

High quality geosynthetic materials themselves are not cheap, and large volumes of excavation arise from the need of a sufficiently deep placement of reinforcing layers. However, the use of local materials and a well-tried technology of reinforced base laying, as well as the increase in the safe upkeep of buildings, give a good economic effect.

### 2 EXPERIMENTAL INVESTIGATIONS

Effective use of geosynthetics for reinforcement under ground mass collapse is possible with the joint account of such factors as physical and mechanical properties of foundation soil, tensile properties of geosynthetics, the depth of reinforcing layers and their number. The optimal choice of these parameters requires rather complex calculations taking into account load – elongation dependences. The existing methods (the method outlined in the British Standard BS 8006, section 8.4 (BSI, 1995 – Fig. 1), the method of Giroud et al (1990), the method of Perrier (1985); R.A.F.A.E.L. – method (Blivet et al, 2002) do not consider the actual tensile force – relative deformation ratio.

They are applied for single-layer reinforcement. Being used to solve geotechnical problems, software packages that implement numerical methods give great inaccuracy, but at the same time they allow to calculate more quickly and check more types of reinforcement including those of multi-layer reinforcement.

Figure 1. BS 8006: Parameters used to determine reinforcement.

The study of reinforced bases under ground mass collapse conducted by the authors allowed to obtain the mechanisms of stress – strain development in the reinforced ground mass depending on the foundation soil properties, the characteristics of the reinforcing elements, their depth and quantity. The results of S. Schwerdt's investigations were also used in the study.

On the basis of the mechanisms obtained we proposed the technique for calculating the reinforced base surface settlement in areas prone to deformation. As in the above-mentioned methods, the calculations were carried out for single-layer reinforcement, but at the same time the change in elongation of the geosynthetic reinforcing material depending on the load was taken into account. To do calculations using this method it is necessary to have load – elongation dependences which are obtained when testing geosynthetics at rupture, in accordance with ISO 10319:2008 (Fig. 2).

In the course of our studies we were doing experiments with account of the current Russian regulations enabling to apply tensile-testing machines to ensure the constant rate of bottom

clamp sinking, the constant strain rate or the fixed rate of load increase (similar to ISO 10319:2008) with relative error indications of breaking load  $\pm 1.0\%$ , with absolute error indications of elongation  $\pm 1.0\text{ mm}$ , with an average rupture duration regulated from  $(30 \pm 15)$  to  $(60 \pm 15)$  sec.

Figure 2. Typical load-elongation curve.

In practice, we had to build these relationships using the results obtained with the help of the tensile-testing machine that provided the constant rate of bottom clamp sinking (Fig. 3, 4).

Figure 3. Example of elongation-load curve according to the test results.

Figure 4. Example of elongation-load curve according to the test results.

The obtained dependences were used in the calculations done with the help of both numerical methods (PLAXIS program) and the developed technique.

### 3 TECHNIQUE OF REINFORCED SOIL BASE CALCULATION

The design scheme of the proposed method is shown in Figure 5.

Figure 5. Design diagram of reinforced ground settlement under earth collapse.

In this method the following assumptions allowing to use formulas well-known in soil mechanics for the calculation of stresses in ground bases were made:

- the reinforced ground mass is in an equilibrium (stabilized) state before the ground collapse formation;
- the reinforcing layer is located in the homogeneous ground;
- the stress-strain state is considered at that moment when the marginal state of the ground mass is reached;
- the deformation form of the ground mass above the reinforcing interlayer has a sectional view of a trapezoid;
- the geosynthetic material does not stretch beyond the collapse region;
- the arch effect is not taken into account.

The algorithm for calculating the proposed technique is based on the tensile force dependence in the geosynthetics  $F_a$  on the size and shape of the collapse, the reinforcing interlayer depth, the surface load and geosynthetic material elongation. Our studies showed that the tensile force – elongation dependence is determined most accurately with the use of the formula similar to that in the BS 8006 standard

$$F_a = 0,5 \cdot k \cdot (\gamma \cdot h + q) \cdot D \cdot \sqrt{1 + \frac{1}{6 \cdot \varepsilon_a}}, \quad (1)$$

where  $k$  is the coefficient taking into account the supposed form of the collapse (for the rectangular collapse – plane problem – it is equal to 1). In the British standard BS 8006 the value of 0.67 for the axisymmetric case is given, but studies showed that higher convergence with the experimental results was obtained when  $k = 0.78$ ;  $\varepsilon_a$  is the specific elongation of the geosynthetic material depending on the tensile force in the reinforcing interlayer, which is determined according to the graphs (for example, as shown in Fig. 2);  $h$  is the depth of the reinforcing layer, m;  $\gamma$  is the specific weight of the ground, which is located above the reinforcing interlayer,  $\text{kN/m}^3$ . If there are ground layers having different specific weight values and located above the reinforcing interlayer, it is necessary to make the following replacement in the formula

$$\gamma \cdot h = \sum_{i=1}^n \gamma_i \cdot h_i \quad (2)$$

where  $n$  is the number of ground layers above the reinforcing interlayer,  $\gamma_i$  is the specific weight of the  $i$ -th ground layer,  $h_i$  is the height of the  $i$ -th ground layer;  $q$  is the equivalent surface load on the reinforcing layer,  $\text{kN/m}$ . Its calculation depends on the surface load amount by analogy with the calculation of the additional pressure (tension) in the ground mass, as well as on the load type, the load area-to-collapse region ratio, the surface load location with respect to the ground collapse;  $D$  is the collapse length (diameter), m.

The main problem when calculating by this method is that at the initial calculation stage we are aware of neither the tensile force  $F_a$ , nor the specific elongation of the geosynthetic material  $\varepsilon_a$  because the actual dependence of the elongation on the tensile load is not taken into account in the formula (1). That's why, we used the successive approximations method accurate to 5%. The received value  $\varepsilon_a$  is used to determine the maximum deflection  $s_a$  of the reinforcing material

$$s_a = \sqrt{3/8 \varepsilon_a D^2}. \quad (3)$$

To calculate the maximum ground surface settlement, the following formula is used,

$$s = \left( \frac{D}{2h \cdot \tan\theta} \right)^2 s_a, \quad (4)$$

where  $\theta$  is the inclination angle of the slip plane to the vertical. The values  $\theta$  depend on the characteristics of the backfill soil. Since it is necessary to determine the maximum surface settlement by the current Russian regulations, in practical calculations  $\theta = \varphi$  is taken. In case the ground layers located above the reinforcing interlayer have different  $\varphi$  values, the following value is used.

$$\theta = \bar{\varphi} = \frac{\sum_{i=1}^n \varphi_i \cdot h_i}{\sum_{i=1}^n h_i} \quad (5)$$

The obtained value of the surface settlement  $s$  is compared with the normative or design values for this construction

project. If the condition  $s \leq s_u$  is not satisfied, then a geosynthetic material with different characteristics is selected and the calculation is done again.

To evaluate the proposed method, its comparison with the results of the experiments and calculations performed by other methods (BS8006, Giroud, Perrier, R.A.F.A.E.L.) as well as PLAXIS and Sofistik programs was carried out. Due to the fact that we were not able to do model experiments in Russia, the data for comparison were taken from Schwerdt's works.

Table 1. Results of calculations

Calculation method	Tensile force in geosynthetic material, $\text{kN/m}$	Deflection of geosynthetic material, mm	Surface settlement, mm
Experiment	105	90	30

# Stress Concentration Ratio and Design Method for Stone Columns using 2D FEA with Equivalent Strips

Ratio de concentration de contraintes et méthode de conception pour les colonnes ballastées en utilisant une analyse aux éléments finis 2D avec des bandes équivalentes

Poon B., Chan K.  
GHD Geotechnics, 57-63, Herbert Street, Artarmon, NSW, Australia

**ABSTRACT:** This paper presents an approach for the prediction of vertical and horizontal displacements of soft ground treated with stone columns in a 2D finite element analysis (FEA). This involved modeling the columns as strips with appropriate strip width, spacing and smeared properties based on stress concentration ratio. Charts to assess the equivalent 2D column stress concentration ratio are provided for the design of full depth and floating columns under the influences of various key parameters. The accuracy of the proposed 2D strip model is investigated by comparing the results with a baseline 3D and axi-symmetric FEA. It is found that the proposed strip model is preferable over the conventional approach using composite block properties to represent the improved soil.

**RÉSUMÉ :** Cet article représente une approche pour la prédiction des déplacements verticaux et horizontaux de sols mous traités avec des colonnes ballastées par une analyse aux éléments finis (FEA) en 2D. Cela implique la modélisation des colonnes en tant que bandes avec une largeur de bande appropriée ainsi que l'espacement et les propriétés des zones d'influence basées sur le ratio de concentration de contrainte. Les graphiques pour évaluer le ratio 2D équivalent de concentration de contraintes sont donnés pour la conception des colonnes profondes et flottantes sous l'influence de divers paramètres. La précision du modèle de bande 2D proposé est étudiée en comparant les résultats avec une base en 3D et d'une analyse aux éléments finis axisymétrique. Il se trouve que le modèle de bande proposé est préférable à l'approche conventionnelle qui utilise les propriétés d'un bloc composite pour représenter le sol amélioré.

**ORDS:** Stone column, stress concentration, ground improvement, numerical analysis.

## 1 INTRODUCTION

Conventionally, the design of stone columns involves the prediction of settlements using a composite material approach in which equivalent strength and deformation parameters are derived using semi-empirical correlation to represent the entire improved soil. While these approaches have been accepted as reasonable methods for settlement prediction, they are less certain for the prediction of horizontal displacement. This paper presents a design approach where stone columns are idealised as equivalent strips in 2D finite element analysis (FEA). The stress distribution between the stone column and surrounding soil is essential for determining the strength parameter of the equivalent strips. A series of design curves for the stress concentration are presented to facilitate parameter derivation in practice. The accuracy of the 2D strip model is investigated by comparing the results with the 3D and axi-symmetric FEA.

## 2 IDEALISED 2D MODELLING APPROACH

For the modeling of stone columns in 2D FEA, the width of the stone column strips can be made to be equal to the width of an equivalent square for the cross-sectional area (Figure 1). The spacing of the strips is equal to the actual spacing,  $b$ , for square column arrangement and  $\sqrt{3}b/2$  for equilateral triangular arrangement. Mohr-Coulomb model is used for the stone columns with Poisson's ratio of 0.3, which is taken to be the same as the soil itself. The equivalent Young's modulus  $E_{eq}$  and the cohesion  $c_{eq}$  of the strips can be calculated based on weighted average approach as given by Eq 1.

$$E_{eq} \text{ (or } c_{eq}) = \frac{E_{soil} \text{ (or } c_{soil}) \cdot A_{soil} + E_{column} \text{ (or } c_{column}) \cdot A_{column}}{A_{soil} + A_{column}} \quad (1)$$

where  $A_{soil}$  and  $A_{column}$  are the areas of the soil and column inside a unit cell within the 2D strip as shown in Figure 1.

Figure 1. 2D stone column strips

The equivalent friction angle  $\phi_{eq}$  of the strips can be derived based on force equilibrium approach as given by

$$\tan(\phi_{eq}) = \frac{A_{soil} \tan(\phi_{soil}) + n \cdot A_{column} \tan(\phi_{column})}{A_{soil} + n \cdot A_{column}} \quad (2)$$

The determination of  $\phi_{eq}$  requires a presumption of stress concentration,  $n$ , which is defined as the ratio of the average applied vertical stress within stone column to the average applied vertical stress of the surrounding soil at the same level. Section 3 presents an appraisal for this parameter. Note that the present 2D FEA is an elasto-plastic analysis in which the decay of excess pore pressure with time was not taken into account.

## 3 STRESS CONCENTRATION OF STONE COLUMN

This section presents a series of elasto-plastic solutions in charts for the stress concentration ( $n$ ) of stone columns founded on (i) rigid boundary and (ii) infinite compressible soil materials. The solutions were obtained based on axisymmetric FEA using PLAXIS software programme for a "unit cell" consisting of a stone column and the surrounding soil within a column's zone of influence. Interface elements were introduced at the soil-column contact to allow for slippage. The interface strength was assumed to be 70% of the original soil strength ( $R_{int} = 0.7$  in PLAXIS). Note that the interface properties have minimal effect on the results as the stone column is in triaxial state.

3.1 Stone columns on rigid base

Figure 3b presents the calculated  $n$  with depth for a particular case where embankment load is applied on stone columns that are founded on rigid base. The selected column configuration and parameters are shown in Figure 2. Note that the embankment fill was modeled as soil elements and the arching stresses developed above the column have been accounted for in the FEA model.

Figure 2. Stone column on rigid base

If the column and soil were appraised as elastic materials, the calculated  $n$  (dash line in Figure 3b) increases from 5 at the top of column, which is consistent with design chart solution provided in FHWA (1983) for embankment supporting columns, to about 14 at depth, which is commensurate with the equal strain solution (soil and column settle at the same rate at depth) given by Balaam and Poulos (1982).

When the column and soil are modeled as Mohr-Coulomb materials, yielding elements begin to form at the column top after a small load (~20kPa) is applied, leading to a reduction in stress concentration. The yielding of the column (hence the reduction of  $n$ ) progresses downwards through the column as the applied load level increases (see the solid curves in Figure 3b). Figure 3a shows the stress state of the unit-cell model after the application of maximum embankment load. It indicates that most yielding elements are confined within the column periphery. The soil is generally elastic and therefore the soil friction angle has little influence on the solution.

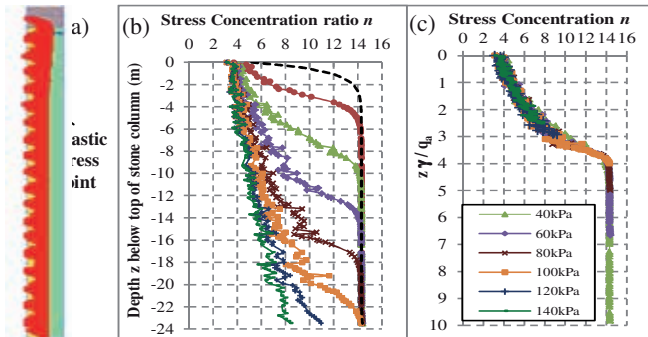

Figure 3. Stone column with rigid base (elasto-plastic solution)

Figure 3c shows a normalised plot in which the depth of the column,  $z$ , was normalized by  $q_a/\gamma$ , where  $q_a$  is the applied fill stress and  $\gamma$  is the total unit weight of the soil. It is found that the normalised stress concentration curves for the different load levels ( $\geq 40$ kPa) lie on a single curve. The turning point of the normalized curve corresponds to the transition from the upper yielding zone to the lower non-yielding zone, which occurs at different  $z$  for the different  $q_a$ . For example, point A in Figure 3c occurs at  $z/\gamma a = 4$ . When  $q_a = 40$ kPa and  $\gamma = 17$ kN/m<sup>3</sup>,  $z = 9.5$ m (B in Fig 3b). Conversely, when  $q_a = 60$ kPa,  $z \approx 14$ m (Point C).

Figure 4 presents a series of normalised curves for the  $n$  value under different modulus ratios, column spacing and friction angles of the stone column. For a given column spacing ratio and friction angle, the stress concentration is higher for higher modulus ratio  $E_c/E_s$ . Conversely, for the columns with a given modulus ratio, the extent of the yielding zone, and hence the reduction of stress concentration, is greater as the spacing ratio increases even though the maximum stress ratio in the columns is ultimately similar. This occurs because there is less confinement for the spaced columns, leading to greater yielding zone and stress reduction within columns. A comparison of the corresponding curves in Figures 4a and 4b shows that the loss

of stress concentration due to yielding is more severe for column material having a lower angle of internal friction.

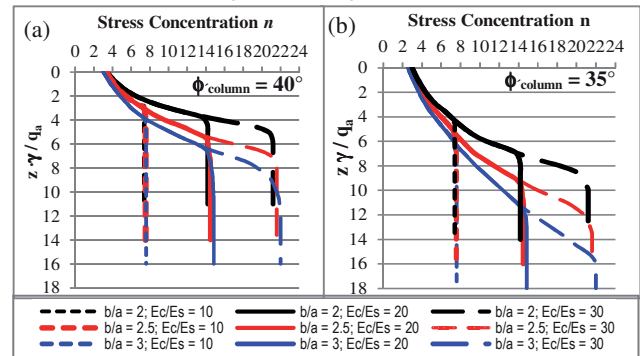

Figure 4. Stone column with rigid base

3.2 Stone columns on compressible soils (elastic appraisal)

For stone columns founded on compressible soil, the elastic FE solution has indicated that there exists a lower equal settlement plane, below which the columns move more than the soil to mobilise positive skin resistance of the soil. More load is transferred from the column to the surrounding soil and therefore the stress concentration  $n$  reduces (see Figure 5a).

Figure 5b shows a plot of normalised distance from the column base  $y/a$  ( $y$  and  $a$  defined in inset in Figure 5b) versus stress concentration reduction ratio  $r (= n/n_{max})$  for the corresponding elastic FEA results given in Figure 5a. The  $n_{max}$  is the maximum computed  $n$  value based on elasticity as shown in Figure 5a. The FEA results for  $r$  near the column base can be approximated by the following logarithmic relationship.

$$r = 1 - \frac{1}{m} \left[ \log \left( \frac{\xi}{y/a} \right) \right] \quad (\text{for } y/a \leq \xi) \quad (3)$$

where  $\xi$  is the influenced zone (also normalized by the column diameter  $a$ ) that is measured from the base of the column to the equal settlement plane (where  $r = 1$ ). The magnitude of  $m$  controls the rate of reduction of  $r$  with  $y/d$ . The higher the  $m$  the more rapid reduction of  $r$  would be towards the column tip.

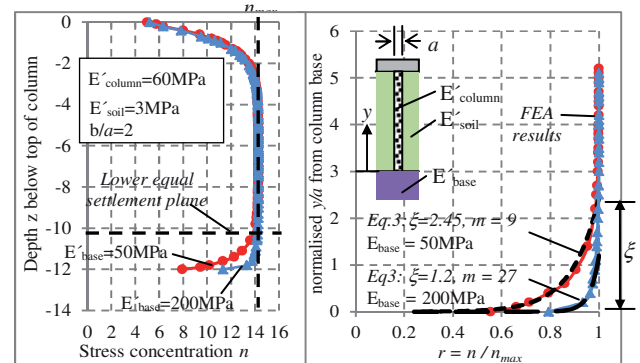

Figure 5. Stone column with compressible base -elastic solution

Figure 5b indicates that as the Young's modulus  $E_{base}$  of the soil beneath the columns increases, the extent of  $\xi$  reduces. Also, the ratio  $r$  reduces more rapidly towards the column tip (i.e.  $m$  increases) as  $E_{base}$  increases. Figure 6 presents the computed  $\xi$  and  $m$  for the different  $E_{base}/E_{column}$  and  $E_{base}/E_{soil}$  ratios based on elastic FEA. The following points can be drawn:

- The influenced zone  $\xi$  at the column base reduces as  $E_{base}/E_{column}$  increases. The reduction may be approximated by a straight line in  $\xi$  vs.  $\log(E_{base}/E_{column})$  plot. Curves 1 and 4 in Figure 6a delineate such relationships for column spacing  $b/a$  of 3 and 2, respectively. A curve in between representing  $b/a = 2.5$  has not been shown for clarity of the figure. Note that these curves can apply to cases where  $E_{base}/E_{soil} \geq 10$  as  $E_{soil}$  has negligible effect on the shape of  $r$  under this condition. For a particular  $b/a$  ratio, the  $\xi$  shows a

lower value as  $E_{base}/E_{soil}$  reduces to less than 10, although the trend of reduction with  $\log(E_{base}/E_{column})$  remains linear and parallel with that for  $E_{base}/E_{soil} \geq 10$  (curves 2 & 3, 5 & 6 in Figure 6a).

- The rate of reduction of  $r$  towards the column tip, represented by the  $m$ , has been found to increase linearly with  $E_{base}/E_{column}$ . Curve 7 in Figure 6b shows such relationship and is applicable for cases with different  $b/a$  ratio up to 3 (limit of parametric range) and with  $E_{base}/E_{soil} \geq 10$ . Curves 8 and 9 delineate the corresponding curves for cases with  $E_{base}/E_{soil} = 2$  and 1.

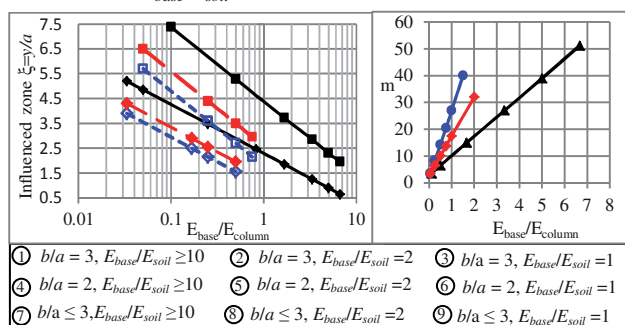

Figure 6. Stone column with compressible base -elastic solution

### 3.3 Stone columns on compressible soils - elasto-plasticity

The effect of compressible base on stress concentration  $n$  is now discussed based on Mohr Coulomb model. In particular, the soils surrounding and below the stone columns have been appraised alternatively using (i) effective shear strength ( $c, \phi$ ) and (ii) undrained shear strength  $s_u$ .

Figure 7a shows the computed  $n$  under different fill loads for the same case as in Figure 2, except that the column is founded on compressible soil that is represented by  $c-\phi$  materials. The stress concentration curves initially follow identical paths as those shown in Figure 3b until they intercept the lower equal settlement plane and thereafter trace along the curve of the elastic solution at the column base. To explain this stress transfer mechanism, the material stress state of the model at the end of simulation (under 140kPa fill stress) is presented (inset in Figure 7a). As before, yielding of the column follows a top-down process. While there is significant yielding of the column due to high stress ratio, there is little yield in the surrounding soil especially towards the column base because of sufficient confinement even with an adopted soil friction angle as low as  $22^\circ$ . Since the soil is elastic, the reduction of  $n$  due to the compressible elastic base soil can be superimposed directly onto the aforementioned reduction due to yielding of column.

Figure 7b presents the results for the case where  $s_u = 30\text{kPa}$  has been adopted for the soils surrounding and below the column. Significant yielding occurs in the soils, which has altered the shape of the stress concentration curves towards the column base as compared to that of the  $c-\phi$  soils. However the differences are not great and for the purpose of assessing  $n$ , the problem can be idealised by assuming that there is no failure in the surrounding soil so that its behavior is essentially elastic.

### 3.4 Procedure for assessing stress concentration

The following procedure for assessing the stress concentration of the stone columns under fill embankment may be proposed:

**Step 1** – Assessing the stress concentration  $n$  along column depth by using charts such as Figure 4, which have accounted for the influence of load level, column spacing, modulus ratio of column and surrounding soil, and yield of the stone column.

**Step 2** – Assess the influence of the compressible base soil on  $n$  based on elasticity by the following equation:

$$n = n_{max} \times r \quad (4)$$

where  $r$  is the stress concentration reduction ratio given in Eq. 3, which is a function of  $\xi$  and  $m$  given in Figure 6.  $n_{max}$  is the maximum elastic  $n$  value below the turning point of each normalised  $z/\gamma q_a - n$  curve in Figure 4.

**Step 3** – Superimpose the solution from Step 2 onto that of Step 1. Thereby, the final  $n$  along the depth of the column is the lower of the two solutions at the same depth.

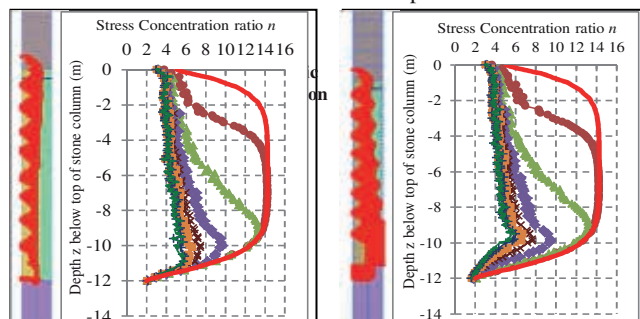

Figure 7. Stone column on compressible (a)  $c-\phi$  and (b)  $s_u$  soil

## 4 COMPARISON WITH FULL 3-D MODELLING

The accuracy of plane strain idealisation of stone columns using equivalent strips in 2D FEA was investigated under self-weight load imparted by a 6m high embankment with 2H:1V batter. The analyses undertaken for the investigation include: *Analysis 1* - Full 3D FEA of embankment over stone columns modeled by solid elements; *Analysis 2* - Axisymmetric FEA of a unit cell consisting stone column; *Analysis 3* - 2D plane strain FEA with the stone columns modeled as strips; and *Analysis 4* - 2D FEA with the soil and columns modeled as equivalent block. The 2D and 3D FEA were carried out using software programme PLAXIS 2D and PLAXIS 3D, respectively.

Table 1 summarises the adopted parameters for all analyses. The 3D FEA is considered a baseline model that comprises a 13m long segment of embankment over soft clay treated with stone columns which are founded on compressible soil. The analysis was repeated with the 0.9m diameter stone columns spaced at 1.7m, 2m and 2.5m in triangular pattern. The 3D FE mesh is shown in Figure 8. The stone columns are modeled using 15 nodes wedge element with interface elements at the column-soil contact. Two cases of interface strength of 100% and 67% of the surrounding soil strengths have been considered.

Table 1. FEA Model Parameters

Analysis	$b/d$	$a_r$	Stone Column Parameters
1,2 3D FEA	2.0,	0.26,	$E_{col}=50\text{MPa}, c_{col}=0\text{kPa}, \phi_{col} = 40^\circ$
	2.3,	0.19,	
	2.9	0.12	
3 - 2D FEA (strips)	2.0	0.26	$E_{strip}=26\text{MPa}, c_{strip}=1\text{kPa}, \phi_{strip} = 36.5^\circ - 38^\circ$ along shaft ; $= 35.5^\circ$ near base
	2.3	0.19	$E_{strip}=22\text{MPa}, c_{strip}=1\text{kPa}, \phi_{strip} = 35.5^\circ - 37^\circ$ along shaft ; $=34^\circ$ near base
	2.9	0.12	$E_{strip}=18\text{MPa}, c_{strip}=1\text{kPa}, \phi_{strip} = 34.5^\circ - 35.5^\circ$ along shaft; $= 33^\circ$ near base
4 - 2D FEA (equiv. block)	2.0	0.26	$E_{block}=6\text{MPa}, c_{block}=1\text{kPa}, \phi_{block} = 30^\circ$
	2.3	0.19	$E_{block}=6\text{MPa}, c_{block}=1\text{kPa}, \phi_{block} = 30^\circ$
	2.9	0.12	$E_{block}=6\text{MPa}, c_{block}=1\text{kPa}, \phi_{block} = 30^\circ$

Soil surrounding columns are  $E_{soil} = 3\text{MPa}, c_{soil} = 2\text{kPa}, \phi_{soil} = 26^\circ$ ;

Soil beneath columns are  $E_{base} = 3\text{MPa}, c_{soil} = 5\text{kPa}, \phi_{soil} = 28^\circ$

In Analysis 3, a 2D plane strain idealisation of the stone columns using equivalent strips was investigated. The strips are divided into several segments, each of which has different strength properties that correspond to the varying stress concentration along the column depth. The dimension and spacing of the 2D strips are as per those outlined in Figure 1.

Analysis 4 presents a conventional 2D approach in which the entire treated soil is represented by a single block with the

equivalent properties,  $\phi_{block}$ ,  $c_{block}$  and  $E_{block}$  derived based on the semi-empirical relationships given by Madhav, 1996.

Figure 8. 3D FEA mesh

The baseline 3D model (Analysis 1) and the 2D strip model (Analysis 3) show similar deformation mechanisms of the stone columns, which can be broadly divided into three zones (see Fig 9a, 9b): Zone 1 away from the fill batter where columns underwent vertical deformation by “bulging”; Zone 2 just behind the crest of the fill batter where columns underwent both vertical and horizontal deformation by “bulging” and “leaning”; and Zone 3 beneath the fill batter where columns underwent mainly leaning. This numerical prediction of the deformation appears to be consistent with the results of the centrifuge model test carried out by Stewart and Fahey (1994). The maximum settlement of the embankment occurs in Zone 2 just before the crest of the fill batter (more than that in Zone 1). This is presumably due to the concurrence of bulging and leaning deformation mechanisms of the stone columns. Conversely, the columns in Zone 3 exhibit the maximum horizontal displacement and are likely due to the prevailing leaning deformation of the stone columns.

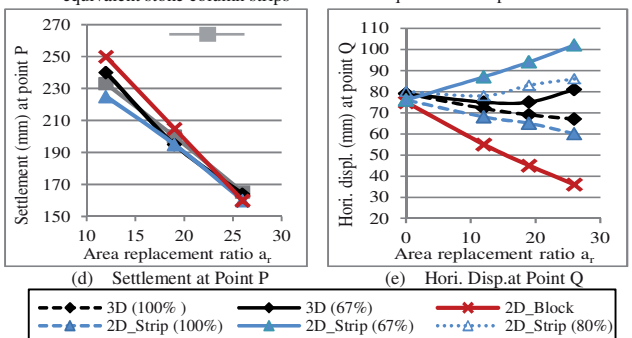

Figure 9. Comparison of FEA results

Figure 9c presents the deformation predicted by the conventional 2D FEA using composite block material (Analysis 4). This method is unable to capture the bulging and leaning deformation of the stone columns. The maximum settlement occurs at the centre of the embankment (i.e. in Zone 1) as opposed to in Zone 2 as predicted by the baseline 3D FEA and the proposed 2D FEA using equivalent strips.

Figure 9d shows a plot of predicted settlements at points P versus area replacement ratio  $a_r$ . All analyses give comparable results, indicating that all the different FE methods are commensurable in terms of settlement prediction under axially symmetric load condition.

Figure 9e presents the predicted horizontal displacement at point Q. The following points are drawn from the results:

- When original soil strengths are used for the interface properties, the result of the 2D strip model (curve 1) compares well with that of the 3D baseline model (curve 2). Both results show a trend of reducing horizontal displacement with  $a_r$ .
- When the interface strength of the columns in the 3D model are reduced to 67% of the soil strengths, the result (curve 3) indicates an initial drop off in horizontal displacement with  $a_r$ , but increases again once  $a_r > 20\%$ . This is due to increasing proportion of yielding elements in the remolded soil as the columns draw closer to each other.
- The application of the same interface strength reduction (67% of surrounding soil strength) in the 2D equivalent strip model has caused excessive yield in the remolded soil and led to increased horizontal displacement with  $a_r$  (curve 4). A better fit to the 3D solution is by changing the interface strength to 80% of the surrounding soil strength (curve 5). Evidently, there needs a regime to determine an equivalent interface strength for the strip model. This merits further research.
- The 2D block model result (curve 6) under-predicts the horizontal displacement when compared with the 3D baseline model predictions. This indicates that the use of isotropic soil properties in the 2D block model, which were derived based on semi-empirical relationships originally for settlement prediction under axially loading condition, have overestimated the reduction in lateral spreading underneath the embankment batter. The use of equivalent strips in the 2D strip model is able to capture the interaction between the soil and the stone column, leading to a better agreement for the lateral deformation with the 3D baseline solution.

## 5 CONCLUSIONS

This paper presents a 2D FEA approach for analysing the response of stone columns under embankment loading. The stone columns are modeled as equivalent strips with the  $c_{eq}$  and  $E_{eq}$  of the strips calculated based on weighted average area approach, and the  $\phi_{eq}$  derived based on force equilibrium method, which requires a presumption of stress concentration ratio of the stone column. For convenience, charts to assess the stress concentration ratio have been generated for full depth and floating stone columns. The solutions cover key parameters including load levels, column spacing ratio,  $E_{column}/E_{soil}$  ratio  $E_{base}/E_{column}$  ratio,  $E_{base}/E_{soil}$  ratio and column friction angles.

The accuracy of the proposed 2D strip model has been investigated by comparing the results of the 3D baseline FEA and the conventional composite approach. It has been shown that the proposed strip model is preferable over the conventional approach for the prediction of horizontal displacement. However, further research is needed to develop a regime to determine equivalent interface strength in the 2D strip method.

# Porosity/cement index to evaluate geomechanical properties of an artificial cemented soil

## Le paramètre porosité/ciment pour l'évaluation des propriétés géomécaniques d'un sol cimenté artificiellement

Rios S., Viana da Fonseca A.  
*Faculty of Engineering of the University of Porto*

**ABSTRACT:** This paper highlights the importance of the porosity/cement index on the evaluation of the geomechanical properties of soil-cement mixtures as a contribution to analyse these materials. This index is defined as the ratio between porosity and volumetric cement content combining the degree of compaction with the cement content. The relevance of these two parameters is defined by an exponent to the volumetric cement content which changes with the type of soil. This paper results from a broad experimental program with unconfined compression tests, indirect tensile tests, triaxial tests and oedometer tests, which were all analysed by this index adjusted by a specific exponent value. The (tensile and compression) strength, the (elastic and initial tangent) stiffness, as well as the compressional behaviour are conveniently represented by this index and a different behaviour is observed when this index is changed.

**RÉSUMÉ :** L'importance du paramètre porosité/ciment dans l'évaluation des propriétés géomécaniques des mélanges sol-ciment est présentée dans cet article comme une contribution pour l'analyse de ces matériaux. Ce paramètre est défini comme le rapport entre la porosité et la teneur volumique en ciment. L'importance relative entre la porosité et la teneur en ciment est introduite en introduisant un exposant à la teneur volumique en ciment dépendant du type de sol. Les résultats d'un vaste programme expérimental incluant essais de compression simples, essais de traction indirect, essais triaxiaux et essais œdométriques sont présentés et analysés par ce paramètre ajusté par un exposant spécifique. La résistance à la compression et à la traction, la rigidité élastique et tangente initiale, ainsi que le comportement en compression sont bien représentés par l'intermédiaire de ce paramètre et un comportement différent est observé si le paramètre est modifié.

**KEYWORDS:** soil-cement, porosity/cement index, tensile strength, compression strength, compressional behaviour.

## 1 INTRODUCTION

Soil-cement mixtures are very interesting for the construction of road and railway platforms, especially in the noble layers of subgrade as well as in transition zones between embankment and concrete structures, where good mechanical properties are required. This solution, not only concurs to improve those characteristics, but also leads to a significant reduction in the economic and environmental costs of these works. Despite these advantages this method has not a generalized application in Portugal due to the lack of design methodologies based on mechanical parameters.

There are several factors affecting the behaviour of cemented soils, such as the type of cement and cement content, the curing time and stress, the water content and porosity. Seeking for a ratio that would reflect the influence of some of these parameters Consoli et al. (2007) presented an index property defined as the ratio of porosity to the volumetric cement content, called porosity/cement ratio ( $n/C_{iv}$ ). Some previous attempts have been made, such as the degree of cementation proposed by Chang and Woods (1992) that concerns the percentage of voids filled with cement, being this parameter developed for sands. Lorenzo and Bergado (2004) have also presented the ratio of the after curing void ratio to the cement content ( $e_o/A_w$ ) proving to be quite interesting for clay mixtures with high values of water and cement content.

Another available parameter is the water/cement ratio used for concrete. However, soil-cement mixtures for road or railway platforms are usually cured in a non saturated condition, which makes the previous ratio inadequate in the analysis of these mixtures behaviour. The main difference between soil-cement mixtures and concrete (besides the cement content) is that during the curing of concrete all voids are completely full of

water and therefore concrete stress-strain behaviour is not dependent on the void ratio but on the water content. In opposition, soil-cement mixtures currently executed in embankments and transport platforms have curing water content lower than the saturation water content and so their compressibility will be related to its porosity. Moreover, while concrete has an almost linear behaviour for a wide range of deformations, soil-cement mixtures have a clear non-linear behaviour since very small strains as a result of the progressive degradation of the cemented structure. Therefore, even if the soil-cement mixture is saturated after the maximum strength has been achieved (i.e. after curing) the curing void ratio still has a very important role on the mechanical behaviour of the mixture.

The influence of the porosity/cement ratio on strength and stiffness parameters is described in Consoli et al. (2012) providing the comparison between two different materials mixed with Portland cement: well graded Porto silty sand and uniform Osorio sand. An advance analysis on the compression and shearing behaviour of cemented Porto silty sand through this parameter is described in Rios et al. (2012).

This paper summarizes some geomechanical properties of cemented Porto silty sand through this index in terms of strength (unconfined, tensile and triaxial), stiffness (initial tangent and unload-reload) and one-dimensional compression.

## 2 MATERIALS AND SPECIMEN PREPARATION

A well graded soil, classified as silty sand (SM) in the unified classification system (ASTM, 1998) was used in this study. The soil is derived from weathered Porto granite which is abundant in Northern Portugal (Viana da Fonseca et al., 2006). Its particle specific gravity is 2.72, and it contains around 30% fines,

although a low plasticity index was obtained ( $I_p = w_L - w_p = 34\% - 31\% = 3\%$ ). From the particle size distribution curve presented in Figure 1 an average diameter  $D_{50}$  equal to 0.25 mm was obtained, as well as uniformity and curvature coefficients of 113 and 2.7 respectively. A high strength Portland cement (CEM I 52.5R) of grain density equal to 3.15 was used as the cementing agent in order to speed up the laboratory tests.

The experimental program is performed with specimens made by the mixture of silty sand, Portland cement and tap water that is compacted statically in three layers in a stainless steel mould. For each specimen, a quantity of fines equal to the weight of cement to be introduced was removed from the soil, in order to have the same grain size distribution curve in the mixture of soil-cement as in the soil itself. Following this procedure the dry density of the soil was also constant throughout the study even though the cement content changed. The specific gravity of the cement-soil mixture was calculated as a weighted average of those of the soil ( $G_s = 2.72$ ) and of the cement ( $G_s = 3.15$ ), and thus it was different for different cement contents.

Figure 1. Grain size distribution curve

### 3 STRENGTH PARAMETERS

#### 3.1 Unconfined compression strength

Strength properties of the cemented sand were evaluated in different ways by means of unconfined compression tests, indirect tensile tests, as well as triaxial tests. First, several specimens moulded to have different cement contents (2%, 3%, 5% and 7%) and dry unit weights (16.4, 17.2, 18.0 and 18.8 kN/m<sup>3</sup>) were tested in unconfined compression in a total of 16 tests. In these tests, the water content was kept equal to 12%. The representation of the unconfined compression strength (UCS) and the ratio of porosity to the volumetric cement content ( $n/C_{iv}$ ) revealed that some adjustment was needed and therefore, an exponent was added to  $C_{iv}$ . This exponent was defined as the value that provides the best correlation coefficient with the data, which, for this material, was found to be 0.21 – Eq. (1).

$$UCS \text{ (kPa)} = 4E+09 (n/C_{iv}^{0.21})^{-4.296} \quad (1)$$

This exponent seems to depend on the type of soil as other authors have found different coefficients when working with different soils (Consoli et al., 2007, 2011): an exponent of 0.28 was found in a residual soil from sandstone (Botucatu soil), while a value of 1.0 was found in an uniform sand (Osorio sand). Based on this parameter, named adjusted porosity/cement ratio ( $n/C_{iv}^{0.21}$ ), the results of different tests were analysed.

#### 1.1 Tensile strength

Taking into account the possibility of shrinkage in cemented materials, the evaluation of the tensile strength is of utmost importance. In that sense, indirect tensile tests following the standard EN 13286-42 (CEN, 2003) were performed on similar specimens whose results were plotted against  $n/C_{iv}^{0.21}$  for which Eq. (2) was obtained,

$$R_{tb} \text{ (kPa)} = 2E+09 (n/C_{iv}^{0.21})^{-4.719} \quad (2)$$

The results showed that the indirect tensile strength ( $R_{tb}$ ) was about 11% of the UCS. In Figure 2 both  $R_{tb}$  and UCS are plotted against  $n/C_{iv}^{0.21}$  in different scales for comparison. It is clear that both trends are very similar (except for the absolute values) corroborating the convenience of the adjusted porosity/cement ratio.

In Consoli et al. (2011), where the data from these tests is plotted together with data from other two soils, it is shown that for the three soils a decrease in porosity promotes an increase in the tensile strength as a consequence of the higher number of contact points between particles which improves the cementation. Also for the other two soils, a unique correlation was found between the adjusted porosity/cement ratio and the indirect tensile strength, the exponent of the ratio depending on the soil.

Figure 2. Indirect tensile strength and unconfined compression strength against the adjusted porosity/cement ratio

#### 3.2 Triaxial tests

Drained triaxial compression tests were performed over soil-cement specimens, which were moulded to have two different adjusted porosity/cement ratios ( $n/C_{iv}^{0.21} = 36$  and 29) corresponding respectively to UCS of 800 kPa and 2000 kPa. For these ratios, two moulding conditions were defined characterized by cement content and dry unit weight while the water content remains constant and equal to 12%. For the first ratio ( $n/C_{iv}^{0.21} = 36$ ), 2 and 4% cement contents were considered which lead to dry unit weights of 16.7 and 15.4 kN/m<sup>3</sup>, respectively. For the second ratio ( $n/C_{iv}^{0.21} = 29$ ) higher strength was needed, so 5 and 7% of cement contents were assumed with 17.0 and 16.4 kN/m<sup>3</sup> of dry unit weight. The tests were performed at three different effective confining pressures (30, 80 and 250 kPa) over specimens moulded in four moulding points, comprising 12 tests (Table 1).

The stress-strain curves (see Figure 3 as an example) clearly evidence that the specimens with  $n/C_{iv}^{0.21} = 29$  have higher peak deviator stresses than the specimens with  $n/C_{iv}^{0.21} = 36$  independently of the cement content. Adding cement to the sand had the effect of increasing the shear strength by up to five times for the adjusted porosity/cement ratio of 36 and tenfold for the adjusted porosity/cement ratio of 29. All specimens initially compressed, followed by significant dilation, which was associated to a peak strength, before strain softening. This is typical of cemented soils, with the maximum rate of dilation taking place right after the peak strength (Viana da Fonseca 1998). The peak strength corresponds to the onset of significant

breakage in the cement, while dilation involves particle rearrangement that is only possible after bonding breakage. Assuming only compressive volumetric deformations up to the point of zero dilation, beyond this point yielding exists, which indicates that the onset of cement breakage is progressive starting even before peak. However, being the peak strength not frictional but controlled by the cement yielding, then most destructuration may take place only at peak.

Table 1. Moulding conditions of the specimens for the triaxial tests

Moulding Point	%C	$\gamma_d$ (kN/m <sup>3</sup> )	$e_0$	w (%)	$n/C_{iv}^{0.21}$	UCS (kPa)	$\sigma'_c$ (kPa)
1	2	16.6	0.61	12	36	800	30
	2	16.5	0.62	12	36	800	80
	2	16.7	0.60	12	36	800	250

	7	16.7	0.61	12	29	2000	250

Figure 3. Stress-strain curves for the confining pressure of 80 kPa.

All the cemented specimens tested in triaxial tests suffered strain localisation. Therefore, it becomes difficult to rely on the local instrumentation at strain levels close and after the peak, but especially at ultimate conditions. In that sense, the stress invariants such as the deviator stress ( $q$ ) and the mean effective stress ( $p'$ ) were not considered representative of the stress state and thus, the stresses acting on the shear plane were calculated by the procedure used by Gasparre (2005) based on the Mohr circles and taking into account the post rupture analysis described by Burland (1990).

Figure 4. Peak strength envelopes by adjusted porosity/cement ratio.

In Figure 4 the stresses acting on the plane are plotted on a ( $\sigma'$ ,  $\tau$ ) graph for peak conditions from which the correspondent strength parameters were obtained. The points are assigned to each adjusted porosity/cement ratio ( $n/C_{iv}^{0.21}$ ) expressed before. It is interesting to notice that for peak conditions two strength envelopes were obtained depending on the index ratio. The adjusted porosity/cement ratio influences the peak angle of friction and cohesion intercept, being the peak envelope for the index  $n/C_{iv}^{0.21}=29$  higher than that for the index equal to 36. This could have been predicted from moulding characteristics as each ratio corresponds to different UCS.

## 4 STIFFNESS PARAMETERS

### 4.1 Initial tangent stiffness

The unconfined compression tests were performed with local measurement of deformation using LDT's and so the stiffness modulus could be evaluated. An initial tangent modulus ( $E_{ti}$ ) was then calculated based on the linear part of the stress-strain curve. Plotting this modulus against the adjusted porosity/cement ratio for the 16 tests presented above, as Figure 5 shows, it can be concluded that the general adjustment of the data is quite reasonable.

Figure 5. Indirect tensile strength and unconfined compression strength against the adjusted porosity/cement ratio

As expected, stiffness parameters are more scattered than strength parameters because strain measurements are always more sensitive to non-homogeneities of the specimen and anchors are introduced in the specimen in single reference points. On the contrary, strength measurements capture more easily an average value of the whole specimen.

### 4.2 Unload-reload moduli

In the triaxial compression tests reported above, a small static cycle was performed during shearing, between 30% and 15% of the expected peak deviatoric stress. These loads were selected to avoid soil yielding before the cycles so the modulus could be assumed elastic. Figure 6 summarizes the results of the unload-reload moduli ( $E_{ur}$ ) obtained for the two adjusted porosity/cement ratio. The values of  $E_{ur}$  obtained from these triaxial tests are higher than the initial tangent modulus ( $E_{ti}$ ) obtained in the unconfined compression tests presented in Figure 5. This can be considered expected because  $E_{ur}$  is usually assumed to follow an elastic pattern, if performed at low ranges of cyclic stress, while in the initial monotonic loading path some compliance errors of strain gauges may be presented. This graph also evidences a clear and almost discrete increase in the stiffness modulus values for the specimens with  $n/C_{iv}^{0.21}=29$  (5% and 7% cement contents) in comparison with the specimens with distinct ratio  $n/C_{iv}^{0.21}=36$  (2% and 4% cement contents). This could be even clearer if the instrumentation

would perform in a completely satisfactory way for the highest cemented mixtures (for 5% and 7% of cement content).

Figure 6. Stiffness modulus obtained in the unload-reload cycles.

### 5 COMPRESSIBILITY PARAMETERS

One-dimension compression tests in oedometer cells with constant rate of deformation (CRD) were performed over soil-cement specimens in the four moulding conditions presented in Table 1. The preparation of the different mixtures for these tests followed the same procedure of the other tests, as expressed briefly in section 2. Due to the size of the mould, the static compaction was performed in one layer, although the soil was placed in several stages followed by tapping. For the calculation of the mean effective stress ( $p'$ ) in each test the value of the coefficient of earth pressure at rest ( $k_0$ ) was considered equal to 1 due to the high compaction degree that the specimens were subjected during moulding (>80% of the Modified Proctor test). Figure 7 shows two of those tests, corresponding to two different porosity cement ratios, indicating that these compressibility curves do not seem to converge.

Figure 7. Void ratio against mean effective stress for two different porosity/cement ratios

However, plotting the tests performed over specimens with the same porosity cement ratio, a unique compressibility line was obtained. The same has happened for the other two tests with the other porosity cement ratio of 36. On the contrary, when specimens with the same cement content but different void ratio were represented no unique line was obtained. These results indicate that this ratio can better reproduce the behaviour in one-dimensional compression than the cement content or initial void ratio alone.

### 6 CONCLUSIONS

This paper presented a great number of data from different tests. Together, they allowed a better understanding of the artificially cemented soil used in this work. Compressive and tensile strength, strength envelopes, stiffness parameters and one-dimensional behaviour were some of the most important issues studied. The adjusted porosity/cement ratio revealed to be very consistent and useful for the analysis of the unconfined

compression strength since a unique trend was obtained between this variable and  $n/C_{iv}^{0.21}$ . A similar trend was obtained for the indirect tensile strength performing tests over specimens moulded in the same conditions. The comparison of the two curves provided a relationship between indirect and compressive strength of about 11%.

The strength envelope values of the cemented specimens tested in triaxial compression were obtained through a procedure based on the Mohr's circles analysis to solve the lack of representativeness of principal stress analysis due to non correspondence of the real localised shear locus. In fact, strain localisation is unavoidable in these very stiff materials, and consequently, the global stress-strain measurements are no longer representative of the conditions throughout the shearing process. Two peak strength envelopes were obtained for each  $n/C_{iv}^{0.21}$  ( $n/C_{iv}^{0.21}=36$ :  $\phi^*=30^\circ$  and  $c^*=253$  kPa;  $n/C_{iv}^{0.21}=29$ :  $\phi^*=39^\circ$  and  $c^*=589$  kPa), showing once again the convenience of this ratio for the analysis of these mixtures behaviour.

This ratio also seems to be very useful to reproduce the one dimensional compression behaviour of the mixture, since for each  $n/C_{iv}^{0.21}$  a single line was obtained for higher stresses.

# Compressive Strength of Fiber-Reinforced Lightly-Cement Stabilized Sand

## Résistance à la compression des sables renforcées par fibres et ciment

Sadek S., Najjar S., Abboud A.

Department of Civil and Environmental Engineering, American University of Beirut

**ABSTRACT:** The stabilization of soils using cementing agents has long gained acceptance and is well established in geotechnical engineering practice. Furthermore, adding discrete fibers to the cement-treated soil has been shown to improve the soil's response to loading and its overall engineering behavior. Limited studies of the behavior of fiber-reinforced cemented sand in the laboratory indicated that the addition of cement and fibers results in an increase in the strength of the composite, especially at high fiber contents and lengths. Cemented sands were found to be brittle compared to un-cemented sands, with the brittleness decreasing with the inclusion of fibers. The objective of this paper is to investigate the effect of randomly distributed fiber reinforcements and cement addition on the response of sandy soils. To achieve this objective, the behavior of cement/fiber-reinforced sands was studied using unconfined compression tests. The parameters that were varied are [1] the cement content (0.5% and 1%), [2] the fiber content (0%, 0.25%, 0.5%, and 1.0%), and [3] fiber lengths (6, 12 and 20 mm). The results of the tests were used to quantify the degree of improvement in strength and stiffness due to the addition of fibers and cement to the cohesionless sand.

**RÉSUMÉ:** La stabilisation des sols en utilisant des agents de cimentation a longtemps été accepté et est bien établie dans la pratique de la géotechnique. De plus, l'ajout de fibres discrètes au sol-ciment a été démontré effectif pour améliorer la réponse du sol au chargement et son comportement mécanique global. Seules quelques études existent où le comportement des sols renforcés par des fibres et ciment a été étudié au laboratoire. Elles ont indiqué que l'addition de ciment et de fibres engendrent une augmentation de la résistance du composite, en particulier à des teneurs en fibres et des longueurs élevées. Les sables cimentés ont été jugés fragiles par rapport aux sables non cimentés; cette fragilité diminue avec l'inclusion de fibres. L'objectif de cet article est d'étudier l'effet de renforts en fibres distribuées de façon aléatoire et l'ajout de ciment sur la réponse des sols sableux. Pour atteindre cet objectif, le comportement de sables enforcés par ajout de ciment / fibres a été étudiée par des essais de compression non confinée. Les paramètres qui ont été variées sont [1] la teneur en ciment (0,5% et 1%), [2] la teneur en fibres (0%, 0,25%, 0,5%, et 1,0%), et la longueur des fibres [3] (6, 12 et 20 mm). Les résultats des tests ont été utilisés pour quantifier le degré d'amélioration de la résistance et de rigidité due à l'ajout de fibres et de ciment au sable pulvérulent.

**KEYWORDS:** fiber-reinforced sand, cement stabilized sands, fibers, cement, unconfined compressive strength.

## 1 INTRODUCTION

The geotechnical and materials/pavement engineering fields are witnessing an increasing interest in exploring soil improvement schemes that are based on the addition of stabilizing agents such as synthetic or natural fibers and/or cementing agents for various applications. The objective is to produce a composite material with improved engineering properties that could be used in lieu of good quality construction material that is typically obtained through non-sustainable and environmentally problematic activities such as quarrying. The composite material with its improved engineering properties could be used to replace conventional base and sub-base material under pavements, or to support foundations of "light" structures or infrastructure, which otherwise could not be adequately supported by the natural soil. The improved material could also be used as backfill behind earth retaining walls and reinforced or stabilized slopes.

The experimental data that is available in the literature for fiber/cement reinforced sands is relatively limited (Maher and Ho 1993, Consoli et al. 1998, Kaniraj and Havanagi 2001, Sobhan and Mashnad 2002, and Consoli et al. 2002). There is a need for designing and implementing a comprehensive experimental testing program that is aimed at investigating the behavior of fiber/cement reinforced sands systematically. To achieve this objective, the behavior of cement/fiber reinforced sands was studied in the laboratory using unconfined compression tests. The parameters that were varied in this study are [1] the cement content (0.5% and 1%), [2] the fiber content (0%, 0.25%, 0.5%, and 1.0%), and [3] fiber lengths (6, 12 and 20 mm). The results of the tests were used to quantify the degree of improvement in strength, stiffness, and ductility due to the addition of fibers and cement to the cohesionless sand.

## 2 EXPERIMENTAL PROGRAM

Twenty unconfined compression tests on fiber/cement reinforced sands were conducted as part of this study.

### 2.1 Material Properties

The sand used in this study is Ottawa Sand with the properties shown in Table 1. The sand classifies as a *poorly graded sand (SP)* according to the Unified Soil Classification System.

The fibers (Fig. 1) chosen for the reinforcement are polypropylene fibers, typically used as secondary reinforcement of lightweight concrete and mortar mix designs. They were adopted because they are available in several lengths, they can be mixed with soil-cement mixtures and satisfy efficiently the intended role of reinforcement. The fibers have a specific gravity of 0.91 g/ml, a tensile strength of 0.38 kN/mm<sup>2</sup> and a young modulus of 3.5 kN/mm<sup>2</sup>. Fiber lengths of 6 mm ±1, 12 mm ±1 and 20 mm ±1 were used in the testing program. The nominal diameter of the fibers was determined in the lab under an electronic microscope to be in the order of 0.1 mm.

Table 1. Table caption (TNR 8), numbered consecutively. Tables placed below caption. TNR 8 for text and numbers in Table.

Soil Property	Value
$D_{10}$ (mm)	0.22
$D_{30}$ (mm)	0.31
$D_{60}$ (mm)	0.42
Coefficient of uniformity ( $D_{60}/D_{10}$ )	1.95
Coefficient of curvature ( $(D_{30})^2/(D_{60}*D_{10})$ )	1.04
Maximum and minimum void ratios ( $e_{max}, e_{min}$ )	(0.75, 0.49)
Specific gravity	2.65

The cement used in this study is normal Portland cement type I. The same sources of cement and sand were used for all the specimens to eliminate all risk of material discrepancy.

## 2.2 Sample Preparation

The specimens used in the UCS tests were prepared in cylindrical PVC split molds to facilitate the extraction of the sample after formation. For a given test, the material quantities were determined based on the target fiber content, cement content, and sand density. Initially, the sand and cement were mixed in dry conditions before adding 5% by weight of water necessary for the hydration of the cement and blending of the mixture. The fibers were then mixed thoroughly with the sand-cement to obtain a final homogenous mix with well-distributed and untangled fibers. It is to be noted that all the mixing was done manually since the use of a mechanical mixer could result in tangling and clodding of the fibers and their segregation from the soil mixture. Each layer was then compacted into the mold to the required height under the effect of a compaction tool which was specifically designed for the purpose. The top surfaces of the 1<sup>st</sup> and 2<sup>nd</sup> layers were scratched prior to putting the new material for the subsequent layer in order to obtain, to the extent possible, a homogenous specimen and eliminate the risk of weak shear planes at the contact surface between two layers.

A curing time of  $8 \pm 1$  days was chosen to allow the cement enough to time to set. Since the curing time is not a parameter which was studied in the testing program, the period of 8 days was chosen as an average time which provides a significant period for curing without unduly prolonging the overall time needed for each test.

## 2.3 Unconfined Compression Strength Tests

The UCS tests were performed according to ASTM D2166 with specimens having a diameter of 5.5 cm and a height of 11 cm giving an acceptable height to diameter ratio of 2. The machine used in the tests is a HUMBOLDT HM-3000 loading frame fully automated and computer software-controlled. The vertical deformation is recorded by an LVDT, while the resisting axial load is recorded by load cells of different capacities. The rate of application of the strain is 0.05 cm/min. The data were recorded automatically every 4 seconds and the test was continued until failure occurred or when the axial strain exceeded 15%.

## 3 TEST RESULTS AND ANALYSIS

Results from twenty unconfined compression tests on fiber/cement reinforced sands are presented in this paper. The tests were restricted to lightly cemented sands (cement content = 0.5% and 1.0%) that were reinforced with fibers of different lengths (6mm, 12mm, and 20mm) at different fiber contents (0%, 0.25%, 0.5%, and 1.0%). The analysis of the tests includes an assessment of the stress-strain behavior and the dependency of the unconfined compressive strength on the reinforcement parameters (fiber content, fiber length, and cement content).

Figure 1. Polypropylene fibers used in the experiments.

## 3.1 Stress-Strain Response

The stress-strain response of specimens that were stabilized with a cement content of 0.5% is presented in Figs. 2a, 2b, and 2c for fiber contents of 0.25%, 0.5%, and 1.0%, respectively. The response of specimens that were reinforced with a cement content of 1.0% is similarly presented in Figs. 3a, 3b, and 3c. On each of the plots, stress-strain curves are presented for different fiber lengths (6mm, 12mm, and 20mm) and for the specimen that was prepared with no fibers.

For specimens that were reinforced with a cement content of 0.5% (Fig. 2), the stress strain curves indicate a consistent increase in stress with strain up to a maximum peak stress value at which failure occurs. The value of the peak and the post peak behavior are a function of the cement content, fiber content, and fiber length. The failure mode as indicated by the value of the strain at failure and by the post peak response is found to be more ductile as the fiber content increased from 0% to 1.0%. In addition, for a given fiber content, ductility was found to improve as the length of fibers increased from 6mm to 20mm.

For the higher cement content of 1.0% (Fig. 3), the behavior of the composite specimens was found to be more brittle compared to their lightly cemented counterparts. The inclusion of fibers added some ductility to the mode of failure, but this effect was minor for the smaller fiber contents (0.25% and 0.50%). The improvement in the mode of failure was only evident in the higher fiber content of 1.0% at all fiber lengths and for the intermediate fiber content of 0.5%, but only at the larger fiber length of 20mm.

## 3.2 Effect of Fiber/Cement on Stiffness

The stress-strain response at the onset of loading in Figs. 2 and 3 could be used as a measure of stiffness for the fiber/cement reinforced specimens. For the smaller cement content, results on Fig. 2 indicate that the stiffness of the specimens was not affected by the addition of fibers except for cases involving the longest fibers (20mm) with fiber contents of 0.25% and 0.50% where the stiffness was found to be improved. For cases involving fibers with a high fiber content of 1.0%, no improvements were observed in the stiffness, irrespective of the fiber length.

A slightly different behavior was observed for the higher cement content of 1.0% where slight improvement in stiffness were observed for the shorter fibers at the smaller fiber contents, with the improvements in stiffness vanishing for the longest fiber and the highest fiber contents, where slight reduction in stiffness was actually observed. This indicates that fibers could result in a softer initial response for higher cement contents, higher fiber content, and longer fibers.

Figure 2. Stress-strain response for cement content of 0.5%.

### 3.3 Effect of Fiber Content on UCS

For a given cement content, the stress-strain curves in Figs. 2 and 3 indicate that the unconfined compressive strength increases as the fiber content increases. The unconfined compressive strength for each test was computed and plotted as a function of the fiber content in Figs. 4a and 5a for cement contents of 0.5% and 1.0%, respectively. For the two cement contents and for all fiber lengths, results indicate a consistent increase in the unconfined compressive strength with fiber content. For a cement content of 0.5%, the UCS increased from about 15 kPa (no fibers) to about 40 kPa (1.0% fibers) for the shortest fiber length of 6mm, and from 15 kPa (no fibers) to about 160 kPa (1.0% fibers) for the longest fiber length of 20mm. For the larger cement content of 1.0%, the UCS increased from about 50 kPa (no fibers) to about 112 kPa and 178 kPa, for the shortest and longest fibers at 1.0% fiber content, respectively.

In order to obtain a quantitative measure of the degree of improvement in the unconfined compressive strength, the ratio of the UCS with fibers to the UCS without fibers was computed and plotted versus the fiber content in Figs. 4b and 5b. These results indicate that the cement content played a significant role in defining the improvement ratio, with the ratio varying from 2 (smallest fiber content and fiber length) to 10 (largest fiber content and fiber length) for a cement ratio of 0.5%, and from about 2 to 4 for the larger cement ratio of 1.0%.

Figure 3. Stress-strain response for cement content of 1.0%.

### 3.4 Effect of Fiber Length on UCS

The effect of the fiber length on the stress-strain response and on the improvement in the UCS is evident in Figs. 2 to 5 and is found to be dependent on the cement content. For a cement content of 0.5%, as the fiber length increases, the unconfined compressive strength increases and the strain at failure increases, indicating improved ductility. The effect of fiber length was found to be more evident at higher fiber contents compared to lower fiber contents. For example, for the small fiber content of 0.25%, the improvement ratio in the UCS increased slightly from 1.7 to 2.6 (for fiber length of 6mm and 20mm) compared to the dramatic increase from 2.6 to 10.6 (for fiber length of 6mm and 20mm) for the larger fiber content of 1.0%.

For the larger cement content of 1.0%, the effect of fiber length on the unconfined compressive strength becomes smaller. For the smaller fiber contents of 0.25% and 0.5%, the difference in the measured values of the UCS is relatively insignificant, with improvement ratios varying in the narrow range of 1.6 to 2.0 (fiber content of 0.25%) and 2.1 to 2.15 (fiber content of 0.50%) for the shortest and longest fibers, respectively. For the largest fiber content of 1.0%, the improvement ratio increases from 2.2 to 3.7, as the fiber length increases from 6mm to 20mm.

Figure 4. Improvement in UCS for cement content of 0.5%.

### 3.5 Effect of Cement Content on UCS

The range of the cement content that was chosen in this study (0.5% to 1.0%) is indicative of lightly-cemented sands. However, the results presented in Figs. 2 to 5 indicate a clear difference in the performance of the composite specimens that were stabilized with 0.5% cement and specimens stabilized with 1.0%, particularly with regards to the contribution of the fibers to the improved compressive strength.

For specimens that were not reinforced with fibers, the increase in cement content from 0.5% to 1.0% increased the unconfined compressive strength from 15 kPa to 50 kPa. With the addition of fibers, results showed that the UCS could be improved by more than 10 times for a cement content of 0.5% but only to 3.7 times for the cement content of 1.0%, indicating a decreased relative efficiency of the fibers at improving the compressive strength as the cement ratio increases.

It should be noted however that the actual maximum value (largest fiber content and fiber length) of the unconfined compressive strength was still higher (about 185 kPa) for the cement content of 1.0% compared to the maximum value (159 kPa) measured for the cement content of 0.5%. For the smaller fiber contents and fiber lengths, the values of the UCS for the cement content of 1% were all higher than those of the 0.5% at the same fiber content and fiber length, indicating that the magnitude of the improved UCS was larger for the higher cement content.

## 4 CONCLUSION

Based on the results of 20 unconfined compression tests that were conducted in this study on fiber-reinforced lightly-cemented sands, the following conclusions can be drawn:

1. The behavior of specimens with higher cement contents is more brittle compared to specimens with lower cement contents. However, brittleness decreased with the inclusion of fibers and the energy absorption capacity increased as the fiber content and length increased.
2. For the smaller cement content, the stiffness of the specimens was not affected by the addition of fibers, except for the cases of 20mm fibers with fiber contents

Figure 5. Improvement in UCS for cement content of 1.0%.

of 0.25% and 0.50%, where the stiffness was found to be improved. For the higher cement content fibers could result in a softer initial response particularly for higher fiber contents and longer fibers.

3. For the both cement contents used, results indicated a consistent increase in the unconfined compressive strength with fiber content. The cement content played a significant role in defining the improvement ratio of the UCS, with the ratio varying from 2 (smallest fiber content and fiber length) to 10 (largest fiber content and fiber length) for a cement ratio of 0.5%, and from about 2 to 4 for the larger cement ratio of 1.0%.
4. For a cement content of 0.5%, as the fiber length increased, the UCS increased and the strain at failure increased, indicating improved ductility, with the effect of fiber length being evident at higher fiber contents compared to lower fiber contents. For the larger cement content of 1.0%, the effect of fiber length on the unconfined compressive strength was less significant.

# Conservatoriumhotel Amsterdam, geotechnical design and monitoring

## Conservatoriumhotel Amsterdam, conception géotechnique et instrumentation

Stoel van der A.E.C.

CRUX Engineering BV Amsterdam & Universiteit Twente

Vink D., Bouma J.

CRUX Engineering BV Delft

**ABSTRACT:** This article deals with the geotechnical design of the building pit and the foundation restoration of the Conservatoriumhotel Amsterdam. It involves a selection of results of analytical and Plaxis calculations and damage predictions regarding vibrations and settlements. The second part of the paper deals with the execution of the works and the important role of a pro-active monitoring-system and careful communication with all stakeholders. It briefly outlines the monitoring plan, type and results of the monitoring and the risk management during implementation. Some measurement results are compared with predictions and two calamities that occurred during the construction will be specifically addressed. This will clearly show the added value of monitoring and active risk management, that eventually has led to the successful completion of this project in 2011.

**RÉSUMÉ :** Cet article traite de la conception géotechnique de la tranchée couverte du bâtiment et reprise en sous œuvre des fondations du Conservatoriumhotel Amsterdam. Il s'agit d'une sélection de résultats de calculs analytiques et Plaxis et des prévisions concernant les dommages dus aux vibrations et les tassements induits. La deuxième partie de l'article traite de l'exécution des travaux et le rôle important que la surveillance pro-active et de la communication prudent avec toutes les investisseurs. Le plan d'instrumentation est brièvement décrit ainsi que le type et le suivi, des résultats et de la gestion des risques lors de la mise en œuvre. De plus les résultats des mesures sont comparés aux prévisions. Deux sinistres qui se sont produits lors de la construction seront abordés. La valeur ajoutée de l'instrumentation est montrée ainsi que la gestion active des risques qui a finalement conduit à la réussite de ce projet en 2011.

**KEYWORDS:** geotechnical design, building pit, Plaxis, monitoring, restoration

## 1 INTRODUCTION

In Amsterdam, at Van Baerlestraat 27, the stately listed building of the "Rijkspostspaarbank" (Imperial Bank, see Figure 1) is situated. It was originally built between 1899 and 1901 by Imperial architect, D.E.C Knuttel. The building was previously reassigned to function as Sweelinck Conservatory and was since 2008 radically converted into a luxurious hotel, including over 9000 m<sup>2</sup> of five star hotel and 85 parking facilities. This conversion has been one of the most expensive (more than 30 million euro) hotel refurbishments ever.

This renovation required a number of radical structural changes that led to a complex task with regard to the geotechnical design. The most important of these tasks was realising a two level parking / basement including a (-3) swimming pool in the courtyard of the existing building. Special attention had to be paid to the many historical details in the buildings that were incorporated in the new design and had to be preserved. In addition, the building location is flanked by two tram lines and the Van Gogh Museum and Rijksmuseum and the Royal Concert Hall, resulting in numerous logistic restrictions.

## 2 SOIL CONDITIONS

At the location, the typical Amsterdam soil profile (Figure 2) is found. The top layer of the first meters below surface level consists of Anthropogenic sand. Below this top layer the Holocene deposits are found until a depth of about 10-15 m below surface level. The Holocene formation can be divided (from top to bottom) into peat, clay, silty sand, clay and peat. The Holocene lies on top of the Pleistocene sands which are divided by an intermediate silty, clayey sand layer. The phreatic water level is found about 0.4 m below surface level.

Figure 1. Aerial photo of the building Stradivarius

Figure 2. Amsterdam soil conditions

### 3 CONSTRUCTION AND BUILDING LAYOUT

In Figure 3, 4 and 7 the lay out of the building and building pit are shown. Because of the very deep excavation next to the pile foundation of the existing building, much precaution had to be paid to settlements and angular distortion (damage) of this listed building. Also, the bending moments in the existing wooden piles were a major concern. This resulted in a staged excavation as shown in Figure 4. Note the different excavation levels of the two excavations A and B, which cause an asymmetrical load situation and displacements. An extra complication was that the building site could only be accessed through a narrow entrance in the eastern part.

Figure 3. Section C-C: new situation (note swimming pool at -3)

Figure 4. Schematic cross-section C-C, NAP = reference level

### 4 GEOTECHNICAL DESIGN

Because of the asymmetrical excavation and the need to assess soil and building deformations, 2D FEM Plaxis calculations were performed. In Figure 5 an example of the used model for section C-C is shown (see Figure 7). Based on the deformations and stresses resulting from this model, the vertical deformations and inclination of the existing building were determined, see Figure 6. The sheet piles and struts were designed in such an iterative way that the damage prediction resulted in an acceptable damage class (see Table 1).

Figure 5. Plaxis geometry section C-C, shallow excavation NAP -6,1m.

Figure 6. Vertical deformations in building, section C-C.

Because of the proximity of the existing building, full of marble stairs and exquisite tiles that had to be preserved, all the applied foundation system were vibration free: the sheet piles AZ26 were pushed and the Hek-piles were screwed.

Table 1. Results damage prediction sect. C-C (based on BRE regulation / Netzel 2010)

$u_v$	L/H	$\beta$	$E_h$	$\Delta/L$	$\epsilon_{tot}$	Damage class
m	-	-	%	-	-	-
-0.0113	1:1605	0.066	0.0002	0.00088	-	Slight (minor aesthetic damage)

L/H = Ratio depth/height of the building  $\Delta$  = Vertical deflection  
 $\beta$  = Relative angular distortion  $\epsilon_h$  = Horizontal strain  
 $\epsilon_{tot}$  = Total building strain  $u_v$  = vertical displacement

### 5 MONITORING

#### 5.1 General

Because of the sensitive nature of the existing building and the high complexity of the execution of the works, an extensive monitoring program was implemented. Figure 7 shows a general overview including the position of the levelling point (bolts) and inclinometers. By measuring the inclination of the sheet piles, an excellent comparison could be made between predictions and execution for all stages of the works. The leveling points were mainly used to verify whether the inclination indeed resulted in the predicted building deformation. This is particularly useful because some deviation from the predictions is not uncommon.

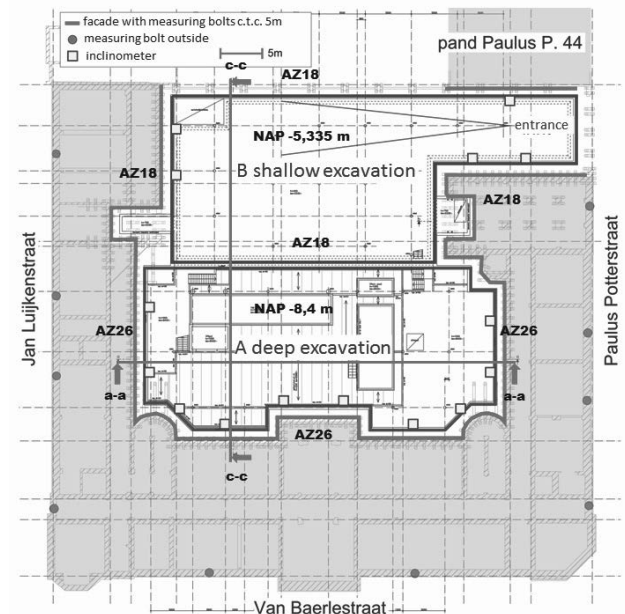

Figure 7. Overview leveling points (bolts) and inclinometers.

The monitoring proved to be particularly valuable because of the occurrence of two incidents during construction.

### 5.2 Incident 1

Incident 1 occurred during the excavation of building pit A. The situation at that time is illustrated by Figure 8 (by a recommendable, remotely operable, permanent webcam!) and Figure 9.

Figure 8 Overview building pit (at the time of incident)

Figure 9. Top view building pit (at the time of incident; © Google)

To limit the displacements the execution sequence has been that, after placement of the sheet piles and the excavation for the NAP -1,5m and -5,0m struts, the water table was first set up again before wet excavation to NAP -10,5m commenced. After hardening of the underwater concrete floor, the water table was lowered again. It was then timely discovered that the -5,0m struts and girder were not in position, see Figure 10. Pumping was stopped immediately to access the situation.

Figure 10. Situation at 2<sup>nd</sup> level girder (collapsed during excavation)

In order to be able to inspect the girder and struts, the water table had to be lowered further than calculated (-6,5m without strut). It was found that, probably because of excavating under the girder, it's consoles were removed, thus causing it to 'hang by a tread'. Because of the extensive monitoring and modelling, an alternative model could be made very quickly based on actual deformations, from which it could be concluded that the deformations resulting from the mitigating measures stayed within acceptable boundaries, see Figure 11. Thus, within three weeks and without significant delay in construction, the strut and girder could be repaired allowing for further excavation of the pit.

Figure 11. Inclinometer & predictions after incident at girder/strut -5.0m

### 5.3 Incident 2

Incident 2 occurred during the excavation of the entrance at building pit B. The situation is illustrated by Figures 12 (before) and 13 (after excavation). At the left side of the pictures, a listed building at Paulus Potterstraat 44 (PP44) is located. During the excavation of building pit B, this building started to settle, as can be seen in Figure 15. The main concern however was that the side at the entrance settled significantly more than the opposite side, thus potentially causing damage.

In November 2009 the monitoring showed that the settlement rate increased alarmingly. The frequency of monitoring was immediately increased and owner, contractor, consultants, insurer and the municipality intensively discussed a solution. This was found in a combination of allowing more deformation as long as no damage resulted from frequent building inspection and, more importantly, the remedial measure of pre-stressing the NAP -4,0m strut with 150 kN/m. The last measure resulted in a stabilisation of deformations that has held up to now. No damage to PP44 was detected.

Figure 12. Building pit at PP44 before incident

Figure 13. Building pit at PP44 during incident

Figure 14. Displacement of building Paulus Potterstraat 44

#### 5.4 Costs

The (interest)cost of a delayed opening of the hotel have been estimated at least at €50.000,- a week. The additional costs of the additional monitoring and damage risk assessment have however, as compared to a basic monitoring program, not exceeded €100.000. When no information would have been available after one of the calamities, construction could have been stopped for months.

### 6 COMPLETED WORKS

The works have been completed in 2011, not only resulting in one of the most luxurious hotels in Amsterdam, but also in a construction of both geotechnical as well as aesthetic beauty. It won the 2012 Dutch Renovation 'Golden Phoenix' award for the most effective reuse of existing property stocks. An impression of the completed work is given in Figure 14 to 16. Figure 19 shows the impressive swimming pool at -3 level, right next to the over 110 years old existing pile foundations.

### 7 CONCLUSIONS

The renovation of the former Rijkspostspaarbank Amsterdam to luxury five star Conservatoriumhotel has been very successful from a geotechnical perspective. Through a sophisticated geotechnical design and a detailed risk analysis of the distortions of the building before construction, combined with a meticulous and proactive monitoring and excellent communication during execution, two major incidents have not

led to significant additional costs and/or delays. The investments that have been necessary to achieve this have been minor compared to the potential cost of the delay that would have resulted from the lack of information without such a system.

# Impact of the soil-stabilization with lime

## Impact de la stabilisation des sols à la chaux

Szendefy J.  
BUTE, Budapest, Hungary

**ABSTRACT:** The protection of environment and economical consideration demands giving the usage of internal soils preference over external materials. Soil-stabilization with lime increase the bearing capacity and treats the properties of cohesive soils due to chemical reactions. During a soil-stabilization with lime, the  $\text{Ca}^{2+}$  ions introduced into the soil attach to the surface of the clay particles, replacing the cations located there previously. Due to the high charging of the  $\text{Ca}^{2+}$  ions, the clay particles coagulate. The coagulation exerts a decisive effect on the soil structure, resulting the plasticity index in a shifting towards a certain zone. This effect leads to the elimination of the silt and clay particles, resulting in an intensive reduction surface of the particle of the stabilizations. Due to the coagulating particles, the friction angle increases, and also the value of cohesion becomes higher. The addition of lime results consequently in a growth of the compression strength of the soil, leading to an increased load bearing capacity. In order to define the internal friction angle ( $\Phi$ ) and the cohesion ( $c$ ), triaxial compression test were done with ten different kind of soils. The soil-stabilization with lime were made with 2 %, 4 %, and 6% additional lime, the temporal aspect has been investigated in ages of 1, 7, and 28 days. In case of admixing an ideal quantity of lime, the soils are shifting towards the value of  $\Phi=40^\circ$ . The extent of growth of the cohesion did not show as clear tendency as the friction angle, but give back a significant increasing. Contrary to the literature, I regard to remark that the positive impacts of soil-stabilization with lime is basically a result of the cation exchange, while the puzzolan reaction playing only a secondary role. It is also important to remark that the lime stabilization of soils is not only suitable for the drying up of soaked soils. With the application of a planned and properly executed stabilization, load bearing capacity of ballast materials can be achieved with local soils regarded or qualified as unsuitable. Accordingly, the ballast and pavement layers can be effectively reduced, and the quantity of delivered external materials minimized.

**RÉSUMÉ :** Les considérations environnementales et économiques font préférer l'utilisation des matériaux locaux aux matériaux extérieurs transportés sur place. Avec ses processus chimiques, la stabilisation des sols à la chaux permet une augmentation de la portance des sols argileux et une amélioration de leurs propriétés. Lors des processus de stabilisation, les ions  $\text{Ca}^{2+}$  remplacent les cations qui s'attachent à la surface des grains d'argile. Les grains d'argile s'agglomèrent à cause de la haute charge des ions  $\text{Ca}^{2+}$ . L'agglomération provoque un changement important dans la structure du sol et, en conséquence, l'indice de plasticité du sol se décale vers une certaine zone. Cet effet élimine les grains d'argile et de limon diminuant ainsi radicalement la surface des grains du sol stabilisé. À cause de l'agglomération des grains, les valeurs de l'angle de frottement interne et de la cohésion augmentent. En ajoutant de la chaux, la compressibilité des sols diminue, en conséquence la portance des sols augmente. Afin d'établir le changement des valeurs de l'angle de frottement interne ( $\Phi$ ) et de la cohésion ( $c$ ) nous avons effectué des essais triaxiaux sur différents sols. Nous avons stabilisé les sols en ajoutant 2%, 4% et 6% de chaux et nous avons mesuré l'effet du temps avec des essais effectués à l'âge de 1 jour, 7 jours et 28 jours. Dans le cas d'une addition de quantité optimale de chaux la valeur de l'angle de frottement interne est de  $40^\circ$ . Dans le cas de la cohésion, il a été impossible de démontrer une tendance, mais une augmentation importante a pu être observée dans tous les cas. Contrairement à la bibliographie technique sur les essais lors de la stabilisation des sols à la chaux, l'agglomération causée par l'échange de cations a un rôle dominant, tandis que les réactions pouzzolanes ont plutôt un rôle secondaire. Il est important de souligner également que la stabilisation des sols à la chaux n'a pas pour seule application le séchage des sols mouillés ou humidifiés. En utilisant une formule bien établie, une portance équivalente au gravier peut être atteinte avec les sols locaux, ainsi les sols locaux qualifiés de non-utilisables peuvent être finalement convenables pour la construction routière. En conséquence l'épaisseur de l'assises de chaussée et celle de la structure de la chaussée peuvent être diminuées efficacement, et la quantité des matériaux extérieurs transportés peut être minimisée.

**KEYWORDS:** soil stabilization with lime, cation exchange, bearing capacity

### 1 INTRODUCTION

The road vehicle and railway traffic are increasing worldwide that require a permanent extension of the infrastructure. In addition to the extension, the high load bearing and economical operation are required in new infrastructure and rehabilitation investments. To satisfy the above demands, the expectation towards pavements, bedding and subsoil is increasing continuously. Similar tendencies can also be experienced at industrial and commercial buildings e.g. their industrial floors, service-roads and parking area.

According to the Hungarian code (ÚT 2-1-222-2002), the above high requirements can essentially be satisfied by granular

soils; the application of transient and cohesive soils are limited. Another argument prevailing against the use of locally transient and cohesive soils is the fact that their characteristics are extraordinarily influenced by rainfall: their workability is decreasing rapidly and their load bearing capacity becomes practically zero. Consequently, they may upset a strict time schedule due to the drastically abbreviated execution times, so their application result significant risks.

The omission of local materials and the delivery and use of extraneous ones arises questions related not only to costs but also to environment protection and to the preservation of national property. The excavation of extraneous materials cause

damages on nature, and the transportation of thousands and millions m<sup>3</sup> of materials to infrastructure and industrial plants also results considerable load to the environment. Beyond the above effects, this significant transportation also abrades, damages and amortizes the already existing infrastructure.

## 2 GENERALLY ABOUT THE SOIL-STABILIZATION WITH LIME

The soil-stabilization with lime is a successful and widespread procedure for several decades in the USA and Western Europe, while this technology is applied in Hungary and in the neighboring countries only for the drying of sodden earthworks. The research work was performed with Hungarian soils, with the aim of supporting the work of designers and contractors to use local soils as high bearing capacity layer and to reduce the thickness of bedding and floors.

Mainly cohesive soils are used to be stabilized with lime, however transient and clayey silty gravely soils can be stabilized satisfactory based on my research. Therefore I modified a figure of a generally used literature (Mitchell & Hooper, 1961.) about the types of suitable soils for stabilization with lime with the modern machineries.

My suggestion based on my laboratory tests and field experience is shown in red in Figure 1.

The stabilized layer can be built of materials mixed in situ or at a distant site, however the soil is generally not moved but worked in at the location of its original place, transforming it into a layer of sufficient load bearing capacity. Bedding and pavement layers are built on to the stabilized layer to achieve the full layer system of a road, runway or industrial floor. However in case of roads exposed to a lower traffic, forestry or agriculture roads, the stabilized layer may also used as pavement.

During the construction of the stabilized layer, the required quantity of lime is spread over the previously executed surface by a truck provided with a dosing head. The quantity of the lime is 8-60 kg/m<sup>2</sup> depending on the thickness of stabilization and on the type of soil. Subsequently the soil is mixed with the lime by a remix machine. In case the process of stabilization requires water, the modern remix machinery is able to add water through the mixing head. Following mixing, the layer is compacted, and the required ground level provided.

The lime improves the soil characteristics through chemical reactions. Chemical reactions start with the mixing and may take several decades. The chemical reactions during the soil stabilization with lime are as follows:

- dissolution of the lime – reduction of the water content;
- cation exchange-coagulation;
- puzzolan reaction-cementation;
- carbonatization – development of limestone.

Figure 1. Delimitation of grain size distribution areas from the point of view of soil-stabilization with lime (Kézdi, 1967., Szendefy, 2008.)

## 3 DELINEATION OF MY RESEARCH

During the research 21 soils were measured in the laboratory of Budapest University of Technology and Economics. The origin soil properties of the measured soils are listed in the Table 1. For the verification of the laboratory tests some in-situ stabilization were analyzed as well.

Figure 2. Red spots show the origin of the soils for laboratory measurements, blue spots show in-situ bearing measurements

After the literature 2, 4, 6% quick lime was added for the soils. The quantity of the lime is the percent of the dried soil. Some measurements was done with hydrate lime as well, but the final determinations are given in quick lime, because it contains only the agent (CaO), which is the unit of necessary active agent

My laboratory and field work included soil mechanics parameters (plasticity, grain size, permeability, Proctor-test, swelling), bearing capacity measurements (triaxial compression test, CBR test, durability test) and geological tests (X-ray, derivatograph, pH).

The soils were dried to the laboratory air humidity, than were determined their moisture content and were determined the quantity of the added lime. The lime and the required water were mixed during 15 minutes than left it rest 45 minutes. After resting they were remixed and compacted with Proctor-machine. After compaction the mixtures were left for curing in waterproof package.

To measure the time effect of soil-stabilization with lime I made measurements 1 hour, 1 day, 3 days, 7 days, 14 days and 31 days after compaction.

I can show only a part of my research because the compass of the article.

## 4 ALTERATION OF THE SOIL STRUCTURE

The clue of soil-stabilization with lime is an alteration of the structure of soil caused by lime. Through the admission of lime, the cohesive soils become crumbly, characterized by a reduced plasticity.

### 4.1. Alteration of plasticity

Several researchers pointed out that the plasticity index of soils decreases even if a very low quantity of lime is added (Wang, 1963., Jan, & Walker, 1963., Kézdi, 1967., Nemesdy, 1983.)

They explain the reduction of the plasticity index with a slight reduction of the liquid limit and with the drastic increase of the plastic limit.

As I saw the clue of stabilization in the alteration of the soil structure, I have performed experiments to find the exact mechanism of changes of the plasticity index, and processed literature data.

During the experiments, several soil types were tested (Ip = 6.4 - 69.2 %), admixing 2 % - 4 % - 6 % of lime at different ages.

Table 1. Origin soil physics parameters

Sign of soil	Plasticity index [%]	Grain size < 0.1mm [%]	Friction angle [°]	Cohesion [kPa]
T1	22,0	88,4	10.5	61.7
T2	18,5	76,6	22.4	88.3
T3	50,0	96,4	11.9	117
T4	12,3	87,6	25.6	72.9
T5	33,5	98,7	11.4	37.6
T6	61,5	99,3	18.2	123
T7	43,4	98,8	22.8	114.8
T8	22,9	90,5		
T9	-	36,8		
T10	69,2	99,5		
T11	34,4	94,1	26.9	124
T12	47,5	-		
T13	-	70,2		
T14	-	41,2		
T15	38,5	-	14.5	104.5
T16	34,8	92,8	20.9	82.5
T17	24,8	88,2		
T18	8,8	76,1		
T19	29,1	91,8		
T20	6,4	74,2		
T21	27,0	-		

The analysis of the results shows that the liquid limit ( $w_l$ ) is shifting towards the zone of  $w_l = 35 - 45$  %, irrespective of the initial values. The high values of the liquid limit decrease drastically, those situated near the zone practically stagnate, and a slight increase was experienced at the low liquid limit values. Similarly to the plastic limit ( $w_p$ ) a tendency of shifting towards a certain zone can be experienced, similarly to the behavior of the liquid limit. This zone is situated at  $w_p = 25 - 35$  %. The plastic limit is generally increasing, however in case of fat clays having high plasticity limit stagnation or decrease can be experienced.

The alteration of Atterberg-limits in the value of the plasticity index ( $I_p$ ) also leads to shifting towards a zone (Figure 3). The value of plasticity index is shifting to the zone delimited by  $I_p = 5 - 15$  %, corresponding to very fine sand and silt type soils, according to the description of the bound soils.

An investigation of the temporal aspects of the impact shows that the above tendencies appear during the first hour following mixing, however the most extreme alteration of the parameters could be measured appr. on day 7. The following period was characterized by stagnation, with slight shifts in case of certain soils toward the properties of an untreated soil.

#### 4.2. Alteration of the grain distribution

The process of increased crumbliness and the more granular soil experienced at the plasticity index were tried to be delimited by an investigation of the grain size distribution. During the grain size distribution test and hydrometration of soil samples treated

with lime, the soil particles settled very rapidly. The settling process took 5-15 minutes.

Figure 3. Alteration of the plasticity index plotted against lime dosage

This rapid sedimentation process produces the grain size distribution curve characterizing soils treated with lime. The section situated above hydrometration of the curve shows a picture identical with that of an untreated soil, plunging however at the section below 0.063 mm. The stabilized soils maintain this character later on, with the only difference that also the proportion of particles of above 0.063 mm becomes slightly higher. These alterations are visualized in Figure 4.

As was suspected this intensive coagulation that is not characteristic for the hydrometration of soils of natural stratification is triggered by the cation exchange taking place during lime stabilization. In order to prove it, the hydrometration was performed with a 15 months old sample, by means of admixing a significant quantity of dispersive material (sodium hexametaphosphate) to the mixture prepared in the measuring glass. During the test, a long lasting, continuous precipitation could be experienced as usual for natural soils. The obtained curve of grain size distribution is indicated in Figure 4 in purple color, showing a high conformity with the curve of an untreated soil.

Figure 4. Alteration of the grain size distribution caused by a lime treatment of medium clay soil

It can be observed with the lapse of time that the more frequent presence of particles of above 0.063 mm of particle diameter can be explained with two other chemical processes of the lime stabilization: the cementation and carbonatization. The investigation of particles of above 0.063 mm by means of microscope and X-ray diffraction demonstrated the presence of aluminates and silicates leading to cementation, together with carbonatized limestone particles.

The results obtained from the investigation of plasticity and the grain size distribution show that the particles of a treated soil coagulate, cohere, resulting from the cation exchange. This coagulation creates a strong connection between the soil particles that cannot be dissolved by water, rendering it durable in the soil.

The coagulation is able to eliminate one of the biggest disadvantages of bound soils, i.e. the relatively high particle surface binding high quantities of water. The high level of water intake reduces namely the shearing strength and consequently the load bearing capacity of the soils.

## 5 ALTERATION OF THE LOAD BEARING CAPACITY OF THE SOIL

Drying and working in soils are facilitated by the addition of lime which is very important to constructors. Therewith the important to designers is an intensive increase of the load bearing capacity based on the effect of lime exerted on the soil structure. The load bearing capacity of soils is determined by their parameters related to shearing strength and deformation.

### 4.3. Alteration of the parameters related to shearing strength

In order to define the internal friction angle ( $\Phi$ ) and the cohesion ( $c$ ), I have performed triaxial compression test over a long range of the above mentioned soils. Similarly to the previous procedures added lime was 2 %, 4 %, and 6 %, the temporal aspect has been investigated in ages of 1, 7, and 31 days.

The evaluation of the measurement results shows a growth of the values of friction angle and cohesion. At the 1 day old samples the growth showed a fully disordered picture, then the alteration of value „ $\Phi$ ” shift towards a single zone as the boundaries of consistency at the age of 31 days. In case of admixing an ideal quantity of lime, the soils are shifting towards the value of  $\Phi=40^\circ$ . A growth can also be measured at lower lime quantities, however its extent does not reach the value of  $40^\circ$  that can be regarded as maximum, while the addition of an excessive lime quantity results in a stagnation or decrease. The curve fitted to the measurement results is visualized in Figure 5.

Figure 5. Increase of the friction angle at an age of 28 days, plotted against the quantity of lime

The equation of the fitted curve based on 10 different soil can be expressed with the following function:

$$\Phi = -0,589 M^2 + 7,07 M + 18,9 \quad (1)$$

where

$\Phi$  - internal friction angle

$M$  - added lime quantity

With the use of the function, the fitting to the points could be expressed with the value of  $R^2=0.77$ .

The function does not work at  $M=0\%$  and it is limited to  $M=8\%$ , which is the rationality quantity of added quick lime.

The extent of growth of the cohesion did not show a consistency similar to the previous one. The improvement amounted generally to several hundreds of per cent, with 150 % experienced in the worst case (Figure 6).

The above demonstrated alterations of the shearing parameters have been measured at an age of 28 days, when only the impact of the cation exchange prevailed to a significant extent among the chemical processes taking place during stabilization.

Further alterations triggered by the puzzolan reaction have been tested on a sample taken at an age of 15 months. According to the results of measurement, no changes could be experienced at the friction angle of the stabilization, it maintained its value of  $\Phi=40^\circ$ , however the value of the cohesion increased to  $c = 787$  kPa, from the value of  $c = 343$  kPa measured at an age of 28 days. The alteration of the shearing parameters clearly demonstrates the cementation effect of the puzzolan reaction.

Figure 6. Increase of the cohesion at an age of 28 days, plotted against lime quantity

## 6 CONCLUSIONS

During a soil stabilization with lime, the  $\text{Ca}^{2+}$  ions introduced into the soil attach to the surface of the clay particles, replacing the cations located there previously. Due to the high charging of the  $\text{Ca}^{2+}$  ions, the clay particles coagulate. The coagulation exerts a decisive effect on the soil structure, resulting the plasticity index in a shifting towards a certain zone. This effect leads to the elimination of the silt and clay particles, resulting in an intensive reduction surface of the particle of the stabilizations.

Due to the coagulating particles, the friction angle increases, and also the value of cohesion becomes higher. The addition of lime results consequently in a growth of the compression strength of the soil, leading to an increased load bearing capacity.

Contrary to the literature, I regard to remark that the positive impacts of lime stabilization of the soil is basically a result of the cation exchange, while the puzzolan reaction playing only a secondary role.

It is also important to remark that the lime stabilization of soils is not only suitable for the drying up of soaked soils. With the application of a planned and properly executed stabilization, load bearing capacity of ballast materials can be achieved with local soils regarded or qualified as unsuitable. Accordingly, the ballast and pavement layers can be effectively reduced, and the quantity of delivered external materials minimized.

# Etude paramétrique en laboratoire du matériau Deep Soil-Mixing

## Laboratory parametric study of the Deep Mixing material

Szymkiewicz F., Le Kouby A., Reiffsteck P., Mosadegh A., Tacita J.-L.  
IFSTTAR, boulevard Newton, Champs-sur-Marne, F-77447 Marne la Vallée Cedex 2

**RÉSUMÉ :** Le Deep Soil-Mixing consiste à mélanger mécaniquement un liant hydraulique avec le sol en place en vue d'améliorer ses propriétés mécaniques. En France, de nouvelles exigences concernant la méthode et le matériau sont apparues à mesure que son champ d'applications s'est étendu. Dans cette communication, le travail de recherche entrepris à l'IFSTTAR est présenté. Il a consisté à mener en laboratoire une étude paramétrique, en réalisant des mélanges dits "de référence". Trois sables et cinq sols fins ont été traités (à l'état pur ou mélangés entre eux) en faisant varier à chaque fois les quantités de ciment et d'eau, afin d'observer l'influence de la granulométrie, de l'argilosité et de la quantité d'eau présente dans le mélange sur la résistance. Les retombées de ce travail sont la proposition d'abaques reliant la résistance au dosage en ciment et au rapport C/E, et des formules permettant pour les sols grenus de prédire la résistance à 28 jours en fonction du pourcentage de fines dans le sol et du dosage en ciment.

**ABSTRACT:** The Soil-Mixing consists in mixing a hydraulic binder into the soil mechanically in order to improve its mechanical properties. In France, these new applications imply new requirements on the method as well as on the material. In this paper, the research work undertaken at IFSTTAR is presented: it consisted in carrying out a parametric study on reference mixtures. Three sands and five fine soils were treated with different cement and water contents to observe the influence of particle size, clay content and the amount of water present in the mixture on its strength. Benefits of this work is the proposal of abaci connecting the strength of the material to its cement content and cement / water ratio (C / E), and formulas allowing the prediction, for granular soils, of the strength of the material at 7 and 28 days depending on the percentage of fines in the soil and on the cement content.

**MOTS-CLÉS:** Deep Mixing, sol, ciment, résistance, compression simple, abaque.

**KEYWORDS:** Deep Mixing, soil, cement, strength, unconfined compression, abacus.

## 1 INTRODUCTION

La méthode du Deep Mixing présente de nombreux avantages (respect de l'environnement, exécution facile et rapide ainsi que coût faible) qui ont grandement contribué à étendre son domaine d'applications (amélioration des sols, confinement des pollutions et réalisation d'éléments structurels). Ces nouvelles applications nécessitent une meilleure compréhension de la méthode et du matériau. Les caractéristiques du matériau Deep Mixing (en particulier l'homogénéité et la continuité) sont de plus en plus étudiées, au fur et à mesure que le domaine d'application s'agrandit. De même, des méthodes de prédiction de la résistance du matériau sont en cours de développement.

Babasaki et al. (1996) citent quatre facteurs qui influencent la croissance de la résistance du matériau: les caractéristiques du liant, la nature et l'état du sol rencontré, le malaxage et les conditions de cure. Porbaha et al. (2000) affirment qu'il est communément admis que la résistance du sol traité au ciment augmente avec le temps, de la même façon qu'un béton. De nombreuses études ont été menées pour proposer des formules en ce qui concerne la prédiction de la résistance du matériau. Bruce (2001) et Topolnicki (2004) ont proposé des relations générales reliant le gain de résistance à la nature du sol à traiter, ainsi que des plages de résistances atteignables pour ces mêmes sols après 28 jours de cure. En outre, des formules ont été proposées pour prédire la résistance du matériau à partir d'un ou plusieurs facteurs énoncés par Babasaki et al. (1996). Pour les bétons, des lois portant sur le développement de la résistance et dépendant uniquement du rapport ciment sur eau du mélange étudié ont été établies. Ces lois ont été testées sur le Soil-Mixing, mais se sont avérées inadéquates.

Mais d'autres formules ont été proposées, en tenant compte du ciment, de l'eau et / ou du contenu en fines du sol traité. Cependant, il n'existe toujours pas de formule largement applicable pour estimer la résistance du matériau et intégrant tous les facteurs qui devraient être pris en compte (CDIT, 2002), car au jour d'aujourd'hui, aucune norme internationale n'existe pour la préparation des échantillons de sol traités en laboratoire (Kitazume et al., 2009). De plus, certaines formules ne peuvent être appliquées qu'à un site particulier, tandis que d'autres ne peuvent être appliquées qu'à certains sols.

Cet article présente les résultats d'une étude paramétrique exhaustive ayant mis l'accent sur la résistance du matériau Deep Mixing. Des relations liant la résistance aux paramètres du Deep Mixing ainsi qu'un abaque pouvant servir au dimensionnement d'ouvrages sont proposées.

## 2 PROGRAMME EXPERIMENTAL

### 2.1 Matériaux

Les sols testés au cours de cette étude vont des sables purs aux argiles pures, avec des limons et des sols artificiels reconstitués à partir de sable de Fontainebleau mélangé avec de l'argile ou du Silica Flour, afin de permettre l'étude de l'impact de la nature et de la quantité des fines sur la résistance du matériau Deep Mixing. Le tableau 1 présente les principales caractéristiques des sols testés.

Tableau 1. Principales caractéristiques granulométriques et valeurs au bleu de méthylène (VBS) des sols utilisés

Soils	d <sub>60</sub> (mm)	d <sub>30</sub> (mm)	d <sub>10</sub> (mm)	Percent passing 2 mm	Percent passing 80 µm	Percent passing 2 µm	VBS
Fontainebleau sand (SF)	0,22	0,18	0,15	100	0,1	0	0,01
Triel sand	0,38	0,23	0,13	89,2	2,33	0	0,1
Fréjus sand	0,5	0,23	0,07	94,25	11,8	0	0,2
Silica Flour (SilicaF)	0,028	0,011	0,004	100	95,2	≈ 5	0,14

Les sols artificiels sont nommés par l'abréviation citée entre parenthèses dans le tableau 1 : par exemple, un sol artificiel fait de 75% de sable de Fontainebleau et 25% de kaolinite Soka sera nommé SF75-kaoS25. Plus de détails sur tous ces sols peuvent être trouvés dans Szymkiewicz (2011).

Le ciment utilisé pour ce programme expérimental est un ciment de haut fourneau contenant au moins 85% de laitier de haut fourneau, avec le reste de clinker Portland et un peu de gypse (Classement Européen: "HRC" CEM III / C 32,5 N CE PM-ES NF). Ce ciment présente une résistance à développement lent, et son temps de prise initial est de 4 heures après hydratation.

## 2.2 Malaxage, coulage et conservation

Les sols ont été traités avec des teneurs en ciment diverses allant de 70 à 400 kg/m<sup>3</sup>, couvrant ainsi toute la gamme usuelle de dosages des applications Deep Mixing. Sol et ciment ont d'abord été soigneusement mélangés à sec et manuellement, afin d'obtenir une consistance uniforme. Ils sont mis dans le malaxeur et l'eau est ajoutée. La teneur en eau du mélange ( $w_i$ ) a été choisie afin d'obtenir un matériau auto-plaçant, ce qui signifie qu'il doit être suffisamment fluide pour s'écouler sous son propre poids. Ainsi,  $w_i$  doit être au moins égale à la limite de liquidité du mélange (Szymkiewicz et al., 2012 b).

Le matériau est ensuite malaxé pendant 5 minutes pour les sols non cohérents et pendant 10 minutes pour les sols cohérents. Le mélange est ensuite coulé dans des moules cylindriques de 52 mm de diamètre, et, pour éviter les bulles d'air dans les échantillons, piqué et vibré.

Les moules sont ensuite bouchés et scellés dans un sac hermétique contenant une humidité relative élevée. Ceux-ci sont conservés à une température de  $20 \pm 3$  ° C jusqu'à la date d'essai (7, 14, 21, 28, 56 et 90 jours).

Le test de compression simple a été choisi principalement pour sa fiabilité et son utilisation internationale. La charge verticale statique a été appliquée à une vitesse constante de 0,3 mm min<sup>-1</sup>. Le déplacement axial externe a été mesuré à l'aide d'un LVDT. Plus de détails peuvent être trouvés dans Szymkiewicz et al. (2012 a).

## 2.3 Représentativité des résultats

De nombreux essais sur tout type de sol ont été effectués, afin d'évaluer la répétitivité, reproductibilité et la répétabilité des résultats (figure 1). La figure 1a montre que la méthode de réalisation des éprouvettes et leurs conditions de cure assurent une bonne répétitivité et reproductibilité des résultats, puisque deux mélanges (Fontainebleau C 265 et C 320) ont été répétés en suivant exactement la même procédure, le lendemain, par le même opérateur (Fontainebleau C 320) et par un autre opérateur

(Fontainebleau C 265). La figure 1b montre que la répétitivité des tests est assurée: le coefficient de variation est égal à 7% pour le Puy du Argile, et égale à 9,3% pour les sols sableux.

Figure 1. Représentativité des résultats : répétibilité et reproductibilité (a) et répétitivité (b).

## 3 RÉSULTATS ET ANALYSES

### 3.1 Effet du ciment et des fines sur la résistance des sols granulaires non plastiques

Consoli et al. (2010) ont proposé une fonction puissance (Eq. 1) comme étant la plus adaptée à la relation expérimentale entre la résistance à la compression simple ( $q_u$ ) et le dosage en ciment (C).

$$q_u = a \times C^b \quad (1)$$

où  $a$  est un paramètre exprimé en kPa et  $b$  un paramètre sans dimension. Les deux sont des paramètres expérimentaux.

Szymkiewicz et al. (2012 a) ont observé la même relation pour différents sols reconstitués ou naturels et non plastiques. Ils ont également observé que les paramètres expérimentaux  $a$  et  $b$  sont fonction (au bout de sept jours de cure) du paramètre  $C_{63}$ , qui représente le pourcentage de fines dans le sol. Ainsi, ils ont

proposé une formule (Eq. 2) permettant de prédire la résistance du matériau Deep Mixing constitué d'un sol non plastique et de ciment, connaissant le  $C_{63}$  du sol, le dosage cible en ciment  $C$  (%), et les teneurs en eau initiale et finale  $w_i$  et  $w_f$  du matériau. Comme les résultats in situ et obtenus en laboratoire sont très comparables dans le cas de sols granulaires, une telle formule peut être utilisée directement pour des applications sur site.

$$q_{u28} = \frac{w_f}{w_i} \times 64.032 \times C^{1.777-0.171 \ln C_{63}} \times C_{63}^{0.544} \quad (2)$$

### 3.2 Effet du ciment, de l'eau et des fines sur la résistance des sols plastiques

Pour les sols cohérents (c'est-à-dire argileux ou limoneux), cependant, il n'est pas si simple d'analyser l'influence du ciment et des fines.

Tout d'abord, alors que la teneur en eau nécessaire pour obtenir un matériau auto-plaçant ne varie pas beaucoup dans le cas des sols strictement non plastiques (puisque les particules de sol sont inertes à l'eau), celle-ci est très variable lorsque des particules d'argile sont présentes dans le sol. D'autre part, le domaine optimal d'ouvrabilité du matériau Deep Mixing (défini par Szymkiewicz et al. (2012) comme la teneur en eau comprise entre les limites de liquidité et de floculation du sol traité (figure 2a)) est très faible dans le cas d'un sol non plastique, tandis qu'au contraire pour les sols traités plastiques, il peut être très important. En outre, le domaine d'ouvrabilité des sols évolue en fonction de la quantité de ciment ajoutée et le type de sol rencontré.

Figure 2. Représentation du domaine d'ouvrabilité (a) et détermination de la teneur en eau optimale (b) du matériau Deep Mixing.

Enfin, des essais sur éprouvettes ayant 28 jours ont également montré l'existence d'une teneur en eau optimale, indépendante de la teneur en ciment du mélange, mais fonction de l'indice de plasticité du sol d'origine (figure 2b). Par conséquent, il est presque impossible de dissocier le dosage en ciment de l'eau lors de l'étude des sols plastiques traités au ciment.

De plus, les sols plastiques présentent une cohésion qu'il est très important de prendre en compte, puisqu'elle apporte un gain de résistance supplémentaire. Pour déterminer l'effet de cette cohésion, des sols constitués de sable et de particules fines non plastiques d'une part, et de sable et de particules fines

plastiques d'autre part, en différentes proportions, ont été traités, à différents dosages en ciment. Les résultats ont montré que, pour un dosage en ciment constant, les sols traités faits de sable à 75% et de particules fines à 25% sont plus résistants que les sols purs traités. Ceci peut s'expliquer en partie par une optimisation de la distribution granulométrique, ce qui augmente la densité du matériau. Cependant, les particules plastiques participent aussi à l'augmentation de la résistance du matériau, via un apport de cohésion non drainée supplémentaire. Les résultats ont montré que cette résistance supplémentaire due à cette cohésion diminue avec l'augmentation de la teneur en ciment. Entre 210 et 320 kg/m<sup>3</sup> de ciment, les particules d'argile cessent d'avoir un effet bénéfique sur la résistance et peuvent commencer à être considérées comme un agent polluant.

Néanmoins, la fonction reliant la résistance au ciment pour les sols plastiques peut encore être exprimée comme une fonction puissance : le paramètre  $b$ , défini précédemment, diminue à mesure que le pourcentage de fines dans le sol augmente (comme pour un sol non plastique, d'ailleurs) jusqu'à ce qu'il atteigne 1. Ensuite, la relation devient linéaire (Eq. 3), de la forme :

$$q_u = c + a \times C^b \quad (3)$$

avec  $b$  toujours égal à 1, et  $a$  et  $c$  des paramètres expérimentaux exprimés en kPa.

Les paramètres  $c$  et  $a$  varient en fonction de la nature du sol (figure 3a), de même qu'en fonction du temps de cure. Cependant, aucune relation logique ne peut être proposée. La teneur en eau initiale du matériau semble quant à elle n'influencer que le paramètre  $c$  (figure 3b).

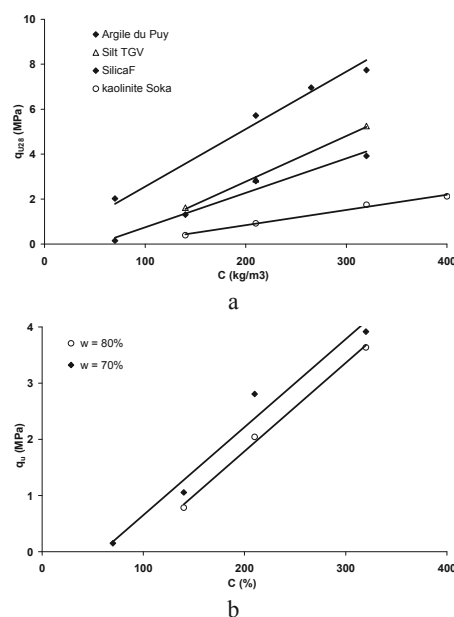

Figure 3. Relation résistance – dosage en ciment pour 4 sols plastiques (a) et pour un sol plastique à différentes teneurs en eau (b).

Dans le cas du Deep Mixing, où le matériau doit être suffisamment fluide pour être auto-plaçant,  $c$  est toujours nul ou négatif. Il existe donc un dosage seuil en ciment qui conditionne le succès du traitement au ciment d'une argile.

On voit bien qu'il est nécessaire de continuer les travaux en se focalisant sur les sols plastiques, puisqu'aucune formulation générale n'a encore pu être proposée qui permettrait de prédire la résistance du matériau.

Figure 4. Abaque résistance – dosage en ciment pour un matériau Deep Mixing auto-plaçant.

### 3.3 Proposition d'un abaque Résistance – Dosage en ciment

Au cours de cette étude, 57 mélanges à partir de 14 sols et 6 dosages en ciment différents ont été réalisés et testés à chaque âge. Un des objectifs de cette étude était la réalisation d'abaques afin d'aider les ingénieurs à déterminer le dosage en ciment nécessaire à la réalisation des travaux à partir de la résistance mécanique nécessaire du matériau. Ces 57 points peuvent donc être placés dans le plan  $C = f(R_{C28})$  pour obtenir un premier abaque (figure 4), qui n'intègre pas de manière précise l'influence de l'eau, mais en tient compte tout de même de manière générale, puisque les mélanges testés ont été réalisés à des teneurs en eau s'étalant de la limite de liquidité à la limite de floculation. Nous avons choisi comme résistance de référence la  $R_{C28}$ , ce qui est toujours très parlant pour les industriels car elle est la référence utilisée pour les bétons, et aussi car c'est la résistance la plus grande que nous puissions prédire pour les mélanges à base de sols grenus. Cet abaque a été validé en la confrontant à des résultats obtenus sur site par des entreprises françaises.

Six zones peuvent être clairement identifiées sur cet abaque : la première représente le domaine des sols très plastiques et des sols organiques. La seconde représente celui des sols moyennement ou peu plastiques, qu'ils soient argileux ou limoneux, tandis que les troisième et quatrième sont dédiées aux sables et graves. Les graves traitées n'ont pas pu être testées en laboratoire, du fait de la petite taille des éprouvettes, qui n'aurait pas assuré une bonne représentativité du matériau. Deux zones un peu particulières se détachent : ce sont les zones 5 et 6 qui sont des zones dites de transition. Elles représentent les résultats présentés au paragraphe 3.1.

## 4 CONCLUSION

Dans cette communication, le travail de recherche mené à l'IFSTTAR depuis plusieurs années, de concert avec les différents acteurs du Deep Mixing français, est présenté. Une relation (validée par des retours chantier et des éléments bibliographiques) est proposée, qui permet de prédire la résistance des sols non plastique traités au ciment selon la méthode du Deep Mixing, c'est-à-dire avec une teneur en eau initiale suffisante pour que le matériau créé soit auto-plaçant, en connaissant seulement la granulométrie du sol, le dosage cible en ciment, et la teneur en eau initiale du mélange (ce qui sous-entend que les paramètres d'exécution sont contrôlés tout au long du chantier).

L'étude montre que la transition d'un sol non plastique à un sol plastique se fait de manière logique, en gardant la même forme de relation entre la résistance finale et le dosage en ciment, même si la nature même des particules argileuse fait que l'eau

et le temps auront un impact beaucoup plus important sur les sols plastiques que sur les sols purement grenus. L'existence d'optimums, en ce qui concerne le couple teneur en eau – dosage en ciment, permet néanmoins d'affirmer qu'il sera bientôt possible de proposer une formulation générale, à un âge donné.

Un abaque, réalisé à partir de cette étude et validé grâce à des retours chantier, est proposé : il permet, de manière simple, de déterminer le dosage en ciment à utiliser afin de s'assurer de l'obtention de la résistance mécanique requise, en fonction de la nature du sol rencontré.

Les perspectives de ce travail sont donc la poursuite de l'étude des sols argileux traités, ainsi que le développement d'une méthode de dimensionnement des ouvrages en matériau Deep Mixing, en mettant l'accent sur l'étude de l'homogénéité du matériau sur site.

**ABSTRACT:** The paper includes discussions on the theory studies and numerical analysis as to stability of slopes reinforced with geotextile encapsulated with lenses of sand. In this study, given the laboratory research conducted on clay reinforced with geotextile encapsulated with lenses of sand, which showed in the high confining stresses due to the suitable interaction of clay and sand particles with geotextile, significant improvement is obtained in shear strength. Considering these results, based on the stability importance of slopes in the engineering projects and optimization, and increasing slopes stability, this technique is used as a reinforcement method in the clay slopes using various methods of reinforcement and the effect of various conditions such as the number of layers of reinforcement, confining pressures has been considered. In the study the numerical finite difference using software FLAC 2D has been applied. The results showed that the slopes with higher height the Sandwich technique to typical reinforcement with geotextile increases factor of stability safety under different studied scenarios because of improvement of intermediate behavior weakness by thin sand layers and the amount of factor of stability safety has been also enhanced, increasing the number of reinforcement layers.

**RÉSUMÉ :** Le document comprend des discussions sur les études théoriques et l'analyse numérique que les pentes stability of renforcés par des géotextiles encapsulés avec des lentilles de sable. Dans cette étude, compte tenu de la recherche en laboratoire menées sur de l'argile renforcée avec géotextile encapsulés avec des lentilles de sable, qui a montré dans les fortes contraintes de confinement en raison de l'interaction appropriée d'argile et de sable avec géotextile, une amélioration significative est obtenue dans la résistance au cisaillement. Compte tenu de ces résultats, basés sur l'importance de la stabilité des slopes in les projets d'ingénierie et d'optimisation, et d'augmenter la stabilité des pentes, cette technique est utilisée comme une méthode de renfort dans les pentes argileuses en utilisant diverses méthodes de renforcement et de l'effet de diverses conditions telles que le nombre de couches de renfort, des pressions de confinement a été pris en compte. Dans l'étude de la différence finie numérique à l'aide du logiciel FLAC 2D a été appliqué. Les résultats ont montré que les pentes à plus forte hauteur de la Technique du sandwich à renfort typique avec un facteur de sécurité augmente géotextile stabilité sous différents scénarios étudiés en raison de l'amélioration de la faiblesse comportement intermédiaire par des couches de sable fin et la quantité de facteur de sécurité de stabilité a été améliorée également, l'augmentation du nombre de couches de consolidation.

## 1 INTRODUCTION

In non-reinforced backfills are constructed using natural materials the constraints from poor materials used, methods and non-favorable environmental and geotechnical conditions on the project site created failures or adverse conditions in the backfill.

Intensity and scope of the failures may be increased to some extent that to impact the general and stability and complete servicing the intended project. In addition in some exceptional cases the project needs stimulate the engineers to consider construction of backfills with special dimensions in slope or height and stability against particular loadings such as earthquake. For example construction of road or rail backfills with more height or backfills with steep (in places due to limited land, the possibility of Transverse extension of backfill base missing) can be considered as specific items. In each of the above mentioned cases the Construction of reinforced backfills with particular materials is felt, to be able to bear external factors effects as well as to have suitable stability in environmental and geotechnical conditions.

In the last three decades, Geosynthetics is widely used with high tension resistance to the soil reinforcement in geotechnical engineering. Makes using thereinforces provides soil tension resistance in the soil and thus reduce lateral deformation of soil and increase overall stability of reinforced soil structures (Abiera, H.O. 1991).

In past decades, mostly the reinforced soil technique has been applied using coarse materials as backfill (Backfill materials). Recently, due to economic considerations, the backfill material with low quality and local access has been used successfully (Bergado et al. 2008). Although you need to determine the geotechnical properties for reinforcement elements and backfill materials to design reinforced soil system, but the mechanism of interaction of soil - reinforcement element, plays an important role.

To consider soil interaction mechanisms – reinforcement element, studies have been done using direct shear and tension tests by various researchers (Zhenggui Wang and Werner Richwien 2002).

In the reinforced clay Soil, the contact resistance is low and consequently, failure in interface occur prior to the reinforcement tension strength to the final extent. Thus, a large percentage of the tension strength of reinforcement not mobilized at failure and cannot be used (Jewell, R.A and Wroth, C.P. 1987).

Experimental results show that the shear stress around reinforcement is high and decreases rapidly with distance from its surface. Thus in the reinforced soil structures with low quality backfill material it is possible that a thin layer with granular material containing high resistance around the reinforcement will be used to control high shear stresses near the reinforce and in the interface (Ghiassian and Jahannia 2004). This method improves the stress transfer mechanism due to a

better interface properties which is called sandwich technique (sandwich technique), In fact, the basis of this method is to provide a thin layer of sand with high strength on both sides of Geotextile, in order to improve the shear strength and deformation behavior of the reinforced clay soil (Unikrishnan.N, Rajagopa.K and.Krishnaswamy,N.R. 2001).

1.1 Studies on clay reinforced

The Studies of Unikrishna et al. (2001) on the reinforced clay with lens of sand (sandwich technique) did show that adding sand improves reinforced soil strength properties. Sand lens thickness, humidity and type of geotextile was paid attention.

Abdi et al. (2009) during large-scale direct shear tests, studied the resistance improvement due to provide the thin layers of sand on either side of the geogrid (sandwich technique) in the clay and reported the results of the study as follows.

- given the Figure (1) one can understand that providing a thin layer of sand with high strength on both sides of reinforcer is very effective to improve plasticity and resistance of clay soils.

- using the buried geogrid system in the sand of fine granular soil (sandwich technique) increases the shear resistance impressively. The buried geogrid system in the sand is more effective on the internal friction of soil and less effective on the coefficient of cohesion.

Figure 1. The relationship between shear stress - shear displacement under confining stress 75 kPa with different thicknesses of sand layers. (Abdi et al., 2009)

Abdi and Arjmand (2011) carried out various experiments on the pullout test on reinforced clay with geogrid encapsulated with thin layers of sand. The Samples have been prepared at the optimum moisture content and maximum dry density weight which have been obtained from Standard density testing Proctor. One-way geogrids used with a sand layer, 6, 10 and 14 mm in thickness. Experimental results showed that the encapsulated geogrid in thin sandy layers increases reinforced clay pullout resistance under the pullout conditions. The results showed that the maximum resistance to pullout increased with confining pressure and the optimal thickness of layer of sand is the same for all normal stresses.

Studies of Tabarsa and Radmehr (2011) on the reinforced clay with lens of sand (sandwich technique) yielded the following results. According to this research the increasing reinforcement layers caused to increase ultimate strength. Also improved the recovery of samples increasing confining stress from 100 to 550 kPa and to confining stress 300 kPa the improvement trend increases and then decreases. (Figure 2)

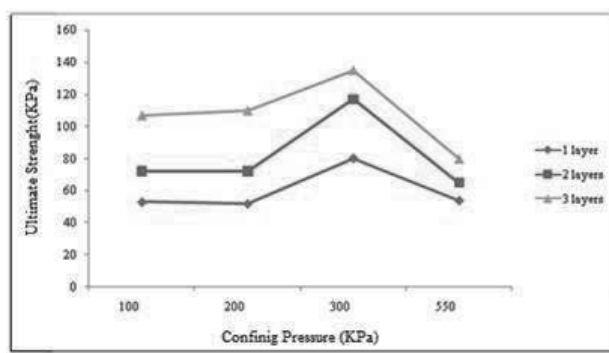

Figure 2. Effect of confining pressure on the reinforced sample, with geotextile and sand in 4 mm thick. (Tabarsa and Radmehr 2011)

Given the abovementioned forms it can be perceived that sample plasticity diminishes increasing the thickness of the layer of sand. Also, recovery percentage of resistance has increased slightly increasing the thickness of the sand in low confining stresses. And in high confining stresses (550 kPa) the high resistance percentage has increased significantly and therefore it can be stated that the high confining stresses impact on the sand performance in the composite system desired result is achieved. Because of the angle of high internal friction of the sand. The Results and research, suggest few studies on the subject of numerical simulation techniques for soil slopes stability analysis which the research has been done in this direction.

2 MODELING AND NUMERICAL ANALYSIS

FLAC software is based on the finite differential method. Finite differential methods used in various engineering issues. Its application in the soil and rock mechanics is common because one can model the big displacements and stresses of soil and rock masses. In the research FLAC 2D software has been used.

3 CHARACTERISTICS OF THE STUDIED MATERIALS

In this study, to analysis the slope stability, the behavioral models Mohr - Coulomb is used. Also nonwoven geotextile have been used for modeling the slopes.

Table 1. details the parameters considered in this study

soil	Density, kg/m <sup>3</sup>	Bulk module, kg/m <sup>2</sup>	Shear module, kg/m <sup>2</sup>	Dilation, degree	Cohesion, kg/m <sup>2</sup>	Angle of internal friction, degree
clay	2000	2E6	3E6	0	20000	15
sand	2000	3E7	4E7	15	2000	39

4 GEOMETRIC PROPERTIES OF SLOPES

In the analysis, four types of slope with different heights of 6, 9, 12 and 15 m with the same slope of 56 degrees have been considered. The method of geotextiles arrangement is shown in Figure 3 in the sandwich technique for the slope 12 meters.

Figure 3. slopes 12-meter, reinforced with sandwich technique

### 5 HOW TO MODEL

First defining the model geometry and then required parameters are considered for different scenarios of various materials.

Given the importance of the boundary conditions on the both sides the slope is anchored in the horizontal direction (x) and in downwardslope horizontal and vertical directions (x, y) are anchored. Then geotextiles with distances equal to 1.5 m with the same length have been modeled. And following given the characteristics of the geotextiles, the suitable interaction parameters are involved between soil and geotextile. Then thin layers of sand with equal 30 cm thickness are considered to simulate the effect of sandwich technique in reinforcement process on the border between the reinforcement element and the clay soil (geotextile), given the different distances between the layers.

### 6 THE RESULTS OF NUMERICAL MODELING

After modeling and static analysis using software it evaluates and compares the factor of stability safety in slopes for different heights and different modes of reinforcement as follows.

#### 6.1 Results of static analysis on slopes with different heights

According to the analysis results, finite differences of reinforced clay slopes are shown as 6, 9, 12, 15 m, factors of safety in different states of reinforcement as computed (figures 4 and 5) and includes three modes 1- clay Model (C), 2 - clay with geotextile (CG), 3 - Sandwich Technique (CGS)

According to the output of numerical modeling analysis and the results shown in the above graphs, adding layers of sand on both sides of geotextiles (sandwich technique) increases significantly factors of safety at different height (6, 9, 12, 15 m). In Figure 6 this technique has a greater impact on stability of clay slopes in above heights and further increases the factor of stability safety.

Figure 4. Comparison of factors of safety in 9 m slope

Figure 5. Comparison of factors of safety in 12 m slope for geotextile distances intervals in both 1 and 1.5 meter

Figure 6. Comparison factors of safety of slop different heights in various states of reinforcement

### 7 CONCLUSION

- Analyses showed that the sandwich technique is an effective method of stabilizing clay slopes for engineers and results of the numerical analysis carried out in vitro studies are consistent with the sandwich technique.

- Sandwich technique is used in clay soils where have the poor and weak interaction with the geotextiles.

- given the acceptable development of a factor of safety using the sandwich technique we can make or design slopes with more height and slope in the engineering projects.

- sandwich technique in the more heights has more impact in the factor of safety increase, because of confining pressure increase and consequently getting better interaction condition between sand and geotextile.

- The factor of stability safety will be increased, increasing number of reinforced layers in the sandwich technique.

## 8 ACKNOWLEDGEMENT

At the end we thank sincerely for cooperation of dear friends Mr. Amir Gharib and Mohsen Mosivand.

**ABSTRACT:** There exists a ground improvement technology that uses calcium carbonate precipitated from carbon dioxide generated by microbial metabolism and calcium sources in the pores of soil. It is known that the mechanical properties of the improved grounds correlate with the amount of calcium carbonate precipitation, but it is unclear how soil density influences calcium carbonate precipitation and the mechanical properties of the improved soil. Toyoura sand specimens of three relative densities are used to precipitate calcium carbonate through microbial metabolism. The injection-improved test and the triaxial test (consolidated-drained condition) are conducted to investigate calcium carbonate precipitation and the mechanical properties of the soil. The results show clearly that more calcium carbonate precipitation occurs in soil with lower relative density, but that in soil with higher relative density, the mechanical properties strengthen as calcium carbonate precipitation increases.

**RÉSUMÉ :** Dans la nature, il existe des micro-organismes qui capturent le dioxyde de carbone et les ions calcium présents dans la terre pour ensuite rejeter du carbonate de calcium. Ces dernières années, en s'appuyant sur le fonctionnement de ces micro-organismes, une technique renforçant la résistance du sol a été développée. Dans le cadre du développement d'une technologie qui renforce le sol à l'aide de métabolisme microbien, la présente étude a mis en évidence expérimentalement que l'influence de la densité relative du sol exerce un effet bénéfique. Tout d'abord, à travers une série de tests de cisaillement, le comportement au cisaillement du sol renforcé par le métabolisme de ces micro-organismes a été mis en avant. Ensuite, il s'est avéré que plus la densité relative du sol était petite, plus la quantité de carbonate de calcium déposée était importante. Cependant, nous avons aussi compris que plus la densité relative du sol était grande, plus les effets renforçant la résistance du sol étaient visibles.

**KEYWORDS:** micro-organism, ureolysis, soil improvement, mechanical properties, triaxial test, calcium carbonate

## 1 INTRODUCTION

To ensure the efficient maintenance of civil engineering structures, which is an issue, ground improvement technologies can be applied to reinforce existing structures. Ground improvement technology that uses calcium carbonate precipitated from carbon dioxide generated by microbial metabolism and calcium sources in the pores of soil is expected to be applicable to ground directly under existing structures because the viscosity of the injected grout is low (Wiffen et al. 2007). It is known that the mechanical properties of grounds improved through the use of this method correlate with the amount of calcium carbonate precipitation (Inagaki et al. 2011), but it is unclear how the relative density of the soil influences the precipitation and the mechanical properties of the improved soil.

In this study, we used *Sporosarcina pasteurii* (ATCC11859) to stimulate microbial metabolism via the following reactions. Our aim was to investigate the relationship between the soil's mechanical properties and calcium carbonate precipitation in three types of Toyoura sands that were compacted by microbial metabolism.

(Ureolysis)

(Calcium carbonate precipitation)

In the tests, microbial broth and a nutrient mixture were injected into the Toyoura sand specimens with three relative densities to improve compaction. In addition, we carried out a triaxial test (consolidated-drained [CD] condition) on the improved specimens. Then, we examined the influence of the relative density of the soil on calcium carbonate precipitation and the soil's mechanical properties.

## 2 TEST METHODS

### 2.1 Method for production of specimens

A half-split mold made of PVC, 15 cm in height and 5 cm in diameter, was used to create the specimens (Fig. 1 and Photo 1). Silicone grease was applied on the internal surface of the mold to prevent the generation of water paths along the wall. Toyoura sands having the physical properties listed in Table 1 were used to create the specimens, and the molds were filled with sand using the air-drop method. The specimens had a relative density of  $Dr = 15\%$  ( $\rho_d = 1.372 \text{ g/cm}^3$ ),  $Dr = 60\%$  ( $\rho_d = 1.504 \text{ g/cm}^3$ ), and  $Dr = 85\%$  ( $\rho_d = 1.589 \text{ g/cm}^3$ ). The specimens were checked for weight and density, fitted with a collar on top, and saturated with distilled water supplied from the bottom. The surface of the specimen of  $Dr = 15\%$  sank significantly during the hydraulic filling. This settlement was measured using vernier calipers, and it was confirmed that the relative density after hydraulic filling was about  $Dr = 30\%$ .

2.2 Curing method (nutrient injection process)

After saturation, 250 ml of microbial broth was injected into each specimen. The microbial broth was made by planting *Sporosarcina pasteurii* in the medium described in Table 2. After confirming that the broth had completely permeated the specimen, 200 ml of the nutrient mixture described in Table 3 was injected into the specimen at 12 h intervals for specified cycles.

Table 1. Physical properties of Toyoura sand

Soil particle density $\rho_s$ ( $g/cm^3$ )	Water content (%)	Max. grain diameter (mm)	50% diameter on the grain size diagram $D_{50}$ (mm)	Fine fraction content (%)	Max. dry density $\rho_{dmax}$ ( $g/cm^3$ )	Min. dry density $\rho_{dmin}$ ( $g/cm^3$ )	Soil suspension pH
2.623	0.0	0.425	0.177	0.6	1.645	1.333	6.3

Figure 1. Schematic diagram of the mold

Photo 1. Photo of the mold

Table 2. Composition of medium

Name of reagent	Added amount
0.13 M Tris (pH = 9)	0.13 mol = 15.75 g
Yeast extract	20 g
(NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	10 g
Distilled water	1 L

Table 3. Composition of nutrient mixture

Name of reagent	Added amount
Nutrient broth	3 g
NH <sub>4</sub> Cl	10 g
NaHCO <sub>3</sub>	2.12 g
Urea	0.5 mol = 30.03 g
CaCl <sub>2</sub>	0.5 mol = 55.49 g
Distilled water	1 L

The mold was cured in a room with a constant temperature set at 22°C. The nutrient mixture that had been injected previously and that remained in the pore was pushed out and drained to maintain the saturated state of the specimen in the mold.

Approximately 12 h after the specified cycles of nutrient injection were completed, 300 ml of distilled water was injected to wash away the nutrient mixture remaining in the pore.

As Table 4 shows, 15 specimens were made. The nutrient mixture was injected into these specimens at various frequencies in order to diversify the amount of CaCO<sub>3</sub> precipitation at each relative density. In addition, three specimens were only saturated with distilled water, and not injected with the broth and nutrient mixture, in order to examine the strength of the Toyoura sand itself.

Table 4. Test cases

Case	Specimen No.	Frequency of nutrient injection (Total injection amount ml)	Curing time (hours)	Initial dry density $\rho_d$ ( $g/cm^3$ )	Initial relative density Dr (%)	CaCO <sub>3</sub> Precipitation ( $kg/m^3$ )

2.3 Triaxial test method

Triaxial tests (CD condition) were conducted using the specimens produced by the method explained in 2.2. To reduce disturbance caused by the demolding/shaping of specimens, the specimens were frozen in the mold after the free water was removed. The specimens that featured high CaCO<sub>3</sub> precipitation were also frozen to equalize test conditions. The frozen specimens were removed from the molds and shaped to 10 cm in height and 5 cm in diameter. The shaped specimens were measured to check the diameter and height and then placed in a triaxial cell and defrosted under a negative pressure of 30 kPa. The defrosting time was set at about 1.5 h, which was the approximate time needed for stabilization of the axial displacement caused by contraction in the process of defrosting. We measured the diameter and the height of the defrosted specimens, covered them with a cell cover, and saturated them with degassed distilled water via the double-negative pressure method. The back pressure was increased to 200 kPa, and effective consolidation stresses of  $\sigma_c' = 100 \text{ kPa}$  were applied for isotropic consolidation. After consolidation, we confirmed that the  $B$  values in all the specimens were 0.95 or higher. Then, axial compression was performed at a strain rate of 0.5%/min. The axial force was measured by the load cell inside the cell, axial strain was measured by the displacement gauge outside the cell, cell pressure and back pressure were measured by the water pressure gauge, and the volume change was measured by the low-capacity differential pressure gauge.

After the triaxial tests were completed, the specimens were dried in a furnace and weighed, and the  $\text{CaCO}_3$  precipitation in each specimen was then obtained by measuring the decrease in mass resulting from  $\text{CaCO}_3$  decomposition by hydrochloric acid.

### 3 TEST RESULTS

#### 3.1 Relationship between the amount of nutrient mixture injected and the $\text{CaCO}_3$ precipitation

Figure 2 shows the relationship between the amount of nutrient mixture injected and the  $\text{CaCO}_3$  precipitation. The quantity of  $\text{CaCO}_3$  precipitation is given per unit volume of the test specimen.

The tendency for  $\text{CaCO}_3$  precipitation to increase as the injections of the nutrient mixture increased can be confirmed for each relative density. When the total injection of the nutrient mixture is less than 800 ml, the differences among specimens with different densities is unclear. When more than 800 ml of the nutrient mixture is injected, the differences among the specimens with different densities are observed. It is confirmed that lower the relative density, the more  $\text{CaCO}_3$  precipitates. This is because the low relative density increases the amount of microbes and nutrients absorbed by the test specimen.

Figure 2. Total amounts of nutrient mixture injected and  $\text{CaCO}_3$  precipitation

#### 3.2 Relationships among axial strain, principal stress difference, and volumetric strain

Figure 3 shows the principal stress difference–axial strain curves and volumetric strain–axial strain curves. Toyoura sands of each relative density saturated only with distilled water (unconsolidated) and those injected with 800 ml of the nutrient mixture and  $\text{CaCO}_3$  precipitation of 51.8–63.7  $\text{kg/m}^3$  are shown in Fig. 3. Photo 2 shows the solidified test specimen after shear.

It can be confirmed that the solidification caused by the  $\text{CaCO}_3$  precipitation leads to an increase in the maximum principal stress. In specimens with about the same  $\text{CaCO}_3$  precipitation, the higher relative density of the soil, the increase in the maximum principal stress difference is the greater. Strain softening behavior is observed when the principal stress difference reaches the maximum in the solidified test specimen. A residual state occurs when axial stress reaches 5% or more; then, the principal stress difference is constant at every relative density, and its value shows no difference at each relative density. It is thought that the principal stress difference becomes equality in the residual domain because the test specimen is sheared along the sliding surface. Photo 2 also shows a shearing plane along the sliding surface. The increase in the volumetric strain on the expansion side is confirmed clearly in the solidified test specimens when the axial strain is small at each relative density in comparison with the unconsolidated test specimens, and the ratio of increase becomes small around an axial strain over 5%.

Figure 3. Relationships among axial strain, principal stress difference, and volumetric strain ( $\sigma'_c = 100 \text{ kPa}$ )

Photo 2. Condition of the test specimen after shear

#### 3.3 Relationship between $\text{CaCO}_3$ precipitation and maximum principal stress difference

Figure 4 shows the relationship between  $\text{CaCO}_3$  precipitation and the maximum principal stress difference. There is no change in the maximum principal stress difference when  $\text{CaCO}_3$  precipitation is less than 30  $\text{kg/m}^3$  at each relative density. At precipitation levels greater than 30  $\text{kg/m}^3$ , the maximum principal stress difference increases monotonically depending on  $\text{CaCO}_3$  precipitation. The increase in strength is remarkable in test specimens have higher relative density but little  $\text{CaCO}_3$  precipitation. In the case of  $\text{Dr} = 85\%$ , in comparison with  $\text{Dr} = 30\%$  and  $\text{Dr} = 60\%$ , the maximum principal stress difference increases even as  $\text{CaCO}_3$  precipitation stays at the same level.

#### 3.4 Relationship between $\text{CaCO}_3$ precipitation and secant modulus

Figure 5 shows the relationship between  $\text{CaCO}_3$  precipitation and the secant modulus. The secant modulus was calculated from the principal stress difference at the axial strain of 0.4%. At each relative density, there is little change when  $\text{CaCO}_3$  precipitation is less than 30  $\text{kg/m}^3$ , however, when  $\text{CaCO}_3$  precipitation is more than 30  $\text{kg/m}^3$ , the secant modulus increases linearly according to the increase in  $\text{CaCO}_3$  precipitation.

Figure 4. Relationship between CaCO<sub>3</sub> precipitation and maximum principal stress difference

Figure 5. Relationship between CaCO<sub>3</sub> precipitation and secant modulus (axial strain 0.4%)

### 3.5 Relationship between CaCO<sub>3</sub> precipitation and axial strain at maximum principal stress difference

Figure 6 shows the relationship between CaCO<sub>3</sub> precipitation and axial strain at the maximum principal stress difference. For each relative density, when CaCO<sub>3</sub> precipitation is less than 60 kg/m<sup>3</sup>, the axial strain at the maximum principal stress difference increases linearly according to the increase in precipitation. When CaCO<sub>3</sub> precipitation is more than 60 kg/m<sup>3</sup>, the axial strain at the maximum principal stress difference remains in the vicinity of 0.5% and shows no difference at each relative density.

Figure 6. Relationship between CaCO<sub>3</sub> precipitation and axial strain at maximum principal stress difference

### 3.6 Relationship between CaCO<sub>3</sub> precipitation and residual stress

Figure 7 shows the relationship between CaCO<sub>3</sub> precipitation and residual stress. The residual stress indicates the minimum principal stress difference, less than axial strain 15%, after the maximum principal stress difference.

There is little change in the residual stress at each relative density up to about 30 kg/m<sup>3</sup> of CaCO<sub>3</sub> precipitation in

comparison with a case of no precipitation. It is confirmed that the residual stress increases as the CaCO<sub>3</sub> precipitation increases at precipitation levels of more than 30 kg/m<sup>3</sup>. The specimens for each relative density show no difference at CaCO<sub>3</sub> precipitation levels less than 60 kg/m<sup>3</sup>, and it is unclear whether a difference is observed at precipitation levels greater than 60kg/m<sup>3</sup>.

Figure 7. Relationship between CaCO<sub>3</sub> precipitation and residual stress

## 4 CONCLUSION

We investigated the influence of the relative density of soil on CaCO<sub>3</sub> precipitation by microbial metabolism and on the soil's mechanical properties. The results of our experiment are as follows:

- The CaCO<sub>3</sub> precipitation tends to increase as the relative density of the soil decreases.
- The maximum principal stress difference increased monotonically with the CaCO<sub>3</sub> precipitation at each relative density. The secant modulus increased linearly.
- The increase in the maximum principal stress difference was remarkable in soils with high relative density.
- The axial strain at the maximum principal stress difference decreased depending on CaCO<sub>3</sub> precipitation in specimens of all relative densities and became constant regardless of CaCO<sub>3</sub> precipitation when it approached 0.5%.
- The residual stress increased monotonically depending on CaCO<sub>3</sub> precipitation, but the differences among the relative densities are unclear.
- A meaningful difference is not seen in the mechanical properties of the soil among specimens with no precipitation and those with CaCO<sub>3</sub> precipitation up to 30 kg/m<sup>3</sup>.

These results indicate that when applying this injection solidification technique in the field, the density of the existing ground will affect the strength increase. Therefore, like a conventional compaction method used in construction, this method would require a combination examination beforehand in order to confirm extreme expression characteristics.

Because the axial strain at the maximum principal stress difference becomes constant regardless of density when CaCO<sub>3</sub> precipitation becomes constant, we suggest that the approximate strength of the soil can be estimated using the secant modulus.

We will investigate the influence of soil density on a permeability change attributable to solidification by microbe metabolism in the future.

**ABSTRACT:** Soils containing dispersed large particles (greater than # 4 sieve) form part of many engineered fills, glacial tills, debris flows, and residual soil deposits. Very little is known about the effect that the large particles have on the shear strength of the soil-large particles mixtures. In this study, the influence of the large particles on the shear strength of the mixtures was evaluated experimentally and numerically. The experimental analysis used direct shear tests on simulated granular materials containing large dispersed particles. The numerical analysis used the Discrete Element Method (DEM). The laboratory and the DEM simulation results indicated that the shear strength of the mixtures increased with the concentration ( $C_a$ ) of the simulated large particles in the mixtures. Also, this study established that the shear strength of the simulated granular materials with dispersed large particles,  $S_c$ , can be obtained if one uses the following relationship:  $S_c = S_m (1 + M C_a)$ . In this relationship,  $S_m$  is the shear strength of the simulated soil matrix in which the large particles are dispersed, and  $M$  is a constant that varied between 1 and 2 for the numerical and laboratory analyses.

**RÉSUMÉ :** Les sols contenant des particules dispersées de grande taille (supérieure à tamis # 4) constituent la majorité des remblais, argiles glacières à blocs, des coulées d'éboulis et des dépôts résiduels de sol utilisés dans la construction. Peu de travaux existent sur l'effet que les grosses particules ont sur la résistance au cisaillement des mélanges de particules de sol de grande taille. Dans cette étude, l'influence des grosses particules sur la résistance au cisaillement des mélanges a été évalué expérimentalement et numériquement. L'analyse expérimentale utilisée essais de cisaillement direct sur simulées matériaux granulaires contenant de grandes particules dispersées. L'analyse numérique utilisé la méthode des éléments discrets (DEM). Les essais en laboratoire et les résultats des simulations ont indiqué que la résistance au cisaillement des mélanges augmente avec la concentration ( $C_a$ ) des particules de grandes tailles simulées. En outre, cette étude a établi que la résistance au cisaillement des matériaux granulaires simulées avec des grosses particules dispersées,  $S_c$ , peut être obtenu si l'on utilise la relation suivante:  $S_c = S_m (1 + M C_a)$ . Dans cette relation,  $S_m$  c'est la résistance au cisaillement de la matrice du sol simulé dans lequel les grosses particules sont dispersées, et  $M$  est constante qui varie entre 1 et 2 pour les analyses numériques et de laboratoire.

**KEYWORDS:** granular mixtures, shear strength, laboratory tests, DEM analysis.

## 1 INTRODUCTION.

Materials forming part of natural slopes and engineered fills have a distinct structure, this consisting of a mixture of a soil matrix (sand) and large particles of gravel that are dispersed (fragments do not interact) in the soil matrix. The rock fragments are composed of materials larger than the No. 4 sieve (Magier and Ravina, 1982; Poesen and Lavee, 1994; Fragaszy et al. 1992; Budiman, et al., 1995 and Vallejo 1989, 2001) (Fig 1). Soil Mechanics has dealt mainly with the study of three main soil types: sands, silts, and clays. However, mixtures of soils such as those shown in Fig. 1 are more commonly found in nature and in earth construction projects than pure sands, silts and clays. Since the determination of the mechanical properties (i.e. shear strength) of mixtures such as those depicted in Fig. 1 has heretofore received scant attention, such an investigation is indeed called for. This study reports on the mechanisms involved with the shear strength of simulated granular materials with dispersed oversized particles.

## 2 LABORATORY TESTING PROGRAM

### 2.1 Equipment and simulated granular materials

For the purpose of understanding the mechanisms involved in the shear strength of granular materials with dispersed large particles an open face, two-dimensional direct shear apparatus.

Figure 1. Natural slope in Wisconsin made of a soil-rock mixture

was used (Fig. 2) This apparatus is called the Plane stress Direct Shear Apparatus (PSDSA) (Vallejo, 1991). The granular matrix will be simulated by a mixture of wooden sticks. Wooden sticks are strong and can be easily shaved into polygons as their cross sectional areas. These polygons resemble the profiles of actual

granular materials (Fig. 3). The wooden sticks forming the granular matrix will have 3 different average diameters. These will be equal of 6, 4, and 2.7 mm. Thus, the granular matrix as a whole will be made of sticks having an average diameter equal to 4.2 mm. The oversized large particles will be simulated by rough wooden circular cylinders with a diameter equal to 12 mm. The irregular sticks as well as the circular cylinders have a length equal to 25 mm. The mixture of wooden sticks and cylinders were placed inside two U forms that comprise the box in the Plane Stress Direct Shear apparatus (PSDSA) (Figs. 2 and 3). The area inside the two U forms is a square area with sides measuring 7.6 cm in length. The open face of the shear apparatus formed by the two U forms allows the recording of the changes taken place in the mixture during shearing. Two proving rings measure the normal and shear forces applied to the mixtures. Dial gauges measure the normal and shear displacements. The changes in fabric experienced by the mixture as well as the interaction between the granular matrix and the large particles during shear was recorded using digital photographs of the open face of the PSDSA .

Figure 2. The Plane Stress Direct Shear Apparatus (PSDSA) (Vallejo, 1991)

Figure 3. Simulated granular mixture in the PSDSA before shearing: (a) sample with no oversized particles, (b) sample with one oversized particle, (c) sample with two oversized particles.

### 2.2 Direct shear testing in the PSDSA

The simulated granular mixtures depicted in Fig. 3 were subjected to shear in the PSDSA. The shear testing of the mixtures were carried out using two normal stresses. These were equal to 99.6 and 199.3 kPa. The rate of shearing of the mixtures was equal to 2mm/min. Fig. 4 shows the shear stress versus the horizontal displacement relationships for the sample containing the matrix alone and the samples with one and two 12 mm in diameter cylinders representing the large particles (Fig.3).

Figure 4. Shear stress versus horizontal displacement for the samples tested in the PSDSA

The peak values of the shear stress plots of Fig. 4 have been used to plot the shear strength versus the area concentration of the large cylinders in the sample. This area concentration is equal to the cross sectional area of the large cylinders in the mixture divided by the area of the whole mixture (7.62 cm x 7.62 cm) (Fig. 3). The resulting plot is shown in Fig. 5. This figure shows that the shear strength of the mixture increases as the number of large cylinders increases in the mixture. An equation that represents this increase is of the form:

$$S_c = S_m (1 + 2C_a) \quad (1)$$

where  $S_c$  is the shear strength of the mixture,  $S_m$  is the shear strength of the matrix, and  $C_a$  is the area concentration of the large cylinders in the mixture. The results of Fig. 5 and Eq. (1) indicate that the overall shear strength of the simulated granular mixtures increases with an increase in the number of the large cylinders. Thus, in the case of real sand-gravel mixtures, it is expected that the shear strength of these mixtures will increase with the volume concentration of the gravel in the mixtures.

Figure 5. Shear strength of the simulated granular mixtures in function of the area concentration of the large cylinders in the mixture.

### 3 ANALYSIS OF THE LABORATORY RESULTS USING THE DISCRETE ELEMENT METHOD (DEM)

#### 3.1 Configuration of the samples

The PFC<sup>2D</sup> program produced by Itasca (Itasca Consulting Group Inc., 2002) was used for the simulation of the direct shear tests on granular material with dispersed oversized particles. The first step on the configuration of the sample was the construction of the shear box. The box had two sections each with a width of 6 cm and a height of 1.5 cm. The two sections were placed on top of each other and after the circular particles were generated inside the box, the gap between the two sections was maintained at 0.5 mm. The depth of the sample was assumed to be equal to 1 m. The shear and normal stiffness of the walls forming the box were set to  $1 \times 10^9$  N/m. The coefficient of friction between the circular particles and the walls was set to 0.7.

After the construction of the box, 1000 particles representing the granular matrix and having a diameter of 0.63 mm were generated inside the box. The density of the particles was set to  $2,500 \text{ kg/m}^3$ , their normal and shear stiffness were set to  $1 \times 10^8$  N/m. Their positions were randomly chosen by the program, having the limitation of no overlap between particles. A normal gravity field ( $9.8 \text{ cm/sec}^2$ ) was used during the simulation. In order to simulate the dispersed oversized particles, 52 particles of diameter equal to 0.63 mm were removed and replaced by an oversize particle measuring 5 mm. If an additional oversize particle was needed to be placed in the sample, the same number of smaller particles were removed and replaced by another large particle of 5 mm in diameter (Fig. 6). The tests were run under a constant normal compressive load equal to  $2 \times 10^4$  N. After the normal compressive force was applied to the sample, the shearing started by moving the upper section of the shear box to the left with a constant velocity of 0.44 mm/sec.

The tests ended when the horizontal displacement was equal to 5 mm. Also, using a subroutine available in the PFC<sup>2D</sup> code, one can obtain the value of the shear stress in function of the horizontal deformation. In this study, the peak shear resistance that was measured in the simulation represents the shear strength of the mixture.

Figure 6. Simulated samples using DEM that contained zero, one, and two large dispersed particles.

#### 3.2 Results of the simulations

The DEM simulations of the direct shear tests were carried out on mixtures having zero, one, and two oversized particles. Figs 7 shows typical DEM results for the samples with zero, one and three oversized particles. These figures show the force chains and their intensity (the thicker the force chains, the bigger are the force chain value, their maximum values are shown on top of the figures) for the samples with 3.5 mm of horizontal displacement.

An analysis of Fig. 7 indicates that the larger force chains which were compressive in nature were directed toward the large particles and were transmitted to them by the smaller surrounding particles. When the horizontal displacement in the simulated test reached a 3.5 mm value, the force chains were inclined at about 45 and 135 degrees with respect to the horizontal axis of the cross sectional area of the large particles. It is usually assumed that when samples of granular materials with oversized particles are subjected to either compressive or direct shear stress conditions, the smaller particles in the mixture distribute the loads uniformly around the perimeter of the bigger particles. This uniform load distribution produces low compressive stresses on the bigger particles which allows them to survive without breakage (Fragaszy et al., 1992). The results shown by Fig. 7 indicate that this is not the case. Under direct shear, the smaller particles concentrate on the oversized particles, large compressive forces that are exerted on a small section of the perimeter of the large particles. These high concentrated compressive forces exerted by the smaller particles

on the large particles have also been found by Cheng and Minh (2009) to be effective in granular mixtures. The peak shear stress values obtained during the shearing of the mixtures shown in Figs. 6 and 7 were plotted against the area concentration of the large cylinders in the mixture. The result of the plot is shown in Fig. 8.

Figure 7. Force chains in the samples with zero, one and two large particles at a horizontal shear displacement equal to 3.5 mm.

Figure 8. Shear strength versus the area concentration of the large cylinders in the simulated granular mixture.

An analysis of Fig. 8 indicates that the presence of the large cylinders in the mixture has a reinforcing effect. That is, as the number of large cylinders increase in the mixture, its shear strength also increases. The best fit line shown in Fig. 8 has an equation of the form:

$$S_c = S_m (1 + C_a) \quad (2)$$

which is very similar to Eq. (1).

It should be noted that the DEM simulations did not represent exactly the shape of the particles forming part of the laboratory experiments. Also, the sizes of the particles used in the laboratory experiments were different than those used in the DEM simulations. However, the general results of the laboratory tests are corroborated by the DEM simulations. In addition, the DEM simulations help to explain the way internal forces are transmitted through the particles in the laboratory experiments. Thus, for the case of real sand-gravel mixtures, it is expected that the shear strength of these mixtures will increase with the volume concentration of the gravel in the mixtures. Also, it should be noted that for the case of embankments and natural slopes, the effectiveness of the oversized particles on the shear strength of the mixtures forming these structures will depend upon if the large particles are located on or near the critical failure surface (Fig.1).

#### 4 CONCLUSIONS

In the present study the shear strength of simulated granular mixtures made of granular matrix in which large particles are embedded was carried out using laboratory and numerical analyses. Results from using both approaches indicated that the presence of the large particles has a reinforcing effect in the mixtures. That is, the greater the number of the large particles in the mixture, the greater is the shear strength of the mixtures.

# Analysis of Displacements of GPA in Normally Consolidated Soft Soil

## L'analyse des déplacements des GPA dans le sol mou Normalement consolidé

**ABSTRACT:** Granular piles (GP) offer most effective and economical solution for ground improvement due to their drainage, densification and reinforcement actions, GPs mitigate liquefaction induced damages. An anchor placed at the base of the granular pile and attached to the footing by a cable or rod transfers the applied pullout force to the bottom of the GP termed as Granular Pile Anchor (GPA). The effective stresses in a normally consolidated saturated soil increase linearly with depth. Consequently, the undrained strength and the deformation modulus of the soil increase linearly with depth. Analysis of the displacements of granular pile anchor is presented considering the influence of the linearly increasing undrained modulus of soil and of the GPA with depth on the load – displacement response of the GPA. A parametric study quantifies effects of the length to diameter ratio of GPA, and the relative stiffness of the GP with respect to that of in situ soil at ground level, on the variations of tip and top displacements of GPA with applied load, variation of shear stresses and pullout load with depth, etc.

**RÉSUMÉ :** Pieux granulaires (GP) offrent une solution plus efficace et économique pour amélioration des sols en raison de leur drainage, la densification et des actions de renforcement, les médecins généralistes atténuer les dommages induits par liquéfaction. Un point d'ancrage placé à la base du pieu granulaire et fixée à la semelle par un câble ou une tige transfère la force de traction appliquée sur le fond de la GP qualifiée de mouillage pieu granulaire (GPA). Les contraintes effectives dans un sol normalement consolidé saturé augmente linéairement avec la profondeur. Par conséquent, la résistance non drainée et le module de déformation du sol augmente linéairement avec la profondeur. L'analyse des déplacements de l'ancrage empiement granulaire est présentée compte tenu de l'influence de plus en plus le module linéaire non drainée du sol et de l'GPA avec la profondeur de la réponse force - déplacement du GPA. Une étude paramétrique de quantifier les effets de la longueur par rapport au diamètre de l'GPA, et la rigidité relative du GP par rapport à celle du sol in situ au niveau du sol, sur les variations de pointe et des déplacements supérieurs de GPA avec la charge appliquée, la variation de cisaillement contraintes et la charge de retrait avec la profondeur, etc

**KEYWORDS:** Granular pile anchor, modulus of deformation, homogenous ground, displacements, load transfer.

### 1 INTRODUCTION.

Granular piles (GP) offer most effective and economical solutions in soft marine clays to counter-act low undrained shear strength and stiffness of the deposits. GPs improve the performance of ground by reinforcement, densification, increasing bearing capacity and resistance to liquefaction by increasing strength and stiffness of ground. GPs are ideally suited as they form elements of low compressibility and high shear strength. The effective stresses in a normally consolidated saturated soil increase linearly with depth. As a result the undrained shear strength and deformation modulus of the soil also increase linearly with depth. The increase in modulus of soil and granular material with depth result in reduced load-displacements response and increased confinement pressure.

The functional utility of the GP in compression is extended by placing an anchor at its base to transfer the pullout load or uplift forces to the base and the assembly is termed as Granular Pile Anchor (GPA). Granular pile treated expansive soil adjusts itself to changes in moisture better than an untreated-soil (Phani Kumar *et al.*, 2004). White *et al.* (2001) studied the application of reinforced geopiers for resisting tensile loads and settlement control. Lillis *et al.* (2004) reported results from in situ tests on pullout response of GPA. Kumar *et al.* (2004) present results from laboratory and field tests on pullout response of GPA in cohesive and cohesionless soils. A linear analysis of displacements of GPA is presented by Madhav *et al.* (2008).

### 2 PROBLEM DEFINITION

A granular pile of length,  $L$ , and diameter,  $d$ , with the soil and pile material characterized by moduli of deformation  $E_s$  and  $E_{gp}$ , and unit weights of  $\gamma_s$  and  $\gamma_{gp}$ , respectively is considered (Fig.1). A force,  $P_o$ , applied at the base of GPA is resisted by the shear stress,  $\tau$ , acting along the periphery of the pile. The force and the stresses acting on the GPA are depicted in Figure 2a. The stresses transferred to the in situ soil are shown in Figure. 2b. The non-homogeneities of deformation moduli of soil,  $E_s$  and granular material,  $E_{gp}$  (Fig. 3 & 4) are defined by the parameters,  $\alpha_s$  &  $\alpha_{gp}$ , to quantify the rate of increase of deformation moduli of in-situ soil and granular material with depth. The Poisson's ratio of the soil is  $\nu_s$ . In order to evaluate the upward displacements of the elements of the soil adjacent to the GPA

Fig. 1 GPA under Pullout

Fig. 2 Forces and Stresses acting on GPA and Soil.

due to the boundary stresses,  $\tau$ , the GPA surface is divided in to 'n' elements of length,  $\Delta L (=L/n)$ . The stress acting on a typical

element, j, is  $\tau_j$ . The displacement at the centre of an element, i, due to stresses acting on element, j, are obtained by the method described by Poulos and Davis (1980).

Integrating numerically, the Mindlin's equation for a point load in the interior of a semi-infinite elastic continuum over the cylindrical periphery of the element, the displacement,  $\rho_{s,ij}$ , of the soil adjacent to the centre of the i<sup>th</sup> element due to stress,  $\tau_j$ , acting on the element, j, considering deformation modulus,  $E_s$ , of the soil, increases linearly with the depth as

$E_s(z) = E_{s0} \left(1 + \alpha_s \frac{z}{L}\right)$  is obtained as

$$\rho_{s,ij} = \frac{d}{E_{s0}} \cdot \frac{I_{s,ij}}{\left(1 + \alpha_s \left(\frac{z_i}{L}\right)\right)} \cdot \tau_j \quad (1)$$

where  $I_{s,ij}$  is the soil displacement influence coefficient. The total soil displacement,  $\rho_{s,i}$ , adjacent to node 'i' due to stresses on all the elements of the GPA, is obtained by summing up all the displacements at node 'i', as

$$\rho_{s,i} = \frac{d}{E_{s0}} \sum_{j=1}^n \frac{I_{s,ij}}{\left(1 + \alpha_s \left(\frac{z_i}{L}\right)\right)} \tau_j \quad (2)$$

The vertical soil displacements adjacent to all the nodes are collected to arrive at

$$\{\rho_s\} = \frac{d}{E_{s0}} [I_s] \{\tau\} \quad (3)$$

where  $\{\rho_s\}$  and  $\{\tau\}$  are respectively the soil displacement and stress vectors of size, n, and elements of the matrix  $[I_s]$  are  $I_{s,ij} = \frac{I_{s,ij}}{\left(1 + \alpha_s \left(\frac{z_i}{L}\right)\right)}$  - non-dimensional soil displacement influence coefficient of GPA, where  $Z'_i = \frac{z_i}{L}$  - normalized depth at i<sup>th</sup> element.

Fig. 3 Variation of  $E_s$  with Depth – Effect of  $\alpha_s$

Fig. 4 Variation of  $E_{gp}$  with Depth – Effect of  $\alpha_{gp}$

### 2.1 DISPLACEMENTS OF GPA

The vertical displacements of GPA are obtained considering it to be compressible. Figure 5 depicts the stresses on an infinitesimal element of GPA of thickness,  $\Delta z$ . Poulos and Davis (1980) have established that lateral/radial stresses have negligible effect on the vertical displacements. Considering the deformation modulus of the granular material,  $E_{gp}$ , to increase linearly with depth, z, as

$$E_{gp}(z) = E_{gp0} \left(1 + \alpha_{gp} \left(\frac{z}{L}\right)\right) \quad (4)$$

The equilibrium of forces in the vertical direction reduces to

$$\frac{d\sigma_z}{dz} + \frac{4}{d} \tau = 0 \quad (5)$$

where  $\sigma_z$  is the normal stress in to the GPA. The stress-strain relationship for GPA material, is

$$\sigma_z = E_{gp} \epsilon_z = -E_{gp} \frac{d\rho_{gp}}{dz} \quad (6)$$

Fig. 5 Stresses acting on an Infinitesimal Element

where  $\epsilon_z$  and  $\rho_{gp}$  are respectively the axial strain and GPA displacement. Substituting for modified  $E_{gp}$  the stress-strain Equation 6 is modified as

$$\sigma_z = E_{gp} \epsilon_z = -E_{gp0} \left(1 + \alpha_{gp} \left(\frac{z}{L}\right)\right) \frac{d\rho_{gp}}{dz} \quad (7)$$

Differentiating Equation 7 with respect to depth, z,

$$\frac{d\sigma_z}{dz} = -E_{gp0} \left[ \left(\frac{\alpha_{gp}}{L}\right) \frac{d\rho_{gp}}{dz} - E_{gp0} \left(1 + \alpha_{gp} \left(\frac{z}{L}\right)\right) \frac{d^2\rho_{gp}}{dz^2} \right] \quad (8)$$

On simplification the differential Equation 8 becomes

$$\frac{d\sigma_z}{dz} = -E_{gp0} \left[ \left(\frac{\alpha_{gp}}{L}\right) \frac{d\rho_{gp}}{dz} + \left(1 + \alpha_{gp} \left(\frac{z}{L}\right)\right) \frac{d^2\rho_{gp}}{dz^2} \right] \quad (9)$$

Combining Equations 5 and 9 simplify

$$-E_{gp0} \left[ \left(\frac{\alpha_{gp}}{L}\right) \frac{d\rho_{gp}}{dz} + \left(1 + \alpha_{gp} \left(\frac{z}{L}\right)\right) \frac{d^2\rho_{gp}}{dz^2} \right] + \frac{4}{d} \tau = 0 \quad (10)$$

Equation 10 is solved along with the boundary conditions: at  $z = 0$  (i.e. at the top of GPA)  $P = 0$  (Free boundary) and at  $z = L$  (tip of the GPA),  $P = P_0$  (the applied load). Equation 10 written in finite difference form reduces to

$$\left\{ \frac{\alpha_{gp}(\rho_{gp,i-1} - \rho_{gp,i+1})}{L} + (1 + \alpha_{gp} z'_i) \frac{(\rho_{gp,i-1} - 2\rho_{gp,i} + \rho_{gp,i+1})}{(\Delta z)^2} \right\} \frac{4}{E_{gpo} d} \tau_i = 0 \quad (11)$$

where  $\Delta z = (L/n)$  – length of differential element of GP. Rearranging the terms in Eq. 11

$$\frac{n^2}{L^2} \left\{ \frac{\alpha_{gp}}{2n} (\rho_{gp,i-1} - \rho_{gp,i+1}) + (1 + \alpha_{gp} z'_i) (\rho_{gp,i-1} - 2\rho_{gp,i} + \rho_{gp,i+1}) \right\} - \frac{4}{E_{gpo} d} \tau_i = 0 \quad (12)$$

Eq. 12 is written as

$$\left\{ a_i \cdot \rho_{gp,i-1} - 2b_i \cdot \rho_{gp,i} + c_i \cdot \rho_{gp,i+1} \right\} - \frac{4L^2}{n^2 \cdot E_{gpo} \cdot d} \tau_i = 0 \quad (13)$$

where  $a_i = \left( 1 + \alpha_{gp} z'_i - \frac{\alpha_{gp}}{2n} \right)$   $b_i = \left( 1 + \alpha_{gp} z'_i \right)$   $c_i = \left( 1 + \alpha_{gp} z'_i + \frac{\alpha_{gp}}{2n} \right)$

$a_i$ ,  $b_i$  and  $c_i$  are displacement influence coefficients.

$\rho_{gp,i}$  and  $\tau_i$  are respectively the displacement at the centre of node ‘i’ and the shear stress on the interface of element, ‘i’, of the GPA. Eq. 13 is written for nodes  $i = 2$  to  $(n-1)$ . Invoking the first boundary condition,  $P=0$  implies  $\sigma_z=0$  and hence strain,  $\epsilon_z=0$ , leads to i.e.,

$$\rho_{gp,1} = \rho_{gp,1'} \quad (14)$$

where  $\rho_{gp,1'}$ —displacement at the imaginary node 1’ above the GPA (Fig. 2a). Eqs. 13 and 14 are combined to arrive at the finite difference equation for node ‘1’, as

$$\left\{ a_1 \cdot \rho_{gp,1'} - 2b_1 \cdot \rho_{gp,1} + c_1 \cdot \rho_{gp,2} \right\} - \frac{4L^2}{n^2 \cdot E_{gpo} \cdot d} \tau_1 = 0 \quad (15)$$

Eq. 15 reduces to

$$\left\{ (a_1 - 2b_1) \rho_{gp,1} + c_1 \cdot \rho_{gp,2} \right\} - \frac{4L^2}{n^2 \cdot E_{gpo} \cdot d} \tau_1 = 0 \quad (16)$$

All the equations for nodes 1 to  $(n-1)$  are collated as

$$[L'_{gp}] \{ \rho_{gp} \} - \frac{4L^2}{E_{gp} \cdot n^2 \cdot d} \{ \tau \} = 0 \quad (17)$$

where  $[L'_{gp}]$  is the displacement coefficient matrix.

The pile displacements equations for nodes 1 to  $(n-1)$  are collated and summarized in Eq. 17. The pile displacement influence coefficients are

$$\begin{bmatrix} (a_1 - 2b_1) & c_1 & 0 & \dots & \dots & \dots & \dots & 0 \\ a_2 & -2b_2 & c_2 & 0 & \dots & \dots & \dots & 0 \\ 0 & a_3 & -2b_3 & c_3 & 0 & \dots & \dots & 0 \\ 0 & 0 & a_4 & -2b_4 & c_4 & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots & a_{n-1} & -2b_{n-1} & c_{n-1} \end{bmatrix} \quad (18)$$

Considering the compatibility of displacements in soil and GPA

$$\{ \rho_S \} = \{ \rho_{gp} \} \quad (19)$$

Combining Eqs. 3 and 17 with Eq. 19

$$[L'_{gp}] \frac{d}{E_{so}} [L'_S] \{ \tau \} - \frac{4L^2}{E_{gpo} \cdot n^2 \cdot d} \{ 1 \} \{ \tau \} = 0 \quad (20)$$

where  $\{ 1 \}$  is the unit vector.

### 3 RESULTS AND DISCUSSION

Equation 20 is solved for the displacements in GPA. The displacements generated along the GPA length are extrapolated to obtain the top,  $\rho_0$ , and the tip,  $\rho_L$ , displacements considering the 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> elements for the top and  $n-2$ ,  $n-1$  and  $n^{\text{th}}$  elements for the tip displacements in the GPA, respectively. The results are presented for the following ranges of parameters.  $L/d$ : 5, 10, 25 and 50;  $K$ : 10 to 10,000; Poisson’s ratio,  $\nu_s$ : 0.5,  $\alpha_s = 0, 0.25, 0.5, 1$  and 2; and  $\alpha_{gp} = 0, 0.25, 0.5, 1$  and 2.

The influence of  $\alpha_s$  on the variation of the shear stresses with depth is presented in Figure 6 for  $L/d=10$ ,  $K=50$ ,  $\nu_s=0.5$  and  $\alpha_{gp}=0, 0.5$  and 1. The variations of the shear stresses with depth are magnified at top as shown in Figure 6(b). The variations of shear stresses with depth are very similar for both values of  $\alpha_s = 0$  and 0.5 and decrease with increasing values of  $\alpha_{gp}$ . The shear stresses at the tip decrease from 6.65 to 5.63 and from 5.25 to 4.39 for  $\alpha_s = 0$  & 0.5 with  $\alpha_{gp}$  increasing from 0 to 1 respectively. On the contrary, the shear stresses at the top increase from 0.35 to 0.41 and 0.77 to 0.86 for  $\alpha_s = 0$  & 0.5 with  $\alpha_{gp}$  increasing from 0 to 1 respectively.

The variations of shear stresses with depth as a function of  $\alpha_{gp}$  are presented in Figure 7 for  $L/d=10$ ,  $K=50$ ,  $\nu_s=0.5$  and for  $\alpha_s = 0, 0.5$  and 1.0. The plots are magnified for the stresses at the top in Figure 7(b). The variation of shear stresses with depth for  $\alpha_{gp} = 0$  & 0.5 are very similar for all  $\alpha_s$ .

Fig. 6 Normalized shear stress,  $\tau^*$  vs. Depth,  $z/L$  for  $L/d = 10$ ,  $K=50$  &  $\nu_s=0.5$  – (a) Effect of  $\alpha_s$  &  $\alpha_{gp}$ . (b) Enlarged at top.

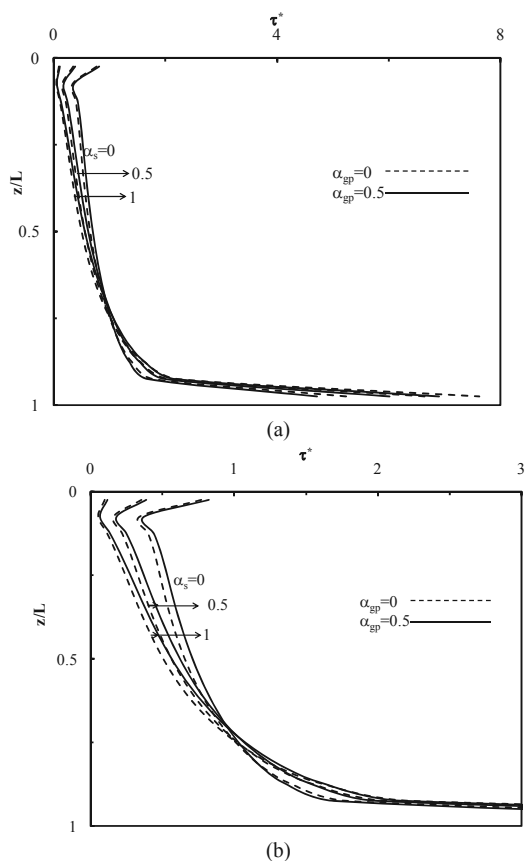

Fig. 7 Normalized shear stress,  $\tau^*$  vs. Depth,  $z/L$  for  $L/d = 10$ ,  $K=50$  &  $v_s=0.5$  – (a) Effect of  $\alpha_s$  &  $\alpha_{gp}$ . (b) Enlarged at top.

The variations of normalized tip displacements with depth for  $\alpha_s = 0$  ( $E_s$  constant with depth) and 0.5 are presented in Figure 8 for  $L/d=10$ ,  $K=50$ ,  $v_s=0.5$  and  $\alpha_{gp}=0, 0.5$  and 1. The displacement coefficients decrease with  $\alpha_{gp}$  at the tip, and increase at the top with  $\alpha_{gp}$  for  $\alpha_{gp}$  increasing from 0 to 1. The variation of  $I_U$  with depth is relatively large for smaller values of  $\alpha_{gp}$  compared to that for  $\alpha_{gp}=1$ . The displacement coefficient at the tip decreases from 1.91 to 1.47 for  $\alpha_s=0$  and from 1.732 to 1.34 for  $\alpha_s=0.5$ .  $I_U$  decreases by about 30% for  $\alpha_s=0.5$  in comparison to that for  $\alpha_s=0$  (homogenous soil).

The influence of  $\alpha_{gp}$ , the rate of increase of deformation modulus of granular material with depth on the variations of the displacement coefficients,  $I_U$  with depth for varying  $\alpha_s$  from 0 to 1,  $L/d=10$ ,  $K=50$  and  $v_s=0.5$  is presented in Figure 9. The displacement coefficient,  $I_U$ , for  $\alpha_s=0$ , at the tip decreases from 1.91 to 1.8 and increases from 1.12 to 1.17 for  $\alpha_{gp} = 0$  and 0.5 respectively. Similarly for  $\alpha_s=0.5$  and 1, the displacements at the tip decrease from 1.47 to 1.39 and 1.14 to 1.10 while at the top they increase from 0.87 to 0.90 and 0.71 to 0.74 for  $\alpha_{gp} = 0$  & 0.5 respectively.

#### 4 CONCLUSION

Analysis of the GPA under the influence of the non-homogeneities of the deformation moduli of the soil and granular material is presented in this paper. The shear stresses near the top of GPA are significantly less for  $\alpha_s$  increasing with depth. Displacements reduce for the deformation moduli parameters of soil and granular material increasing linearly with depth ( $\alpha_s=0.5$  &  $\alpha_{gp}=0.5$ ). The displacements reduce by 30% with depth for  $\alpha_s=0.5$  and 6% for  $\alpha_{gp}=0.5$  in comparison to those for  $\alpha_s=0$  and  $\alpha_{gp}=0$  respectively.

Fig. 8 Normalized displacement coefficient,  $I_U$  vs. Depth,  $z/L$  for  $L/d=10$ ,  $K=50$  &  $v_s=0.5$  – Effects of  $\alpha_s$  &  $\alpha_{gp}$ .

Fig. 9 Normalized displacement coefficient,  $I_U$  vs. Depth,  $z/L$  for  $L/d=10$ ,  $K=50$  &  $v_s=0.5$  – Effect of  $\alpha_{gp}$  &  $\alpha_s$ .

**ABSTRACT:** The present paper proposes technical solutions for a road design project comprising both bridges and high embankments in the Region of Western Greece, where major geotechnical issues had to be dealt with. The very low P-y reaction of the soft silty clays and the eventual liquefaction of the silty sand layers embedded within the foundation soil, the high ground water table and the high seismicity of the area, led to the decision to improve the top part of the natural soil given the necessity for an acceptable solution in terms of both dimensions and cost. Among other possible methods of soil improvement, the application of stone columns followed by preloading was selected. A comparative parametric stability analysis of the bridge embankments and the pile foundations for bridge piers, with or without the presence of stone columns, quantified the benefits from the proposed ground improvement method and verified that the completion of this project is feasible within acceptable performance, safety and cost limits.

**RÉSUMÉ :** La communication propose des solutions techniques pour l'élaboration d'un projet de route qui comprend des ponts et des remblais de grande hauteur dans la région de la Grèce occidentale où il a fallu faire face à des problèmes géotechniques importants. La très faible résistance des argiles limoneuses molles aux sollicitations horizontales et la liquéfaction éventuelle des couches du terrain formées de sables limoneux qui sont contenues dans le sol de la fondation, la nappe phréatique élevée et la haute séismicité de la région, ont conduit à la décision d'améliorer la partie supérieure du sol naturel en prenant en considération la nécessité de trouver une solution acceptable en ce qui concerne les dimensions et le coût. Parmi d'autres méthodes d'amélioration du sol, il a été choisie l'utilisation des colonnes ballastées suivie d'un préchargement du sol. Une analyse paramétrique comparative de stabilité des remblais des ponts et des fondations des piliers des ponts avec ou sans la présence des colonnes ballastées, quantifient les bénéfices obtenus par l'utilisation de la méthode d'amélioration du sol proposée et vérifie que l'achèvement de ce projet est réalisable avec une performance acceptable en termes de sécurité et de coûts

### 1 INTRODUCTION

A significant project for road infrastructure is currently under way in western Greece, prefecture of Aitolokarnania, concerning the construction of a 13,1km part of a public provincial road connecting the municipality of Astakos to the bridge of Gouria.

Owner of the project is the Greek State and the Supervising Authority is the Directorate of Studies for Road Works, General Directorate of Road Works, Ministry of Development, Competitiveness, Infrastructure, Transport and Networks. Following the necessary competitive procedure, the design of the project was assigned to a joint scheme of specialized design offices, covering the involved scientific areas.

This paper focuses on the technical solutions proposed for the geotechnical issues that arose with reference to the stability of embankments and bridge foundation.

### 2 PROJECT OVERVIEW

The importance of this project lies in its expected contribution to the improvement of road access towards western Aitolokarnania and mainly the touristic zone of Astakos-Mytikas-Palairos. It is also anticipated to take over some of the traffic load of other local axis and to support the increase in use of an existing tunnel nearby. What is more important though, is the expected traffic load assumption for the shipbuilding and industrial zone of Astakos, which in the future will be the base for development in the whole area.

The realization of the project will improve the accessibility of the area and will facilitate road connection between cities and existing or planned infrastructure, decreasing time demands and improving safety and comfort requirements

This road axis under study forms a part of the connection of Astakos and the port of Platygiali with the major motorway of "Ionia Odos", passing through the bridge of Gouria and the existing tunnel of Saint Elias. The road section is 11,0m wide (1 lane per direction). From geotechnical point of view, it is to be mentioned that the whole project comprises 6 bridges (15-105m long) and a significant length of embankments between 2 and 7 meters high.

Major geological and geotechnical issues that arise for the last 10km of the road are related to the very low altitude of the ground and the lack of inclination, the high ground water table, the insufficient drainage system and the presence of silty clays and sands, often with high content of organics. The whole situation is aggravated by the liquefaction potential of the silty sand layers embedded within the foundation soil, in connection with the high seismicity of the area.

During the preliminary design stages, it became obvious that the most significant geotechnical problems for the realization of the project would be related to the load bearing capacity of the soil, the expected subsidence under static loading and the eventual liquefaction phenomena.

### 3 GEOTECHNICAL CONDITIONS

The area where the bridge foundation will be constructed consists of soft and compressible saturated alluvial soils, while the water table is located at ground level. The prevailing

geotechnical conditions at these areas can be simplified in two main profiles.

**Soil profile I (Fig. 1)** is encountered in the majority of the bridge sites. Its main characteristic is the surficial layer of fine-grained medium plasticity soil. According to the geotechnical exploration results, this soil layer consists mainly of low to medium plasticity silts (ML) and clays (CL), with thin layers of high plasticity silts (MH), fat clays (CH) and organic clays (OL). The thickness of this layer varies between about 22.5 to 35m. Below this layer, to the depth of 40m, either a medium to dense non-cohesive soil unit (SC, SM) or a dense cohesive soil unit (CL) are present. Rock or any other rock-like geological formation was not encountered at any of the locations explored.

Profile I	Profile II
ML, CL, MH, CH, OL $\gamma=17-19\text{kN/m}^3$ , $c_u=10-30\text{kPa}$ , $E_s=0.5-3\text{MPa}$ , $q_t=0.5-4.3\text{MPa}$ , $FC=49-100\%$ , $PI=4-48\%$ 22.5-35m	ML, CL, MH, CH, OL same as Profile I 7m
	SM $\gamma=17-19\text{kN/m}^3$ , $q_t=4.5\text{MPa}$ , $N_{sp}=18$ , $FC=7-20\%$ 15m
	22.5-35m
SC, SM or CL $\gamma=21\text{kN/m}^3$ , $E_s=12-18\text{MPa}$ , $c_u=65-100\text{kPa}$ or $\phi=34-35^\circ$ 40m	SC, SM or CL $\gamma=21\text{kN/m}^3$ , $E_s=12-18\text{MPa}$ , $c_u=65-100\text{kPa}$ or $\phi=34-35^\circ$ 40m

Figure 1: Representative geotechnical profiles

Figure 2: Distribution of undrained shear strength with depth for profile I conditions, before and after the improvement

Figure 2 presents an estimation of the undrained shear strength of the surficial fine-grained soil unit of Profile I, based on the results of typical CPT & SPT recordings. An estimation of undrained shear strength for normally consolidated clays is also presented, based on Jamiolkowski et al. (1985) (see Eq.1):

$$S_u = 0.25 \sigma'_{vo} \quad (1)$$

where  $\sigma'_{vo}$  is the geostatic effective vertical stress. Comparing these two estimations, it is concluded that the surficial fine-grained layer is normally or even at some depths under-consolidated, with low values of undrained shear strength. Thus, the bearing capacity of this formation is considered low and significant settlements are expected during loading, with the necessary consolidation time to exceed the acceptable time limits (horizontal coefficient of consolidation ranging between

$c_h=7 \times 10^{-7} - 9 \times 10^{-6} \text{ m}^2/\text{sec}$  based on CPTu dissipation tests). The lateral resistance of this layer is also considered very low, leading to large horizontal displacements and structural forces, especially during seismic loading.

With regard to the seismic response, profile I belongs to group type S1 according to EC8. The average shear wave velocity  $V_{s,30}$  generally ranges between 85 and 140m/sec, as computed from the CPT recordings:

$$G_{\max,0} = (q_t - \sigma_v) \times 0.0188 \times 10^{0.55I_c + 1.68} \quad (2)$$

where  $I_c$  is a soil behavior type index (Robertson, 2009). Thus, special study is required for the definition of the seismic action, which will take into account the non-linear response of the soil layers and the dependence of soil moduli and internal damping on cyclic strain amplitude.

**Profile II (Fig. 1)** represents the soil conditions prevailing at one bridge site. The soil conditions resemble those of Profile I, with the exception of an 8m thick layer of loose silty sand that interrupts the surficial fine-grained formation. This non-cohesive formation (SM according to USCS) is relatively close to ground surface (at the depth of 7m), while it is classified as non-plastic, with fines content between 7 and 20% and potentially liquefiable under seismic conditions.

A preliminary liquefaction analysis with NCEER methodology (Youd et al. 2001) for CPT recordings revealed that this non-cohesive formation is liquefiable. As shown in Fig. 4, the factor of safety against liquefaction is well below unity for the silty sand layer, revealing its high liquefaction potential. Hence, although this soil layer presents higher stiffness ( $V_{s,30}=140\text{m/s}$ ) and bearing capacity for static loading, as compared to the clay layer, its liquefaction potential deteriorates its mechanical properties. Thus, during earthquake loading, loss of bearing capacity, lateral stiffness degradation and settlements are expected to occur, increasing this way superstructure displacements and structural forces. Furthermore, Profile II is now characterized as Group type S2 according to EC8 and special study is needed to define the seismic action and the exact liquefaction potential.

#### 4 DESIGN CONCEPT

As a result of the existing poor soil conditions, the foundation of the foreseen bridge piers on surface foundations was excluded and was replaced by a group of piles with a rigid pile cap. However, due to the high seismicity of the area, the very low P-y reaction of the soft silty clays and the eventual liquefaction of the silty sand layer led to extreme internal forces of the piles and increased dis-proportionally the cost of the project. Hence, the necessity of an acceptable solution in terms of both dimensions and cost, led to the decision to improve the top part of the natural soil.

Among a number of possible methods of soil improvement that were examined, it was decided to proceed with the application of gravel piles followed by preloading. Plastic drains are also prescribed to act as secondary drainage system for greater soil depths.

The main aim of pre-loading was to increase the undrained shear strength of the surficial fine-grained soil unit. The improved undrained shear strength (when the increase of effective stress due to surcharge exceeded 10% of its initial value), was estimated according to Eq. 4:

$$S_{u,f} = S_{u,0} \text{OCR}^{0.8} \quad (3)$$

with  $S_{u,0}$  reflecting the anticipated undrained shear strength for normally consolidated clays (see Eq. 2). The increase of effective vertical stress at each depth was computed according to the well known Westergaard solutions, taking into account the increase of soil stiffness at upper layers, where gravel pile installation accompanies pre-loading. The effect of pre-loading reduces with depth, while a percentage of the surcharge load is used for the increase of OCR, due to the distribution of the external load between gravel piles and original soil. Despite that, the anticipated increase of undrained shear strength at upper layers (i.e. at layers that are crucial for the overall safety

of the bridge embankments) is considered substantial, while its secondary effects such as the acceleration of consolidation at layers that were found under-consolidated and the reduction of downdrag forces at piles (i.e. by allowing the consolidating soil to settle before construction) increase its efficiency. The prescribed pre-loading embankment were wider from the bridge embankment / pile cap by 2.5-3.0m at each side, in order to apply uniform stress at the area of interest, while its height generally varies between 3 and 7m.

Stage construction of pre-loading embankment was decided (with height increments between 1.5-2.0m), due to the poor soil conditions, followed by continuous settlement and pore-pressure dissipation recordings. Figure 2 presents the anticipated final (after improvement) distribution of  $S_u$  with depth for the CPT recording presented in Section 3.

Gravel pile installment is prescribed ahead of pre-loading, consisting of 0.80m diameter piles in a 1.80 x 1.80m square arrangement (denoting replacement percentage equal to  $a_s = 0.78 \times (0.8/1.8)^2 = 15.4\%$ ). Gravel pile length varies between 8 and 13m, depending on soil conditions.

The installation of gravel piles increased the mechanical properties of the upper cohesive fine-grained layers and subsequently increased the general stability of bridge & pre-loading embankments. The following equivalent strength parameters were used (Van Impe & De Beer, 1983):

$$c_{eq} = (1-a_s) S_{u,f} \quad (4a)$$

$$\tan\phi_{eq} = [na_s / (na_s + 1 - a_s)] \tan\phi_1 \quad (4b)$$

where  $c_{eq}$  &  $\phi_{eq}$  denote the equivalent cohesion & friction angle of the composite system respectively,  $\phi_1$  denotes the friction angle of gravels (assumed equal to  $42^\circ$ ),  $a_s$  denotes the replacement ratio (equal to 0.154) and  $n$  denotes the ratio of the load taken by the gravel pile versus the surcharge load. The contribution of geostatic stresses is omitted; while outside the embankment limits (where no surcharge is applied)  $n$  equals 1.0. The improved shear strength of the composite system, combined with the increase of the undrained shear strength due to pre-loading proved adequate for the construction of the bridge embankments with acceptable factor of safety under both static and seismic conditions (e.g. the static F.S. increased from 0.64 to 1.51 for a representative height of 4m).

Note that, besides the improvement of shear strength characteristics, the inclusion of gravel columns combined with pre-loading has altered the seismic ground response relative to free-field. In order to take into account this effect, the shear wave velocity and the spring stiffness in P-y curves of the relevant soil layers were appropriately increased. Namely, the formula presented by Baez & Martin (1993) was used for the estimation of the maximum shear modulus of the composite system:

$$G_{max,eq} = G_{max,i} a_s + G_{max,p} (1-a_s) \quad (5)$$

where  $G_{max,eq}$  is the maximum equivalent shear modulus,  $G_{max,i}$  is the maximum shear modulus of the fine-grained layer after pre-loading,  $G_{max,p}$  is the maximum shear modulus of the gravel pile and  $a_s$  is the replacement ratio (here 0.154). The maximum shear modulus of the fine-grained layer after pre-loading was computed as follows (Weiler, 1988):

$$G_{max,i} = G_{max,o} OCR^{0.5} \quad (6)$$

where  $G_{max,o}$  is the maximum shear modulus of unimproved soil, as computed by Eq. 2. The maximum shear modulus of the gravel pile was computed assuming a dense configuration ( $e=0.55$ ). Figure 3 presents the shear wave velocity profile of the composite system for the CPT recording of Fig. 1. The average shear wave velocity  $V_{s,30}$  for this profile increased from 86 to 140m/s, reflecting stiffer ground conditions. This increase was also implemented to the P-y curves, by increasing the horizontal subgrade reaction coefficient  $k$ . The increase was assumed proportional to the ratio  $G_{max,eq}/G_{max,o}$ , while for the

unimproved soil coefficient  $k$  was computed according to DIN4014 for bored cast-in-place piles.

For the case of Profile II, where a non-cohesive liquefiable layer is present, the gravel piles are expected to act as a countermeasure against liquefaction. The gravel piles will be constructed via bottom-feed vibro-replacement, while a proper gradation curve range is prescribed in order to ensure the effective drainage of earthquake-induced excess pore-pressures. During vibro-replacement, the non-cohesive layer is expected to be densified and increase its resistance to liquefaction. Based on Mizuno et al. (1987), the average measured tip resistance is expected to increase between gravel piles from 4.5MPa to 9.5MPa, providing an adequate liquefaction resistance. Figure 4 compares results from the preliminary (before improvement) and the detailed (after ground improvement) liquefaction study, which show the minimization of liquefaction potential. The densification of the non-cohesive layer due to pre-loading and the potential dissipation of excess pore pressures were conservatively ignored. It is noted that even if densification was ignored, drainage through gravel piles would retain excess pore pressure ratio  $r_u$  well below 0.5, as computed according to Seed & Booker (1977) and Bouckovalas et al. (2011) for the given characteristics and gravel pile geometry.

Figure 3: Distribution of shear wave velocity with depth for profile I, before and after the improvement

Figure 4: Factor of safety against liquefaction for Profile II, before (preliminary results) and after improvement (detailed study).

Finally, consolidation process is expected to be accelerated with the presence of gravel piles. Excess pore pressures for each loading stage are expected to diminish within 19 days, assuming conservatively only radial flow towards the gravel piles and

horizontal coefficient of consolidation equal to  $c_h=7 \times 10^{-7} \text{m/s}^2$ . The actual consolidation time is expected to be even lower, considering the actual 2D water flow, the presence of horizontal layers of higher permeability and the additional discharge from the secondary pipe drains that are prescribed.

## 5 SEISMIC GROUND RESPONSE ANALYSES

Besides ground improvement, detailed ground response analyses were also crucial for the successful completion of the project. Since, both Profile I & II belong to group type S1 & S2 according to EC8, special study was necessary to define the proper seismic action and the exact liquefaction potential. Thus, 1D equivalent linear analyses were performed with the equivalent-linear frequency domain method (e.g. Schnabel et al. 1972). Modulus reduction and hysteretic damping curves were used as a function of cyclic strain amplitude (Vucetic & Dobry, 1991), and introduced the non-linear behavior of soil layers in ground response analyses, according to its layers' plasticity index. According to EC8 provisions, three different accelerograms were used, which cover a wide range of frequencies and are representative of the seismic region.

Shear wave velocities of the improved ground were computed according to Eq. 5, while the peak ground acceleration at bedrock outcrop was calibrated to 0.24g, according to the Greek Annex of EC8 for the area under investigation. Since no bedrock was found, artificial bedrock was used at the end of each borehole, while the bedrock shear wave velocity was assumed to range between 300 and 550m/s, providing a high impedance ratio compared with the soil column characteristics. Thus, radiation damping was conservatively minimized. Fig. 5 shows representative results from ground response analyses conducted in Profile II. Significant de-amplification of the seismic motion is observed, due to the flexibility of the soil column but also due to the non-linearity exhibited by the soil layers. The computed peak ground acceleration at ground surface ranges between 0.20 to 0.24g, significantly lower from the 0.32g required by EC8 for the flexible soil type D. Thus, the structural forces due to seismic loading were significantly reduced, while the factor of safety against liquefaction was substantially increased.

Figure 5: Distribution of peak ground acceleration with depth for Profile II using three different accelerograms.

## 6 CONCLUSION

The present paper presents details of the technical solution proposed for a road design project in Western Greece, where major geotechnical issues had to be dealt with for the

foundation of bridges and high embankments. Geotechnical investigations revealed very poor soil conditions consisting of silty clays and sands, often with high content of organics, and high ground water table that locally appeared on the ground surface. As a result, the foundation of foreseen bridge piers on surface foundations was excluded and was replaced by a group of piles with a rigid pile cap. Among a number of possible methods of soil improvement that were examined, it was finally decided to proceed with the application of stone columns followed by preloading. This way, the following were accomplished:

- increase of the general stability of the bridge embankments
- increase of the bearing capacity of foundation soil layers
- reduction of internal forces of piles
- acceleration of the stage of primary consolidation of silty clay-sands and
- reduction of the liquefaction potential of sandy layers.

All of the above effects were verified by site-specific computations and implemented to the design of the relevant works

## 7 ACKNOWLEDGEMENTS

Authors acknowledge the assistance of Harris Lamarinis, Civil Engineer M.Sc. on the geotechnical investigations and the preliminary liquefaction analyses.

# Subgrade improvement measures for the main rescue roads in the urban redevelopment area HafenCity in Hamburg

Mesures d'amélioration du sol de fondation des principales routes de secours dans la zone du réaménagement urbaine de la HafenCity à Hamburg

Weihrauch S., Oehrlein S.

*Grundbauingenieure Steinfeld und Partner GbR, Hamburg*

Vollmert L.

**ABSTRACT:** The level of many streets in Hamburg's HafenCity is being raised by around 3 m to ensure safety from flooding. The marshy soils in this area— mainly clay (a soft clay) and peat – necessitate the use of different foundation-soil improvement concepts for the limitation of settlement; these have to take account of the surrounding infrastructure (buildings, river-bank structures, services). The Honkongstrasse serves as a good example of such concepts. Stress and deformation measurements were carried out on the site, in which the concept of a "pile-supported, geogrid-reinforced sand sub-base layer" was used; this paper reports on the results.

**RÉSUMÉ:** Dans le quartier d'HafenCity à Hamburg, la plupart des routes seront surélevées jusqu'à 3 mètres pour atteindre le niveau de protection contre les eaux. Les sols en place, d'origine marécageuse, sont constitués d'argile et de tourbe. Du fait de l'hétérogénéité des sols, et en fonction des ouvrages existants (bâtiments, murs de rive, tuyaux enterrés), différentes approches ont été appliquées pour améliorer les sols et limiter les tassements. Dans cette communication, le cas d'étude de la rue « Hongkong » sera présenté. Dans ce projet, des géogrilles sont utilisées en renforcement d'une couche de forme sableuse pour la répartition des contraintes. Une instrumentation complète a été mise en place. Des mesures de contraintes et de déformation ont été effectuées. Les résultats de cette instrumentation sont présentés dans cette communication.

**KEYWORDS:** urban redevelopment, soil improvement, geogrid, piled embankment, expanded clay, pre-loading

## 1. INTRODUCTION

At the HafenCity in Hamburg, previously part of the harbour area, the current inner-city area south of the historic warehouse district is being extended by some 40 % to a total of 157 hectares (Figure 1). 5,500 dwellings for 12,000 residents are to be constructed, along with office space for 40,000 employees.

In the course of these infrastructure projects, the trafficked areas – with the exception of the quay and embankment promenades – are being raised from the current MSL +5 m to MSL +7.5 m to + 8.0 m, to make them safe for flood events.

Figure1: City-planning concept of the HafenCity Hamburg (as of January 2008)

The soil conditions around today's Honkongstrasse (formerly Magdeburger Strasse) are typical for the HafenCity Hamburg. Fill material of low bearing capacity overlies soft organic layers of clay and peat which in turn overly firm sands (Figure 2). Raising the level of the road embankment by approximately 3.0 m would have resulted in long-term settlements of between 300 and 400 mm, and significant differential settlements would have been expected.

The following subgrade-improvement methods are used to limit settlement in the HafenCity:

- pre-emption of settlement with a sand pre-loading layer and vertical drains
- use of lightweight materials (expanded clay)
- construction of a piled, geogrid-reinforced sand layer

The choice of method depends largely on the local boundary conditions. On the Honkongstrasse site, all three methods were used on different sections. Measurements of stresses and deformations were carried out on the section with the piled, geogrid-reinforced sand layer. The paper therefore concentrates in greater detail on this method.

## 2. METHOD DESCRIPTION AND CONCEPT

### 2.1 Sand pre-loading layer and vertical drains

If the local boundary conditions e.g. space available, existing and planned services, local structures (buildings, river-bank structures, sewers) and the time constraints permit, the use of a sand pre-

loading layer and vertical drains to pre-empt settlements is an economical standard method.

To accelerate consolidation, vertical drains are installed in the area to be loaded. The planned, elevated cross-section is then constructed, and an additional 2.0 to 3.0 m thick sand pre-load is placed.

The consolidation of the weak organic layers is monitored over time using settlement gauges.

After the time required for settlement (usually at least three months), during which no further construction takes place, the sand pre-load is removed to the agreed planned height and the structure passes out of the responsibility of the earthworks contractor.

## 2.2 Use of lightweight aggregates (expanded clay)

In areas where pre-emption of settlement is impractical because of local structures or services, lightweight aggregates are often used. These materials significantly reduce settlements resulting from the raising of ground levels.

For forecast residual settlements of around 50 to 70 mm, the lightweight materials are placed to a depth of around MSL + 2 m.

The expanded-clay layer is wrapped in a nonwoven geotextile to prevent particle displacement and leaching-in of soil.

The use of expanded clay is regulated in the "Merkblatt über die Verwendung von Blähton als Leichtbaustoff im Untergrund von Straßen" of the Forschungsgesellschaft für Straßen- und Verkehrswesen (FGSV).

## 2.3 Construction of a piled, geogrid-reinforced sand layer

### 2.3.1 Construction method and system chosen

The system is characterised by vertical columns (lime-cement treated gravel, unreinforced) and an overlying sand layer horizontally reinforced with geogrids. Use is made of the arching effect of the overburden sandy soil while the foundation soil acts as a bedding layer. In contrast to concrete slabs on (reinforced concrete-) piles, in which the individual elements are very stiff in comparison to the surrounding soils, there is a pronounced interaction between the columns, geogrid and the foundation soil in the system described here.

In contrast to the methods described under 2.1 and 2.2, the foundation soil in this system is only subjected to low additional stresses. The major part of the vertical stresses is transferred in a concentrated manner by the vertical columns into the firm foundation soil. The system settlements remain proportionally very small both during and after the construction phase.

When correctly designed, the system possesses significant reserves of bearing capacity, so that subsequent interventions and changes within limits in the foundation soil have no influence on the serviceability of the structure.

The placement grid of the supporting elements should be designed to transfer the geogrid loads in an orthogonal manner. For Hongkongstrasse, this resulted in a rectangular grid with a spacing of 2.3 m normal to the embankment axis and 2.5 m in the axial direction; the diameter of the elements was 0.6 m (Figure 2). Reinforced-concrete columns with continuous steel reinforcement were used at the edge of the structure to cope with a bending moment (e.g. should any excavation be required at a later date) as a result of lateral pressure.

The geogrid-reinforcement is installed 150 mm above the columns in order to guarantee adequate safety against shear during the construction phase, and in case of large settlements. The reinforcement is placed at right angles to the placement grid, so that the layers are cross-laid in the longitudinal and transverse directions of the embankment.

In the transverse direction, the constructive situation leaves practically no room to anchor the geogrid. The design requirement

of a short-term tensile strength of 400 kN/m is therefore assigned to two layers, which are wrapped round at the edges of the structure, and overlapped in the upper layer.

Figure 2: Cross section – piled sand layer

Figure 3: Detail A – sketch of system showing reinforcement placing (vertical scale greater than horizontal)

### 2.3.2 Points of constructive relevance near Hongkongstrasse

To avoid the risk of subsequent construction activity of investors endangering or destroying sections which have already been built, an area of 1.0 m of the traffic section must be able to be removed. Fill which intrudes into investor areas must also be removable.

In order to prevent any damage to the embankment-support system, the geogrid-reinforced fill layer was built with sufficient overlap (Figure 3). The outer section can thus be removed in the course of normal earthworks.

### 2.3.3 Design and verifications

The design of the support system is performed for the columns and the geogrid-reinforced fill layer in co-ordination with one another.

The columns are designed for the total load, and the contribution of the subsoil to load bearing and subgrade reaction between the columns is neglected.

The geogrid-reinforced layer was designed according to a verification concept which has already been used and proven itself several times in HafenCity Hamburg. The limit bearing capacity was first verified in accordance with a suggestion from Kempfert et al. (1997). A conservative value for subgrade reaction was used. This verification procedure does not enable any deformations to be inferred.

However, verification of serviceability and of deformation limitation is compulsory for all construction projects in the HafenCity Hamburg. A complementary design procedure was

therefore adopted, using a method developed and extended from EBGeo, which at the time of planning was only available in its 2004 draft stage. This extended design method was verified for similar subsoil and loading conditions (Vollmert et al., 2006). The anticipated further settlements at the level of the reinforcement were estimated at less than 50 mm after termination of construction.

Comparisons with the current EBGeo (2010), available in its final form now that construction is complete, show that the design and verification of the system is sufficiently robust to cater even for the special case "Loss of Subgrade Reaction" in Load Case 3.

It must however be noted, that extreme changes in subgrade-reaction conditions – such as its total loss – will result in load redistribution in the sub-base layer. The long-term influence of these on the serviceability can currently not be finally estimated and is the subject of research. Taking serviceability aspects into account, a conservative, realistic estimate of foundation conditions is therefore critical in the design of such subsoil-improvement projects.

### 2.3.4 Accompanying measurement

The selection of the subgrade-reaction value at the underside of the reinforced layer is therefore a critical starting parameter for design. Values for this are usually derived from the stiffness modulus of the subgrade and the thickness of the weak soil layers. The actual reaction is, however, a variable whose value depends on, among other things, the soil improvement during the construction phase, consolidation processes, the stiffness of the geogrid-reinforced foundation layer and the sub-base layer.

In order to obtain further information on the subgrade reaction and the actual behaviour of the structure, it is necessary to investigate such structures in-situ. During the development of Hongkongstrasse, boundary conditions for monitoring with a measurement system were ideal, as not only the foundation soil conditions, but also the geometric conditions and the alterations anticipated in the medium term (development of the investor areas and resulting encroachments into the stress distribution in the structure) were seen as exemplary for the particular situation of HafenCity Hamburg.

The objective of the measurement programme is therefore the investigation and measurement of

- the state of stress in the geogrid
- the development of soil arching, taking construction and operational conditions into account
- the proportions of the load allocated to the supports and the weak layer
- the influence of variations in water-table level in the foundation soil, and
- the deformation situation at foundation level.

## 3. CONSTRUCTION AND MEASUREMENTS RESULTS

### 3.1 Sand pre-loading layer and vertical drains

After the necessary clearing away of foundations, the removal of old services and the search for unexploded ordinance, in the southern part of Hongkongstrasse, vertical drains were hydraulically driven into the foundation soil. Plastic strip drains with a width  $b$  of around 100 mm were used.

In installing the strip drains it was required to ensure that a depth of soft soil of around  $d = 1.0$  m remained under the drains as a natural barrier to the lower groundwater aquifer (lower sands).

After this, the sand layer (including any pre-load) was placed. Sand with a silt content  $\leq 5\%$  by weight, a uniformity coefficient  $U$  of approx. 2 and a rating of Z0 in accordance with the LAGA guidelines was to be used. The sands were compacted in layers to at least medium compaction density.

Below the level at which the sand was laid, settlement-measuring rods, each adjustable in length and with a base plate (1 m x 1 m) were installed, and these were continuously monitored while the pre-load was in place. A plot of settlement against time is shown in Figure 4.

### 3.2 Use of lightweight aggregate (expanded clay)

Lightweight aggregate in the form of expanded clay was used in the northern area of Hongkongstrasse.

Various active services crossed the construction area and it had to be ensured that these were not damaged during the excavation of trenches, around 3.5 m deep. In the area of the services, the expanded clay was installed in so-called big bags as a foundation for the services. In the remaining areas, the expanded clay was placed, spread, and compacted in layers to the design height (base of sand protection layer) (Figure 5).

Figure 4: Development of settlement during loading phase

### 3.3 Piled, geogrid-reinforced sand base layer

#### 3.2.1 Construction

For the required design working load of 500 kN, partial-displacement bored columns with a diameter of 420 mm and an unreinforced, fresh-in-fresh tapered cast cap C25/30 with a cap diameter of 600 mm were installed by GKT Spezialtiefbau GmbH working for Eggers Umwelttechnik GmbH.

High-strength, high-modulus geogrids Secugrid 200/40 R6 and Secugrid 400/40 R6 were used to reinforce the sand base-layer. The construction of the geogrid-reinforced sand layer had to be carried out with overlap. A length of grid from the lower layer, which was laid across the width of the base layer, was rolled and stored at the edge of the fill. After the lengthwise reinforcement and the fill had been placed, the stored roll was pulled up, wrapped round the fill, and overlapped by the length required in the design calculations (Figure 6). For a workmanlike placing it is therefore necessary to ensure that the roll overlaps are arranged in a staggered pattern in order to avoid distortion and twisting of the geogrids.

The results of the measurements have been published by Weihrauch et al. (2010) indicating the expected performance as well as meeting the deformation requirements as given by the design.

#### 4. CONCLUDING REMARKS

Three quite different methods of soil improvement techniques were used in the area of Hongkongstrasse. The prime objective of the soil improvement is, in all cases, the reduction of subsequent settlements in order to guarantee the serviceability of the trafficked areas under operating conditions.

The decisive factors in the choice of construction method are the local conditions, the time constraints, and the economic conditions applicable to the section being planned or built.

Settlement pre-emption with vertical drains and a sand pre-load requires a relatively long lead time. Significant associated settlements must be expected in the immediate vicinity; in the case of existing buildings or services these will usually have to be classified as unacceptable. On the other hand, the foundation soil remains more or less undisturbed in its stratification and composition, and is free of construction elements.

In contrast to this, soil improvement using expanded clay, i.e. a lightweight aggregate, involves only very small additional settlements. This method is therefore advantageous mainly at the interface with existing structures, and with existing roads. Because of the cohesionless nature and the low compressive strength of expanded clay, difficulties can be experienced later if services and anchorage layers are installed, or reconstruction work carried out.

With its columns and the geogrid layers, the pile-supported base-course method contains the most construction components. Depending on the construction process of the columns, this method can be used even close to existing structures. Particularly in cases of large fill depths – and these are typical of the HafenCity – services can be constructed at a later date without problems. And the structure can be continued without a break in the adjoining construction section; building over existing elements

such as pipes is not a problem. Perforation of the geogrid-reinforced base, e.g. by anchor layers, is possible in principle.

The sandfill material can be assumed to incur the lowest cost as regards the pure construction costs of the structure. Under the conditions applying at the HafenCity, the pile-supported, geogrid-reinforced method is usually somewhat cheaper to construct than an expanded-clay fill layer. Absolute costs must be ascertained taking into account project-specific reconstruction, protection and follow-on measures. In addition to the cost aspect, the time flexibility for individual measures, and their technical feasibility under local conditions, are decisive criteria.

The authors wish to thank HafenCity Hamburg, Eggers Umwelttechnik GmbH and Tilman Kaden Landschaftsbau, Bad Segeberg for their support and permission for publication.

Thanks are due to NAUE GmbH & Co. KG for providing the instrumented geogrids and technical support.

# Fiber Reinforced Cement Treated Clay

## Fibro-ciment renforcé argile traitée

Xiao H.W., Lee F.H., Zhang M.H., Yeoh S.Y.  
National University of Singapore, Singapore

**ABSTRACT:** Cement-treated soil has been used widely in ground improvement for several decades. However, its behavior, especially at high cement content, is highly brittle. Previous studies have shown that addition of both fibers and cement in soil improvement seems to be more efficient and attractive than adding fibers or cement alone. This paper presents an experimental study on fiber-reinforced cement-treated marine clay. Two different types of fibers and fiber lengths as well as different fiber contents (0.0%-0.32%) will be investigated with cement content ranging from 20%-50% and water content ranging from 100%-167%. The experiment results indicate that the strength and ductility of cement-admixed marine clay improve significantly with increasing fiber content until an optimum fiber content is reached. It was found that the factors affecting the behavior of fiber-reinforced cement-treated marine clay, such as fiber content, type and cut length and cement soil mix ratio, are not independent. In general, for water content not higher than 100% and cement content higher than 20%, using 12-mm polyvinyl alcohol fiber was found to give higher strength and better ductility than polypropylene or shorter fibers.

**RÉSUMÉ :** Des études précédentes ont démontré que l'incorporation de fibres et du ciment dans l'amélioration de sol semble être plus efficace et attrayante qu'en ajoutant seulement les fibres ou le ciment. Cet écrit présente une étude expérimentale de l'argile marine traitée au ciment et renforcée avec fibres. Deux différents types et longueurs de fibres de même que des teneurs en fibre différentes (0.0%-0.32%) seront examinés avec une teneur en ciment qui s'étend de 20%-50% et d'eau qui s'étend de 100%-167%. Les résultats de l'expérience indiquent que la résistance et la ductilité du ciment-sol sont améliorées de manière significative avec le contenu croissant de fibres jusqu'à ce qu'une teneur en fibre optimale soit atteinte. Il a été trouvé que les facteurs qui affectent le comportement de l'argile marine traitée au ciment et renforcée avec fibres, tel que la teneur en fibres, la longueur et le type de fibre et la proportion du mélange du sol-ciment, ne sont pas indépendants. En général, pour une teneur en eau ne dépassant pas les 100% et une teneur en ciment de plus de 20%, il a été constaté que l'utilisation de la fibre d'alcool de polyvinyl de 12mm offre une plus haute résistance et une meilleure ductilité que le polypropylène ou des fibres plus courtes.

**KEYWORDS:** fiber reinforcement, cement treated soil, brittleness index, compressive strength

## 1 INTRODUCTION

Cement-treated soil has been used widely in ground improvement during the past forty years and is becoming more attractive and efficient method for soil treatment due to its economy, availability and feasibility. However, cement-treated soil, especially at high cement content, tends to be brittle. Previous studies have shown that fiber-reinforcement increases the strength and ductility while decreasing the stiffness of the soil (e.g., Gray & Ohashi 1983). Recent studies have also shown that incorporation of both fibers and cement in soil improvement seems to be more efficient than fibers or cement alone (e.g., Maher and Ho 1993, Consoli et al. 1998). Maher and Ho's work presented a basic study of the mechanical behavior of artificially cemented sand reinforced with randomly distributed glass fibers.

The use of randomly distributed fiber as a new reinforcement material for cement-treated soil has been receiving increasing attention in recent years (e.g., Consoli et al. 2003, Khattak and Alarshidi 2006, Tang et al. 2007, Park 2009; Consoli et al 2011; Ud-din et al. 2011). Previous research works, however, have focused mainly on low cement content ( $\leq 10\%$ ), sand or sandy soil and particular fiber. In this paper, different fiber types (PP & PVA), fiber lengths (6 & 12mm) and fiber contents (0.0%-0.32% by volume of mixture) will be investigated with different cement and water contents for Singapore marine clay treatment. The specimens were made in laboratory and tested with unconfined compression loading. The strength and ductility of the FRCT marine clay specimens were then analyzed based on the experiment results.

## 2 EXPERIMENT INVESTIGATIONS

The materials used in the study are Singapore upper marine clay, type I Ordinary Portland cement, and fibers. The constituents of the clay are 24.13% of colloid, 21.77% of clay,

47.71% of silt and 6.39% of very fine to medium sand. Two different fibers were used, namely polypropylene (PP) and polyvinyl alcohol (PVA) fibers. PVA fibers are commonly used in concrete reinforcement to improve the tensile and flexural strength of concrete. The properties of the fibers are given in Table 1. A naphthalene-based superplasticizer (Rheobuilder 1000) was used in some mixtures for workability purpose.

Table 1 Physical and mechanical properties of fibers

Fiber Type	Length (mm)	Diameter (micron)	Aspect ratio	Tensile strength (MPa)	Elastic modulus (GPa)	Density (kg/m <sup>3</sup> )
PP6	6	26	231	540	7	910
PP12	12	26	462	540	7	910
PVA6	6	26	231	1600	40	1300
PVA12	12	38	316	1500	40	1300

The cement soil mix ratio will be expressed in the form of S:C:W wherein S is mass of soil solid, C the mass of cement and W the mass of water at the point of mixing. The cement content  $A_w$  is defined as the ratio of mass of cement to the mass of soil solid. The water content  $C_w$  is defined as the ratio of mass of water to the total mass of soil solid and cement. In this study, the cement content ranges from 20 to 50% by weight of soil solid while the water content ranges from 100 to 167% by weight of cement and soil solid. The fiber content is defined as the ratio of volume of fiber to the total volume of the mixture at the point of mixing, and ranges from 0 to 0.32%. The ductility of the fiber-reinforced cement-treated (FRCT) soil is designated herein by the brittleness index (BI), which is defined as the ratio of the peak strength to the strength at a prescribed post-peak strain.

The natural marine clay was first mixed with the prescribed amount of water to achieve 100% moisture content and remoulded. Cement slurry with the water-cement ratio needed to achieve the desired mix ratio was then added to marine clay in a Hobart Mixer and mixed at a rotational speed of 125rpm for around 5 minutes. The fiber was finally added to cement soil mixing and mixed for another 10 minutes. For mixtures with water content of 100%, the superplasticizer was used to improve their workability. The dosage of the superplasticizer was 1.13-2.27l/100kg soil+cement solids. The mixture was placed into a 50mm (diameter) by 100mm (height) cylindrical polyvinyl chloride (PVC) split-mould. No compaction was applied during placement. Specimens were then submerged in distilled water within their split-moulds without loading for curing. The specimens were then taken out after 7 days for unconfined compression testing. The test procedure followed those prescribed in ISO/TS 17892 (2004). The strain rate used for the unconfined compression test was 1.32%/min.

### 3 EXPERIMENT RESULTS AND ANALYSIS

#### 3.1 Stress strain behavior

Figure 1 shows the typical stress strain behavior of FRCT soil specimens under unconfined compression. Compared to purely cement-treated soil, fiber reinforcement increases the strength and ductility significantly, the ductility increasing with fiber content.

Figure 1. Stress strain behavior for FRCT soil specimens with 6mm long fiber. (a) 50% cement content and 100% water content; (b) 50% cement content and 167% water content.

#### 3.2 Effect of fiber content

Figures 2-3 present the effect of fiber content on peak strength and brittle index of FRCT soil specimens. As Figure 2a shows, for both PP and PVA reinforced specimens with mix ratio 2:1:3 (cement content 50%, water content 100%), the peak strength increases with fiber content until a certain fiber content (0.16-0.24%), after which it decreases slightly. A similar trend is also observed in Figure 2b for specimens with mix ratio 2:1:5 (cement content 50%, water content 167%).

Figure 2. Effect of fiber content on strength for FRCT soil specimens. (a) Specimens with mix ratio 2:1:3 (cement content 50%, water content 100%); (b) Specimens with mix ratio 2:1:5 (cement content 50%, water content 167%).

Figures 3a-3b show that the BI, evaluated at four different axial strain levels between 2% and 20%, reduces significantly with both PP and PVA fiber content for specimens with mix ratio 2:1:3. A similar trend is also observed from Figures 3c-3d for specimens with mix ratio 2:1:5. At higher fiber content, that is, higher than 0.32% for mix ratio 2:1:3 and 0.24% for mix ratio 2:1:5, the results were very scattered due to the poor workability of the mix, which can be observed in Figure 1b. Hence, with current mixing condition, the optimum fiber content, taking into account performance and workability, is 0.32% and 0.24% for specimens with mix ratio 2:1:3 and 2:1:5 respectively. For mix ratios 2:1:4, 20:7:27 and 5:1:6, the optimum fiber content is 0.24%.

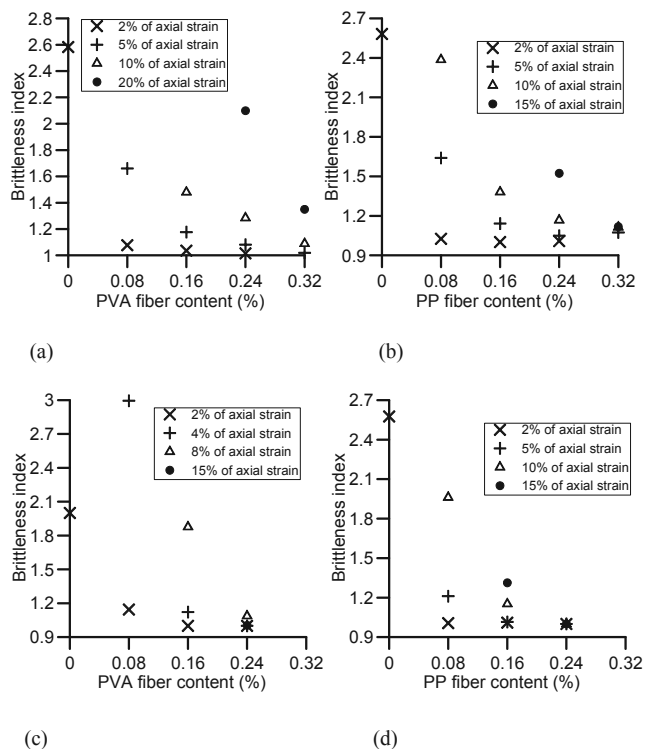

Figure 3. Effect of fiber content on ductility for FRCT soil specimens. (a) PVA reinforced specimens with mix ratio 2:1:3 (cement content 50%, water content 100%); (b) PP reinforced specimens with mix ratio 2:1:3 (cement content 50%, water content 100%); (c) PVA reinforced specimens with mix ratio 2:1:5 (cement content 50%, water content 167%); (d) PP reinforced specimens with mix ratio 2:1:5 (cement content 50%, water content 167%).

3.3 Effect of fiber length

For 12mm fiber reinforcement, 0.08% and 0.16% fiber content was used. It was found that 0.16% fiber reinforcement is much better than 0.08% fiber reinforcement (see Figure 4). Hence, only results of 0.16% fiber content were compared. Figure 5 presents the effect of fiber length on the strength and ductility of the FRCT soil. It can be seen from Figure 5a that for PVA-reinforced specimens, 12mm fiber confers distinctly higher strength than 6-mm fibers. For PP fibers, the difference in peak strength is small.

Figure 5b shows that for specimens with different mix ratio and a given type of fiber (PVA), longer fibers consistently give a lower BI than shorter fibers; the difference increasing with strain level. Similar trend is also observed in specimens reinforced by PP fibers. Therefore, the effect of fiber length on ductility of FRCT soil is significant for both PP and PVA fiber type.

Figure 4. Ductility of RFCT soil with 0.08% and 0.16% 12mm long fiber (50% cement and 100% water content).

(a) Comparison in peak strength for specimens with 50% cement content, 100%-167% water content, and 0.16% of 12mm or 6 mm long fiber (HL, HM, HH denote cement and water content, see Table 2).

(b) Brittleness versus strain for specimens with different mix ratio and 0.16% of 12mm or 6mm long fiber.

Figure 5. Effect of fiber length on strength and ductility for RFCT soil specimens.

3.4 Effect of fiber type

For simplicity and convenience, FRCT soil specimens are categorized in Table 2 according to their cement content and water content together with their performance at optimum fiber

content. As discussed in the previous section, the optimum short fiber content is 0.32% for mix ratio 2:1:3 while it is 0.24% for mix ratio 2:1:4, 2:1:5, 20:7:27 and 5:1:6. For long fiber, the optimum fiber content is 0.16%.

Figures 6-7 present the effect of fiber type on the strength and BI of the FRCA soil. It can be seen from Table 2 and Figure 6 that 12mm PVA fiber reinforcement always gives higher strength than 12mm PP fiber reinforcement due to PVA's higher strength. For water content at and below 133% and cement content not less than 35%, 6mm PVA fiber reinforcement gives higher strength than 6mm PP fiber reinforcement due to the same reason above. For low cement content (20%) and low water content (100%) or high cement (50%) and high water content (167%), short PP fiber gives slightly higher strength than short PVA fiber.

Table 2. Peak strength and BI of specimens with different mix ratios and fiber types, at optimum fiber content.

Mix proportion	2:1:3	2:1:4	2:1:5	20:7:27	5:1:6	
A <sub>w</sub> (%)	50	50	50	35	20	
C <sub>w</sub> (%)	100	133	167	100	100	
category	high A <sub>w</sub> , low C <sub>w</sub> (HL)	high A <sub>w</sub> , mid C <sub>w</sub> (HM)	high A <sub>w</sub> & C <sub>w</sub> (HH)	mid A <sub>w</sub> , low C <sub>w</sub> (ML)	low A <sub>w</sub> & C <sub>w</sub> (LL)	
Peak strength (kPa)	SF	1494 (PVA), 1240 (PP)	752 (PVA), 632 (PP)	386 (PVA), 405 (PP)	1053 (PVA), 874 (PP)	455 (PVA), 471 (PP)
	LF	1445 (PVA), 1354 (PP)	761 (PVA), 628 (PP)	403 (PVA), 313 (PP)	NA	NA
Ductility	SF	PVA>PP	PVA=PP	PVA=PP	PVA=PP	PVA<PP
	LF	PVA>PP	PVA=PP	PVA>PP	NA	NA
Performance	PVA>PP	PVA>PP	PVA ≈ PP (short) PVA>PP (long)	PVA>PP	PVA<PP	

Note: SF and LF denotes short and long fiber respectively

Figure 6. Effect of fiber type on strength of RFCT soil specimens with 20%-50% cement content, 100%-167% water content, 0.24-0.32% of 6mm long fiber or 0.16% of 12mm long fiber.

For 12mm fiber reinforcement, Figure 7a shows that for specimens with high cement content (50%) and low or high water content (100% or 167%), PVA fiber gives lower BI values at four different strain levels between 5%-25% than PP fiber. For specimens with high cement content and mid high water content (133%), no fiber type effect is observed. This may

be explained as below. For high cement content and low water content, there is stronger interaction between PVA fiber and cement-soil body due to PVA's higher strength, which results in higher ductility in long PVA fiber reinforced soil specimens. For high cement and water content, there is high PP fiber concentration due to PP's higher aspect ratio, which induces lower ductility in long PP fiber reinforced soil specimens.

For 6mm fiber reinforcement, Figure 7b shows that for low water content (100%) and high cement content (50%), PVA fiber gives lower BI values at four different strain levels between 2%-15% than PP fiber. For low cement content (20%) and low water content, PVA gives higher BI values than PP fiber. This suggests that short PP fiber interacts with cement-soil body better than PVA fiber of the same length, at low cement and water content. Figures 7b-7c also show that for mid-high cement (35%) and low water content or high cement and mid to high water content, fiber type effect is very small. Therefore, short PVA fiber generally gives ductility not lower than PP fiber except for low cement content and low water content.

(a) Brittleness index versus strain for 12mm long fiber reinforcement (fiber content, 0.16%).

(b) Brittleness index versus strain for 6mm long fiber reinforcement (low water content, 100%; cement content, 20%-50%; fiber content 0.24-0.32%).

(c) Brittleness index versus strain for 6mm long fiber reinforcement (mid to high water content, 133%-167%; high cement content, 50%; fiber content, 0.24%).

Figure 7. Effect of fiber type on ductility for RFCT soil specimens with 20%-50% cement content, 100%-167% water content, fiber cut length 6-12mm and 0.16-0.32% fiber.

In summary, as Table 2 shows, by considering of the strength and ductility of FRCT soil specimens, PVA fiber reinforcement is generally better than PP fiber except for low cement content and water content.

#### 4 CONCLUSIONS

Based on the results and analysis, the main conclusions may be drawn as below.

The strength and ductility of cement-treated marine clay was improved significantly by fiber reinforcement. There is optimum fiber content, considering performance and workability of cement-treated soil specimens. PVA fiber reinforcement is generally better than PP fiber reinforcement except for low cement content and water content.

It was observed that the fiber cut length has significant effect on the ductility of cement-treated soil. However, the cut length effect on strength for PP fiber reinforcement is much smaller than that for PVA fiber reinforcement.

# Large-scale Piled Raft with Grid-Form Deep Mixing Walls on Soft Ground

Comportement en vraie grandeur d'une fondation mixte radier-pieux établie dans un sol meuble amélioré par quadrillage de mélange profond de sol

Yamashita K., Wakai S., Hamada J.

*Research & Development Institute, Takenaka Corporation, Chiba, Japan*

**ABSTRACT:** This paper offers a case history of a large-scale piled raft supporting a twelve-story building founded on liquefiable sand underlain by soft cohesive soil in Tokyo. The building, 55.7 m in height above the ground surface and measuring 120 m by 100 m in plan, is a steel-framed structure with a base isolation system of laminated rubber bearings. An assessment of a potential of liquefaction during earthquakes indicated that the loose clayey sand between depths of 5 and 15 m had a potential of liquefaction during earthquakes with the peak horizontal ground acceleration of  $3.0 \text{ m/s}^2$ . Therefore, a piled raft combined with grid-form deep cement mixing walls was employed to cope with the liquefiable sand and also to reduce settlements of the soft cohesive soil below the sand. To confirm the validity of the foundation design, field measurements were carried out on the foundation settlements, the axial loads of the piles, the contact pressures between raft and soil and the pore-water pressure beneath the raft from the beginning of construction to 11 months after the end of construction.

**RÉSUMÉ :** Cet article présente une étude de cas en vraie grandeur d'une fondation mixte radier-pieux d'un bâtiment à douze niveaux construit à Tokyo. Cette fondation est établie dans une couche de sable liquéfiable reposant sur une couche de sol cohérent et meuble. Le bâtiment, qui fait 120 m par 100 m dans le plan et 55.7 m en hauteur au-dessus du sol, a une structure métallique en portiques. Il est isolé à sa base par un système d'appareils d'appui en élastomère fretté. Le potentiel de liquéfaction estimé du sable argileux entre 5 et 15 m de profondeur serait atteint sous une accélération horizontale maximum de  $3.0 \text{ m/s}^2$ . Pour pallier à ce phénomène et réduire le tassement de la couche sous-jacente de sol cohérent et meuble, une fondation mixte radier-pieux a été adoptée en combinaison avec l'amélioration, en forme de quadrillage, de la couche de sable par mélange profond. L'article discute le comportement de cette fondation sur la base d'une série de mesures sur site, qui se sont poursuivies depuis le début jusqu'à onze mois après la fin de la construction du bâtiment. Le dimensionnement de cette fondation est estimé convenable considérant les mesures de tassement, des forces axiales sur pieux, des contraintes sur le sol et de la pression de l'eau interstitielle sous le radier.

**KEYWORDS:** piled raft foundation, deep cement mixing wall, soft ground, field measurements, settlement, load sharing

## 1 INTRODUCTION

In recent years there has been an increasing recognition that the use of piles to reduce raft settlements can lead to considerable economy without compromising the safety and performance of the foundation (Poulos, 2001). Detailed investigations of many high-rise buildings founded on piled rafts in Germany have been carried out (Katzenbach et al. 2000). Piled raft foundations have been used for many buildings in Japan and the settlement and the load sharing between raft and piles have been carefully investigated for the selected buildings (Yamashita et al. 2011a; Yamashita et al. 2011b). It has become necessary to develop more reliable seismic design methods for piled rafts, particularly in highly seismic areas such as Japan.

This paper offers a case history of a large-scale piled raft supporting a twelve-story building founded on liquefiable sand underlain by soft cohesive soil in Tokyo. To cope with the liquefiable sand and also to reduce settlements of the soft cohesive soil below the loose sand, piled raft foundation combined with grid-form deep cement mixing walls was employed. To confirm the validity of the foundation design, field measurements were carried out on the foundation settlements, the axial loads of the piles, the contact pressures between the raft and soil and the pore-water pressure beneath the raft from the beginning of construction to 11 months after the end of construction. During the construction period, the 2011 off the Pacific coast of Tohoku Earthquake struck the site of the building. The effects of the earthquake on the settlement

and the load sharing between the raft and the piles are also discussed.

## 2 BUILDING AND SOIL CONDITIONS

The twelve-story office building is located in Tokyo, 0.3 km southeast from the twelve-story residential building (Yamashita et al., 2011b). Figure 1 shows a schematic view of the building and the foundation with a soil profile. The building, 55.7 m in height above the ground surface and measuring 120 m by 100 m in plan, is a steel-framed structure with a base isolation system of laminated rubber bearings. The foundation levels were between depths of 3.6 and 7.2 m.

The subsoil consists of an alluvial stratum to a depth of 44 m below the ground surface, underlain by a diluvial very dense sand. The ground water table appears approximately 3 m below the ground surface. The soil profile down to a depth of 15 m is made of fill which consists of loose clayey sand, sandy clay and rubble. Between the depths of 15 to 44 m, there lie very soft to medium silty clay which is slightly overconsolidated with an OCR of 1.3 or higher. The shear wave velocities derived from a P-S logging were 150 m/s at the foundation levels and 290 m/s in the dense sand below the depth of 44 m.

## 3 FOUNDATION DESIGN

Figure 1. Schematic view of the building and foundation with soil profile

### 3.1 Ground improvement

An assessment of a potential of liquefaction during earthquakes indicated that the loose clayey sand between the depths of 5 to 15 m had a potential of liquefaction during earthquakes with the peak horizontal ground acceleration of  $3.0 \text{ m/s}^2$ . The foundation level was between depths of 3.6 and 7.2 m, therefore, grid-form deep cement mixing walls were introduced to cope with the liquefiable clayey sand below the raft. Figure 2 shows the grid-form deep cement mixing walls constructed by TOFT method. The high-modulus soil-cement walls confine loose sand so as not to cause excessive shear deformation to the loose sand during earthquakes. The effectiveness of the TOFT method for the prevention of liquefaction was confirmed during the 1995 Hyogoken-Nambu earthquake (Tokimatsu et al., 1996).

### 3.2 Design of piled raft

The average contact pressure over the raft is 187 kPa. To improve bearing capacity of the raft, the grid-form deep cement mixing walls were extended to the depth of 20 m with the bottom being embedded in the silty clay with undrained shear strength of 100 kPa or higher. Furthermore, to reduce the settlement and the differential settlement to an acceptable level, 180 pre-tensioned spun high-strength concrete (PHC) piles of 0.6 to 1.2 m in diameter were used. The pile toes were embedded in the very dense sand below the depth of 44 m enough to ensure the toe resistance as well as the frictional resistance. The pile was constructed by inserting the precast piles into a pre-augered borehole filled with mixed-in-place soil cement. Figure 3 shows a layout of the piles and the grid-form deep cement mixing walls.

## 4 INSTRUMENTATION

The locations of the monitoring devices are shown in Figs. 3 and 4. Four piles, P1, P2, P3 and P4, were provided with a couple of LVDT-type strain gauges at depths of 8.5 m (near pile head), 20.0 m and 47.0 m (near pile toe) from the ground

Figure 2. Grid-form deep cement mixing method

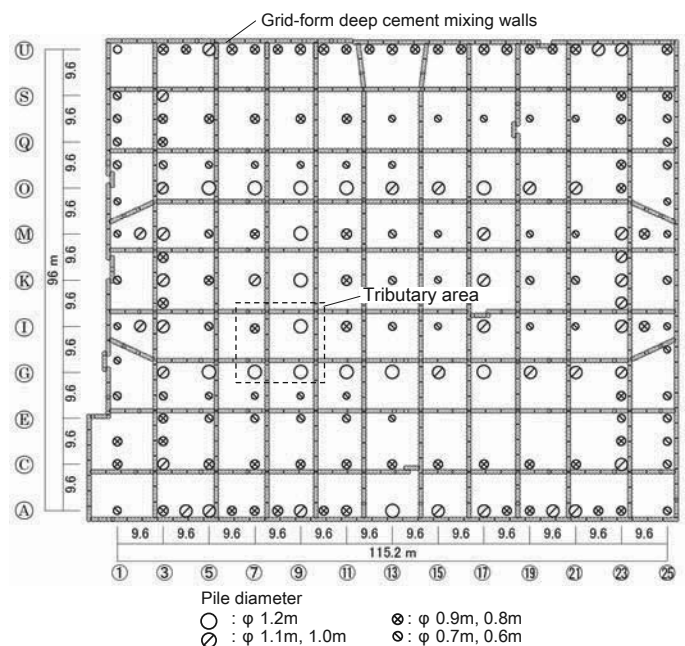

Figure 3. Layout of piles and grid-form deep cement mixing walls

surface. In the tributary area of the instrumented piles, six earth pressure cells and one piezometer were installed beneath the raft at the depth of 7.2 m. Earth pressure cells E1-E3 were installed on the intact soil and earth pressure cells D1-D3 were installed on the deep mixing walls. The vertical ground displacements below the raft were measured by differential settlement gauges. LVDT-type transducers were installed beneath the raft at depths of 8.5 m, 14.0 m, 20.0 m, 35.0 m and 50.0 m to measure the relative displacements to a reference point at a depth of 60.0 m. The settlements of the foundation were measured at the monitoring points on the raft by an optical level. The measurement of the vertical ground displacements was begun during the excavation for the foundation construction. The measurement of the axial loads of the piles, the contact pressures and the pore-water pressure beneath the raft was begun just before the casting of the 0.6-m thick foundation slab.

## 5 RESULTS OF MEASUREMENTS

### 5.1 Foundation settlement

Figure 5 shows the measured vertical ground displacements below the raft. The measured ground displacement at the depth of 8.5 m after the casting of the foundation slab, was approximately equal to the foundation settlement. The foundation settlement increased considerably just before the end of construction (November 15, 2011) due to the water pouring into the underground pits. Thereafter, the foundation settlement became stable and reached 21 mm 11 months after the end of construction (November 3, 2012). Figure 6 shows the settlement profile of the raft measured by the optical level just before the end of construction. The measured settlements were 12 to 24 mm and the maximum angular rotation of the raft was 1/1400 radian which satisfied the design requirements.

### 5.2 Pile load and contact pressures

Figure 7 shows the development of the measured axial loads of piles P1-P4. The axial loads also increased considerably just before the end of construction due to the water pouring. Thereafter, the pile-head loads reached 4.7-11.2 MN in November, 2012. Figure 8 shows the distribution of the measured axial loads on pile P1. Since the piles were surrounded by the deep mixing walls to a depth of 20.0 m, the skin friction of the pile shaft between the depths of 8.5 m and 20.0 m was quite small. The average skin friction between the depths of 20.0 m and 47.0 m was 76 kPa. The ratio of the pile-toe load to the pile-head load was 0.21 in November, 2012. Figure 9 shows the development of the measured contact pressures between the raft and the soil and the pore-water pressure beneath the raft. The measured contact pressures between the raft and the intact soil seemed to reach a state of equilibrium in early stage of the construction, while those between the raft and the deep mixing walls increased with construction loading in the same way as the axial loads of the piles. The measured contact pressures between the raft and the deep mixing walls were 137-180 kPa and those between the raft and the intact soil were 66-72 kPa just before the end of construction. The measured pore-water pressure was approximately 40 kPa.

### 5.3 Load sharing between raft and piles

Figure 10 shows the time-dependent load sharing among the piles, the soil, the deep mixing walls and the buoyancy in the tributary area of the instrumented piles shown in Fig. 4. The sum of the measured pile-head loads and the raft load in the tributary area varied from 61.3 to 62.0 MN after the end of construction, which was generally consistent with the design load of 64.0 MN. Figure 11 shows the ratios of the load carried

(b) Axial loads of pile P1

Figure 7. Measured axial loads of piles

by the piles to the effective load and that to the total load in the tributary area versus time. The ratio of the load carried by the piles to the effective load was estimated to be 0.70 just before the end of construction and increased only slightly to 0.71 in November, 2012. Meanwhile, the ratio of the effective load carried by the deep mixing walls to the effective load was 0.14 and the ratio of that carried by the intact soil to the effective load was 0.15 in November, 2012.

#### 5.4 Effects of earthquake on settlement and load sharing

On March 11, 2011, nine months before the end of construction, the 2011 off the Pacific coast of Tohoku Earthquake struck the site of the building. At the site of the twelve-story residential building, the peak horizontal ground acceleration of  $1.75 \text{ m/s}^2$  was observed (Yamashita et al. 2012). Although the contact pressures between the raft and the deep mixing walls were increased markedly as shown in Fig. 9(a), no significant changes in the foundation settlement or the load sharing between the raft and the piles were observed after the earthquake, as shown in Figs. 5 and 11.

### 6 CONCLUSIONS

Field measurements were carried out on the foundation settlement and the load sharing between the raft and the piles for the large-scale piled raft with the grid-form deep cement mixing walls on soft ground in Tokyo. The foundation settlement reached 21 mm and the ratio of the load carried by the piles to the effective load in the tributary area was estimated to be 0.71 11 months after the end of construction. During the construction period, the 2011 off the Pacific coast of Tohoku Earthquake struck the site of the building. Based on the measurement results, no significant changes in the foundation settlement or the load sharing were observed after the earthquake. Consequently, it is confirmed that a large-scale piled raft, combined with grid-form deep mixing walls, works effectively in grounds consisting of liquefiable sand and soft cohesive soil.

### 7 ACKNOWLEDGEMENTS

The authors are grateful to Messrs. H. Matsuzaki, H. Nagaoka of Takenaka Corporation and Mr. N. Nakayama (formerly of Takenaka Corporation) for their contribution to the foundation design.

**ABSTRACT:** While Portland cement (PC) is the most widely used binder for soil stabilisation, there are significant environmental impacts associated with its production in terms of high energy consumption and CO<sub>2</sub> emission. Hence, the development of new low carbon foot-print alternative cements has been encouraged. In this paper, reactive magnesia (MgO) was used as a soil stabilisation binder and the MgO-stabilised soils were carbonated by gaseous CO<sub>2</sub> to improve the mechanical properties of the soil and reduce the CO<sub>2</sub> emission. The mechanical and microstructural properties of the carbonated MgO stabilised soils were investigated by using unconfined compressive testing, x-ray diffraction (XRD) and scanning electron microscopy (SEM). The results showed that the strength development rates of carbonated MgO-stabilised soils were much faster than those PC- and MgO-stabilised soils, and the unconfined compressive strength of highly carbonated MgO-stabilised soils was close to that of 28-day ambient cured PC-stabilised soils. The XRD and SEM results indicated that nesquehonite (MgCO<sub>3</sub>·3H<sub>2</sub>O) was the main product of the carbonated MgO-stabilised soils and responsible for the significant strength development.

**RÉSUMÉ :** Alors que le ciment Portland est le liant le plus utilisé pour la stabilisation des sols, il y a d'importants impacts environnementaux associés à sa production en termes de consommation d'énergie élevée et d'émission de CO<sub>2</sub>. Par conséquent, le développement de nouveaux ciments alternatifs à basse teneur en carbone a été encouragé. Dans cet article, la magnésie réactive (MgO) a été utilisée comme liant pour la stabilisation des sols et les sols stabilisés à la magnésie ont été carbonatés par du CO<sub>2</sub> gazeux afin d'améliorer les propriétés mécaniques des sols et de réduire les émissions de CO<sub>2</sub>. Les propriétés mécaniques et microstructurelles des sols stabilisés à la magnésie et carbonatés ont été étudiées en utilisant des essais de compression simples, la diffractométrie de rayons X (DRX), et la microscopie électronique à balayage (MEB). Les résultats montrent que le développement de la résistance des sols stabilisés à la magnésie et carbonatés était beaucoup plus rapide que celui du ciment Portland avec prise à l'air ambiant et celui des sols stabilisés à la magnésie. Ils ont également montré que la résistance à la compression uniaxiale des sols stabilisés à la magnésie et carbonatés était proche de celle des sols stabilisés au ciment Portland avec prise à l'air ambiant pendant 28 jours. Les résultats des DRX et MEB ont indiqués que la nesquehonite (MgCO<sub>3</sub>·3H<sub>2</sub>O) était le produit principal des sols stabilisés à la magnésie et carbonatés, et responsable de la forte augmentation de la résistance.

**KEYWORDS:** soil stabilisation, reactive MgO, carbonation, unconfined compressive strength, microstructure.

## 1 INTRODUCTION

Soil-cement mix technology is one of the most widely used ground improvement methods, with Portland cement (PC) being the most commonly employed binder (Sherwood 1993, Bergado et al. 1996, Al-Tabbaa, 2003). However, there are significant environmental impacts associated with the production of PC in terms of high energy consumption and CO<sub>2</sub> emissions (0.85t CO<sub>2</sub>/t PC), and hence is responsible for 5-8% of anthropogenic CO<sub>2</sub> emissions worldwide (WBCSD, 2002; IPCC, 2004).

In order to reduce the usage of PC, new alternative cements have been encouraged. Reactive magnesia (MgO) cements recently emerged as a more sustainable alternative to PC (Harrison 2008). Reactive MgO is generally calcinated from magnesite (MgCO<sub>3</sub>) at temperatures of ~700-800°C and should not be confused with dead burned MgO manufactured at a temperature higher than 1400°C, which is known to cause an unsoundness problem in PC due to its delayed hydration behavior (Shand, 2006).

Extensive research has been conducted at the University of Cambridge since 2004 into the reactive MgO cements, as detailed in Al-Tabbaa (2013). Reactive MgO hydrates, much faster than dead burned MgO, to form brucite (Mg(OH)<sub>2</sub>). Although brucite has a very limited binding ability, it could carbonate to form one or more of the hydrated magnesium carbonates, namely nesquehonite (MgCO<sub>3</sub>·3H<sub>2</sub>O), hydromagnesite (Mg<sub>5</sub>(CO<sub>3</sub>)<sub>4</sub>(OH)<sub>2</sub>·5H<sub>2</sub>O) and/or dypingite

(Mg<sub>5</sub>(CO<sub>3</sub>)<sub>4</sub>(OH)<sub>2</sub>·4H<sub>2</sub>O). The hydration of MgO and carbonation of brucite both are expansive reactions, which significantly fill available pores. These hydrated magnesium carbonates also form well ramified networks of massive crystals with a very effective binding ability resulting in substantial and rapid strength increase. For example, in porous construction blocks, they significantly outperformed corresponding PC blocks with strengths of 200-300% higher (Liska 2009; Unluer 2012). High levels of carbonation have been achieved in full-scale porous blocks trial production (Liska et al. 2012a and b), reabsorbing most of the CO<sub>2</sub> generated during the decomposition of the magnesite.

In this paper, reactive MgO was initially used as a soil stabilisation binder and the MgO-soil samples were carbonated by CO<sub>2</sub> gas to improve the mechanical properties of the soil and reduce the CO<sub>2</sub> emission. This initial work is thereafter complemented by investigating the impact of relevant variables including soil type, soil water content, binder content and carbonation method (Yi et al., 2012), as well as by using a laboratory-scale auger to model the installation of carbonated soil-MgO deep mixed columns (Yi et al. 2013).

## 2 MATERIALS AND METHODS

### 2.1 Binders, soils and sample preparations

A model soil was used, namely a slightly clayey silty sand, consisting of 90% sharp sand, 5% kaolin clay and 5% silica flour. The sharp sand (obtained from Ridgeons, Cambridge, UK), had a D<sub>50</sub> of 0.8 mm and coefficient of uniformity of 4.3, and the kaolin clay (obtained from Richard Baker Harrison, Ilford, UK) had a liquid limit of 51% and plastic limit of 30%. The silica flour was obtained from David Ball Group, Cambridge. The water content of the soil was 10%. Reactive MgO (obtained from Richard Baker Harrison, Ilford, UK) and PC (obtained from Castle Cement, UK) were applied at 13% dry content to the soil. The reactive MgO had the following oxide composition: MgO: 97.2%, CaO: 1.2%, SiO<sub>2</sub>: 1.2%, Al<sub>2</sub>O<sub>3</sub>: 0.2% and Fe<sub>2</sub>O<sub>3</sub>: 0.2%, while the PC had: CaO: 63.6%, SiO<sub>2</sub>: 13.6%, Al<sub>2</sub>O<sub>3</sub>: 10.2%, Fe<sub>2</sub>O<sub>3</sub>: 2.7%, SO<sub>3</sub>: 6.9%, MgO: 0.6% and K<sub>2</sub>O: 0.9%.

The sharp sand, kaolin clay and silica flour were initially mixed and homogenised for 5 minutes in a bench-top food mixer after which water was added and the mixing continued for further 5 minutes. The MgO was then applied to the model soil and the entire system was then mixed twice for 5 minutes with an inspection inbetween the two intervals. The homogenised mix was then placed in cylindrical moulds, with 50 mm diameter and 100 mm height, applying consistent moderate compaction in three layers by rodding and eliminating any trapped air pockets. The samples were demoulded ~1 hour later, then placed in the triaxial apparatus and subjected to the carbonation procedures detailed below. A subset of MgO and PC stabilised samples was also cured in their moulds under “ambient” conditions, of 20±2°C and 95±3% relative humidity, for 1, 7, 28 and 90 days.

### 2.2 Carbonation procedure and testing

A triaxial apparatus was used to permeate pressurised gaseous CO<sub>2</sub> through the MgO-treated soil as shown in Figure 1. The samples were subjected to 400 kPa confining pressure and then followed by upward permeation of the gaseous CO<sub>2</sub>. First, the CO<sub>2</sub> outflow tap was open during the carbonation process, and the inflow CO<sub>2</sub> pressure was maintained at a low value of 20 kPa to reduce leakage. However, the CO<sub>2</sub> leakage was still serious, and hence only four carbonation periods were conducted using this method, which were 0.75, 1.5, 3 and 6 hours. Thereafter, the carbonation process was modified: the CO<sub>2</sub> outflow tap was closed two minutes after turning on the CO<sub>2</sub> inlet while keeping the inlet open therefore maintaining the CO<sub>2</sub> pressure at the 200 kPa level for the designated carbonation periods: 0.75, 1.5, 3, 6, 12, 24, 48 and 96 hours. Besides, a subset of samples carbonated for 24 hours using this method was then cured under ambient conditions for 7, 28 and 90 days.

Figure 1. The triaxial cell used for MgO-stabilised soil carbonation.

In addition, an incubator, with 20% CO<sub>2</sub> concentration (1 bar) at 20±2°C and relative humidity of 95±3%, was also used to carbonate MgO-stabilised soils for comparison purposes. The carbonation periods were 12, 24, 48, 96 and 168 hours (7 days). A subset of samples carbonated for 7 days using this method were then cured under ambient conditions for 28 and 90 days.

All the samples were tested in triplicate for their unconfined compressive strength (UCS) at a constant displacement rate of 1.14 mm/min. X-ray diffraction analysis (XRD) and scanning electron microscopy (SEM) were conducted for selected mixes.

## 3 RESULTS AND DISCUSSIONS

### 3.1 Unconfined compressive strength

Figure 2 shows the UCS of MgO-stabilised soils carbonated using different carbonation methods. The MgO-stabilised soils carbonated in an incubator, which is generally used to carbonate the MgO-based construction blocks (Liska 2009; Unluer 2012), took ~96 hours of carbonation to reach a maximum UCS value (~8 MPa). While those carbonated in triaxial cell with 200 kPa CO<sub>2</sub> stationary showed similar strength development behavior but with much faster rate, whereby after ~3 hours the stabilised soil also reached a similar maximum UCS value. The UCS of the MgO-stabilised soils carbonated in triaxial cell with 20 kPa CO<sub>2</sub> flow through for 45 minutes was much lower than those with 200 kPa CO<sub>2</sub> stationary, mainly due to the lower CO<sub>2</sub> pressure of the former (Yi et al. 2012). However, the attained strength is approximately the same regardless of the CO<sub>2</sub> pressure applied and its concentration. Figure 2 indicates that there is no need to keep the CO<sub>2</sub> flowing through the sample during the carbonation process, which causes CO<sub>2</sub> leakage.

Figure 2. UCS of MgO-stabilised soils carbonated in incubator, triaxial cell with 20 kPa CO<sub>2</sub> flow through and 200 kPa CO<sub>2</sub> stationary.

Figure 3 presents the UCS of uncarbonated MgO- and PC-stabilised soils and carbonated MgO-stabilised soils cured under ambient conditions. It is evident that the UCS values of the uncarbonated MgO-stabilised soil are much lower than those PC-stabilised soils, and both of the two mixes took ~28 days to finish most of their strength development. Comparing of Figure 2 and Figure 3 indicates that the carbonation significantly increased the UCS of MgO-stabilised soils in a very short time, and the UCS of highly carbonated MgO-stabilised soils was close to that of the 28-day PC-stabilised soils, which was ~10 times that of 28-day uncarbonated MgO-stabilised soils. However, the ambient curing period did not affect the strength of carbonated MgO-stabilised soil significantly, indicating the carbonated MgO-stabilised soil could be used to support a structure just after the completion of the carbonation procedure.

This is confirmed by the results of laboratory-scale auger installed soil-MgO deep mixed columns (Yi et al. 2013).

Figure 3. UCS of uncarbonated MgO- and PC-stabilised soils and carbonated MgO-stabilised soils versus ambient curing period.

### 3.2 X-ray diffraction

Figure 4 shows the XRD diffractograms of the MgO-stabilised soils ambient cured for 28 days (uncarbonated) and carbonated in incubator for 12 hours and 7 days, the MgO-stabilised soils carbonated in triaxial cell with 20 kPa CO<sub>2</sub> flow through for 45 minutes, 3 hours and 6 hours, as well as the MgO-stabilised soils carbonated in triaxial cell with 200 kPa CO<sub>2</sub> stationary for 45 minutes, 3 hours and 4 days. Two strong brucite (Mg(OH)<sub>2</sub>) peaks and a weak MgO peak are detected for the 28-day ambient cured MgO-stabilised soil (Figure 4a). For the carbonated samples, the disappearance of the brucite peak together with the gradually weakening of the MgO peak suggest the carbonation of the MgO resulting in the formation of nesquehonite (MgCO<sub>3</sub>·3H<sub>2</sub>O). With no other changes in the mineralogy, this correlates with the rapid and significant strength development of carbonated MgO-stabilised soils.

Additionally, the MgO peak was detected in all the carbonated MgO-stabilised soils, including those carbonated in an incubator for 7 days and in a triaxial cell with 200 kPa CO<sub>2</sub> stationary for 4 days, which were much stronger than that in the 28-day ambient cured sample. These results indicated that the water content (10%) was not enough for all the MgO (13%) to carbonate to form nesquehonite. Hence the MgO content should be linked to the water content of the soil, as well as its porosity.

Figure 4. XRD diffractograms of MgO-stabilised soils: (a) ambient cured for 28 days and carbonated in incubator; (b) carbonated in triaxial cell with 20 kPa CO<sub>2</sub> flow through; and (c) carbonated in triaxial cell with 200 kPa CO<sub>2</sub> stationary. The abbreviations stand for: B-Brucite, C-Calcite, Mg-MgO, N-Nesquehonite, Q-Quartz.

### 3.3 Scanning electron microscopy

Typical SEM micrographs of the MgO-stabilised soils ambient cured for 28 days (uncarbonated), carbonated in triaxial cell with 200 kPa CO<sub>2</sub> stationary for 45 minutes and 4 days, as well as that carbonated in an incubator for 7 days are shown in Figure 5.

The 28-day ambient cured sample (Figure 5a) exhibits the presence of brucite, which has a very limited binding ability due to its poorly interconnected structure (Liska 2009; Unluer 2012). All the carbonated MgO-stabilised soils (Figure 5b, c and d) display formation of nesquehonite, consistent with the XRD results. Besides, brucite was also observed in Figure 5b confirming that there was only partial carbonation at 45 minutes, and which then disappeared at 4 days (Figure 5c) confirming that the carbonation proceeded to a high degree.

(a)

(b)

(c)

(d)

Figure 5. Scanning electron micrographs of the MgO-stabilised soils: (a) ambient cured for 28 days (uncarbonated); carbonated in triaxial cell with 200 kPa CO<sub>2</sub> pressure for (b) 0.75 hours and (c) 4 days; (d) carbonated in incubator for 7 days.

#### 4 CONCLUSION

The results showed that the carbonation significantly increased the strength of MgO stabilised soil, and the UCS of highly carbonated MgO stabilised soil was close to that of the 28-day ambient cured PC-stabilised soil, which was ~10 times that of 28-day uncarbonated ambient cured MgO-stabilised soil. The carbonation of MgO stabilised soil in the triaxial cell with high CO<sub>2</sub> pressure happened much faster than in the incubator, the former could be finished in a few hours while the latter took a few days. Dissimilar to the uncarbonated ambient cured MgO- or PC-stabilised soil, the UCS of highly carbonated MgO stabilised soil did not increase with ambient curing period. The XRD and SEM results indicated that nesquehonite, one of the hydrated magnesium carbonates, was the main product of the carbonated MgO in soil.

#### 5 ACKNOWLEDGEMENTS

The experimental work presented in this paper was carried out at the Geotechnical & Environmental Laboratory, Department of Engineering, University of Cambridge, in the academic year 2009-2010 when the first author was a visiting researcher there. The funding from CSC, NSSFC (51279032) and MOST (2012BAJ01B02-01) of China is gratefully acknowledged. The authors sincerely appreciate the French abstract translation by Marine Deruelle.

**ABSTRACT:** This paper contains the research findings of reinforced soil cement properties manufactured by drilling mixing method. Application of soil cement for solution of specific geotechnical problems is considered herein in terms of specific examples. In the field of coastal geotechnical engineering the hybrid coastal hydraulic engineering structures and sheet piling using reinforced concrete semi-shells have been developed. Full-scale physical simulation of pressing-in and removal of steel piles is carried out using a modular coordination pile-pressing system.

**RÉSUMÉ :** Cet article présente les résultats de l'étude des caractéristiques de matériau renforcé sol-ciment fabriqué par forage et mélange en place. L'utilisation de mélange sol-ciment pour la résolution de certains problèmes géotechniques est considérée à partir d'exemples précis. Dans le domaine de la géotechnique côtière, des ouvrages mixtes côtiers et maritimes ont été construits, ainsi que des pieux à rainures, fabriqués en utilisant des demies coques en béton armé. La simulation physique à grande échelle des processus d'enfoncement et d'extraction des pieux en acier est réalisée par application d'un système de coordination modulaire d'enfoncement des pieux.

**KEYWORDS:** soil cement, drilled pile, roll displacement of buildings, pile-pressing system.

## 1 DRILLED PILES IN UNSTABLE SOILS

Drilled piles installation in unstable soils is specified by conditions to secure wellbore stability prior to concrete placing. We know some well-drilling methods in such soils under protection of well casing being removed at concrete placing or under drilling mud protection followed by underwater concreting. SOLETANCHE METHOD of drilled piles installation is now very much in evidence as well. It involves the cored screw dipping into the soil to the projected drilling depth and feeding of concrete mixture through such screw under pressure with simultaneous screw lifting.

However the aforesaid methods have their faults, specifically:

- application of well casings results in considerable increasing of works costs, and in some cases it's not possible to remove well casings. Moreover floated soil may escape from drill hole into the well casing thus damaging neighboring buildings and constructions;
- the way to install reinforcement cage into the piles manufactured by SOLETANCHE technology seems rather problematic, whereas drifting sand penetration to the drill hole at drilling is not improbable;
- drilling under the drilling mud and underwater concreting prevents floated soil escaping into the well casing, but on the other hand, makes material quality control more complicated and increases labor intensity.

Mixed technology of drilled piles manufacturing provides primarily manufacturing of soil-cement elements (SCE) with dia. 0.8-1.2 m using drilling mixing method or jet method (Van Impe 2005, Bruce 2000, Larsson 2003). As soon as the soil concrete reaches 30% of its rated capacity, a well hole shall be drilled along the element's center line up to the projected drilling depth, so that the width of a soil concrete shell around it amounted to 150 mm. It serves to protect a drill hole against ingress of water and/or unstable soil for a specific period. Reinforcement cage is mounted in a dry drill hole and the concreting is performed.

The soil cement shells also provide increasing of bearing capacity of composite drilled piles at vertical and horizontal load actions owing to SCE which provide the contact surface between a pile and the soil.

The development works for manufacturing of 8 meter long composite drilled piles were carried out in conditions of bedding of water-saturated loess clay soils.

The following factors were determined in process of the research conducted:

- prism strength and concrete content in soil cement in the samples taken from the pile shaft after 28 days of concrete damp curing ( $\sigma$ , mPa),
- SCE diameter (D, mm),
- drill well cross section in SCE (D', mm),
- availability of loose soil cement in drill hole bottom
- drill hole water flow 2 hours prior to surveillance (h, mm),

- concrete content in soil cement using method of estimation of part of hydrated cement as for the time of research conducting ( $\Delta$ , %),
- visual inspection of reinforcement cage mounting,
- testing of concreting sampling.

Four average piles were selected from a pile field consisting of 256 piles, which data are specified in Figure 1 (1 – fill-up ground, 5-6 – flow loamy soils, 7 – semisolid clays) and in Table 1.

Figure 1 – Composite pile diagram: 1 – soil cement shell, 2 – cast-in-place reinforced concrete pile, 3 – reinforcement cage.

Table 1. Test piles installation indices

No	$\sigma$ , mPa	D, mm	$\Delta$ , %	D', mm	h, m
1	3.4	801	22	512	0.1
2	3.7	786	21.4	524	0.05
3	3.2	790	20	518	-
4	3.5	793	20.6	510	0.1

Findings of pilot works related to installation of composite drilled piles in soil cement shells testifies the following:

- soil cement elements buried in the clay-pans correspond to the design size and properties. In 7 days after their installation they can be lightly drilled and hold wellbore walls in flow clay-bearing soils;
- up to 10 cm of loose soil cement remains in drill holes and can be compacted using earth rammer and impregnated with fluid soil cement;
- drill hole water flow makes ca. 20l per hour, what just insignificantly influences the results of drill hole concreting;
- reinforcement cage mounting and drill hole concreting can be easily performed.

## 2 SOIL CEMENT PILES

Prism strength of soil cement manufactured by drilling mixing method or jet method without using of reinforcing chemical additives makes 1,5...4 mPa depending on water and cement content (M. Zotsenko, Yu. Vynnykov, 2011). In many instances such material strength seems insufficient for manufacturing of underground supporting frames, so there is a necessity to increase the soil cement strength.

This problem can be solved having applied reinforcing of soil cement structures with steel reinforcement. Correspondence of thermal-expansion coefficients of these materials apart from rather high grip of reinforcement on soil cement as well as its high waterproofing capacity is deemed to be the ground for collaboration of soil cement and steel reinforcement.

Effect of reinforcement on soil concrete strength was studied in vitro by testing of pile models of scale 1:4. Models dimensions made up 100 x 100 x 400 mm (Fig. 2). 4 series each per 6 samples were investigated. Samples of the first series were not reinforced, while the samples of the following series were reinforced 1,13%, 2,03% и 3,14% ( $P_r$ ,%) correspondingly. End surfaces of reinforcement cages were equipped with supporting plates with longitudinal reinforcement bars rigidly fastened thereto. Reinforcement protective coating made 20 mm.

Figure 2. Axial compression testing of test samples

Soil cement was produced in vitro using the drilling mixing method, i.e. no stabilization of loess soil-water-cement mixture was carried out. M400 Portland cement content amounted to 20% by weight of soil skeleton. The soil-water-cement ratio with consideration for soil natural humidity made up W/C (Water/Cement) = 2.7. At that its slump of concrete cone flowability amounted to 11 cm.

Properties of constructive materials used in the above experiment are shown in Table 2.

Table 2. Materials mechanical properties

Reinforcement properties		Soil cement properties	
$E_s$ , mPa	$R_{sc}$ , mPa	$E_s$ , mPa	$R_b$ , mPa
210000	225	2000	1.12

All samples were subject to the axial compression test, during which the average values of their bearing capacity were determined, see Table 3.

Table 3. Values of bearing capacity of soil cement prisms

Series No.	Section reinforcement percent $\mu$ , %	Average values of bearing capacity N, kN	Coefficient of variation, v
1	0.00	11.20	0.21
2	1.13	42.50	0.19
3	2.01	62.70	0.17
4	3.14	84.00	0.18

Definition of bearing capacity of steel soil cement prisms by materials was performed using two methods to select the most acceptable one for calculation of structural analysis of steel soil cement structures.

The first method of testing the axially loaded elements' strength with given dimensions, reinforcement quantity and loads is equated as

$$N = \varphi(R_b A + R_{sc} A_{s,tot}), \quad (1)$$

where  $N$  is a required axial force;  $\varphi$  – coefficient equal to 0,92 in this case;  $R_b$  – prism strength of soil cement;  $A$  – normal prism section area of 0,01 m<sup>2</sup>;  $R_{sc}$  – reinforcement rated compressing strength equal to 225 mPa;  $A_{s,tot}$  – total area of main reinforcement.

Rated values of abovementioned indices, as well as model bearing capacity and expected bearing capacity of full-scale piles are shown in Table 4.

Table 4. Bearing capacity of soil cement prisms and piles by materials (using the first calculation method)

Series No.	$\rho_f$ , %	$A_{s_s}$ , mm <sup>2</sup>	$N$ , kN	$N$ , kN full-scale pile
1	0.00	0	11.20	179
2	1.13	113	33.70	661
3	2.01	201	51.91	1019
4	3.14	314	75.30	1478

The second method constitutes the method of calculation of oblique loaded reinforced concrete elements in accordance with deformation model in the stress-strain state in its supercritical stage. Axial compression figures its special case. Dynamic pile formula for definition by material of standard cross-section is given by

$$N_U = A_b \left[ AR_b \eta_U + \frac{R_b \eta_U (K - \eta_U)}{1 + (K - 2)\eta_U} \right], \quad (2)$$

where  $A$ ,  $\eta_U$ ,  $K$  are bearing capacity coefficients.

Table 5 illustrates the bearing capacity of steel soil cement prisms and expected bearing capacity of soil cement piles.

Table 5. Bearing capacity of soil cement prisms and full-scale piles (determined by the second method)

Series Nos.	$A$	$\eta_u$	$K$	$N_u$ , kN	$N$ , kN, full-scale piles
1	0	1	1.70	11.20	179
2	1.54	1.40	1.70	32.20	635
3	2.73	1.60	1.70	52.41	1033
4	4.27	1.79	1.70	81.68	1616

Figure 3 contains relationship: bearing capacity of steel soil cement samples – ratio of standard cross-section reinforcement. It also contains relationships determined analytically according to the aforementioned methods.

Figure 3. Relationship between bearing capacity of soil cement piles by material  $N$  and ratio of standard cross-section reinforcement  $\rho_f$  based on the following data: 1 – calculation by the first method, 2 – calculation by the second method, 3 – according to in vitro data.

On basis of the research performed it may be concluded as follows:

- Application of longitudinal reinforcement enables to considerably increase the soil cement strength;
- Comparison of data of analytical calculations of soil cement strength with in vitro data showed that the described methods of reinforced concrete structures calculation can be used for calculation of steel soil cement structures strength;
- As for the two above calculation methods the calculation according to the deformation model shall be given preference, since it is aimed at calculation of structures at combined loading. Moreover this method seems to be less sensitive to soil cement parameter variability.

### 3 USE OF SOIL CEMENT FOR REGULATION OF SETTLEMENT SPEED OF BUILDINGS AT RECTIFYING THEIR ROLL DISPLACEMENT

The method of soil drilling out from bottom of less subsided foundations for rectifying of roll displacement of buildings is widely used in Ukraine. For this purpose underworking of the bottom with help of horizontal drill holes of variable diameters is usually performed (V. Shokarev, V. Shapoval, 2009).

Technological parameters calculation for underworking of soil under foundation (diameter and pitch of drill holes) is carried out by formula

$$S = d \cdot t, \quad (3)$$

where  $S$  is the required settlement for rectifying of roll displacement of a building;  $d$  – drill hole diameter;  $t$  – pitch of a drill hole.

Possessing the research findings related to changing of zero-air dry unit weight ( $\rho_d$ ) under bottom of foundation and experimental data on critical density of soil ( $\rho_{cr}$ ) – vertical pressure relationship we can determine the soil layer depth, where drilling of horizontal drill holes and soil structure destruction will be carried out

$$h = \frac{S}{1 - \rho_d / \rho_{cr}}. \quad (4)$$

Time of conditional stabilization of building's settlement shall be determined by formula

$$T = \frac{tg \rho}{V}, \quad (5)$$

where  $V$  is the value of conditional stabilization equal to 0.143 cm per day.

Influence coefficient  $tg \rho$  shall be determined by quotation

$$tg \rho = \frac{S - S_1}{\ln t / t_1}, \quad (6)$$

where  $S$ ,  $S_1$  means the value of building's settlement received according monitoring data;  $t$ ,  $t_1$  means time interval between monitoring stages.

If stabilization of building's settlement during rectifying of its roll displacement takes place prior to fulfillment of required settlement, additional breaking up of soil under foundation bottom shall be necessary. In order to forecast the time of stabilization of building's settlement after fulfillment of required settlement the soil cement mortar using drilling mixing technology shall be fed to the foundation bottom. It allows to reduce the building's settlement speed and to achieve the required value.

#### 4 INNOVATIVE SOLUTIONS FOR COASTAL HYDRAULIC ENGINEERING

A new structure of the retaining wall has been worked out to provide, firstly, resistance to heavy loads stipulated by soil pressure behind the coastal sheet piled wall and, secondly, simplifying of construction technology for deep water quay wall due to absence of traditional anchor devices. Retaining wall (Fig. 4) includes steel sheet piles installed along the structure, soil backfilling behind the wall and transversal sheet piled rows (counterforts) connected with axial wall. Counterforts are made of sheet piles of different length and have a shape of rectangular trapezoid. The length of the sheet piles in counterforts is decreased according to the distance from the axial wall and width of the transversal rows is increased downwards. Sheet piles' heads are joined by the cap. In such structure the idea of counterforts is not only to increase a rigidity of the retaining wall while withstanding the applied loads but also to reduce effectively soil pressure behind the wall.

Figure 4. Sheet piling wall with counterforts: a – cross-section; b – plan. 1 – axial sheet piling; 2 – soil backfilling; 3 – sheet piled counterforts; 4 – cap.

A new construction of the bulkhead is worked out to increase the bearing capacity of the coastal protection wall or quay wall as well as to reduce their material consumption (Fig. 5). The structure incorporates the front wall and soil backfilling behind it. Anchor bearers are made of “comb” type as several small anchor plates fixed along the rigid core. Anchor force is taken by all plates of the comb simultaneously. It provides increasing of the bearing capacity both of the anchorage and of the structure in whole (keeping the same material consumption for the anchorage as at the traditional solutions with one large anchor plate). On the other hand proposed structure may provide decreasing of the material consumption (keeping the same structure's bearing capacity as at the known facilities).

Figure 5. Anchored bulkhead with anchor bearer of new “comb” type: 1 – sheet piling; 2 – backfilling; 3 – tie-rod; 4 – rigid core; 5 – anchor plates.

The basic research for full-scale physical modeling on press-in and extraction equipment was based on the Modular Piling System. This multifunctional equipment has been developed with the intended purpose of implanting prefabricated construction elements using the press-in method. The piling system is equipped with the original hydraulic piling machine (Fig. 6) with wedge-operated clamps (testing devise) and a modular coordinating skidding system (MKS).

Figure 6. Modular section of the piling system MKS: 1 – press-in piling machine; 2 – longitudinal guides (skid tracks); 3 – transverse guides (cross slide).

In terms of its impact capability the piling machine is completely quiet and vibrations in the ground are at an absolute minimum allowing for the machine to work on certain highly sensitive ground areas, extremely small spaces, and in historical preservation areas. The strategic technological advantages of the piling system are high productivity, precision and quality control.

Depending on the features of the project, location of the piles in terms of engineering and geological conditions of the site, pressing construction elements into the ground could be provided with the flow-line and coordinating installation methods.
